There are many types of regenerative set, some extremely simple and others more complicated. The original Armstrong regenerative circuit is shown in Fig. 1. Fig. 2 shows a more modern application of the regenerative principle and at the same time a more complicated one. (See *Regeneration, Super Regeneration* and *Super Heterodyne.*)

ARRESTER—A device used for by-passing heavy electrical discharges in the atmosphere in the vicinity of the antenna when they strike the antenna. It ordinarily consists of a small gap between two metallic points connected in series with the antenna and ground in order to protect the apparatus and property against danger. (See *Lightning Arrester.*)

A. R. R. L.—Abbreviation for American Radio Relay League.

ARTIFICIAL ANTENNA — See *Mute Antenna.*

ARTIFICIAL MAGNET—A magnet produced by magnetizing a piece of steel that previously had no magnetic attraction. May be produced by rubbing a *natural magnet* or another artificial magnet across a piece of hard steel in the same direction a number of times. (See *Electro-magnet.*)

ASSUMED DIRECTION OF CURRENT FLOW—The direction which an electric current is assumed to take in its flow. Current is generally considered as leaving the *positive* terminal of its source, flowing through the circuits external to the source, and thence to the *negative* terminal of the source. The direction of flow within the source itself is from the negative to the positive terminal. (See *Theory of Current Flow.*)

ASTATIC COILS—Coils wound in such a manner that, when connected together, they neutralize each other's effect and produce no external *magnetic field.* They are used in the measurement of *inductance.*

ASYMMETRIC CONDUCTOR — One that permits the flow of greater current in one direction than in another. Non-symmetrical as to conductivity.

ASYMMETRICAL EFFECT—The lack of symmetry in the directional effect in a loop or frame aerial due to lack of symmetry in construction. (See *Loop Aerial.*)

ASYNCHRONOUS—A term used in referring to AC (Alternating Current) motors or generators and also to *dischargers* used in radio transmission. As applied to alternating current machines it is signified that the speed of rotation of the machine does not have any definite relation to the *frequency* of the currents produced—thus, out of *synchronism.* (See *Synchronous.*)

An asynchronous radio circuit is one which is not tuned to, or in syntony with, the frequency of the *oscillations* impressed on it. (See *Aperiodic.*)

ASYNCHRONOUS ROTARY DISCHARGE—A spark discharge produced at electrodes of a *rotary discharger* (*q. v.*) for transmitting radio signals, in which the spark rate or number of sparks per second has no relation to the *frequency* of the *alternating current.* (See *Spark Discharge.*)

ASYNCHRONOUS SPARK GAP—See *Spark Gap.*

ATMOSPHERIC ABSORPTION — The portion of the total reduction of radiated power due to atmospheric conductivity, reflection and refraction. The amount of energy loss in radio transmission due to atmospheric factors. This applies only to *electromagnetic waves* (*q.v.*) in *motion in the ether* and should not be confused with the reception losses due to atmospheric disturbances.

ATMOSPHERICS — See *X's, Strays, Static.*

ATTENUATION — of the electric or magnetic intensity or of the average energy density in electric waves refers to the reduction in strength with increase of distance traversed due to absorption or equivalent losses, as distinguished from the reduction in strength due to geometrical divergence. In free space, the geometrical divergence of waves from a small source involves a diminution of the average energy density in accordance with the inverse square law; plane waves (e. g., along wires) suffer no reduction by divergence, but undergo attenuation due to resistance and other line faults. (See *Attenuation, Geometrical Divergence*).

ATTENUATION, GEOMETRICAL DIVERGENCE—The gradual decrease in strength of electromagnetic waves (radio signals) as the distance which they have traversed increases. The effect on the waves as they travel through the air is essentially the same as in the case of light waves. Now if a beam of light is viewed one mile from its source it will have a certain intensity, but if it is viewed again from a distance of two miles the intensity will be much less. In the case of radio waves, the intensity is said to decrease as the square of the increased distance traveled; that is to say, if they have a certain power at a distance of five miles from the transmitter, the same waves at twice the distance or ten miles will be found to have a strength only one-quarter as great. Similarly, if the waves travel fifteen miles or three times the distance, the signal strength will be only one-ninth that of the same waves at a distance of five miles from the transmitter.

AUDIBILITY—The measure of strength of received radio signals as heard in a telephone receiver connected to the radio receiving apparatus. A radio telegraph signal which is at all audible can be read, i.e., the dots and dashes distinguished from one another; radio broadcast programs heard with at least some degree of clarity.

AUDIBILITY (Radio Telegraph)—A measure of the ratio of the telephone current producing a signal in a telephone receiver to that producing a barely audible signal. (A barely audible signal is one which just permits the differentiation of the dot and dash elements of the letters sent in code.) In the simple shunted telephone method of measuring signals the audibility is defined as:

$$\frac{s+t}{s}$$

where s and t are the *impedances* of shunt and telephone respectively.

AUDIBILITY FACTOR—A measure of signal strength obtained by observing the *resistance* to be placed in shunt with the telephones of a receiving station to reduce the signals to unit audibility. Approximately, the audibility factor is proportional to the power absorbed from the signal waves by the receiving apparatus. Unit audibility is the strength of signal at which dots and dashes can just be discriminated.

AUDIBILITY METER—A device for comparison of the strength of received signals, either from different stations or with different circuits by means of a variable *resistance* shunted (placed) across the phones. This resistance is decreased until the signals are just audible in the phones. Now, if another station is tuned in, or the circuit changed in some manner, the signals may either be entirely inaudible or they may be much louder, this giving an idea of the *comparative* strength without actual measurement. A popular type of Audibility Meter is shown in the above illustration.

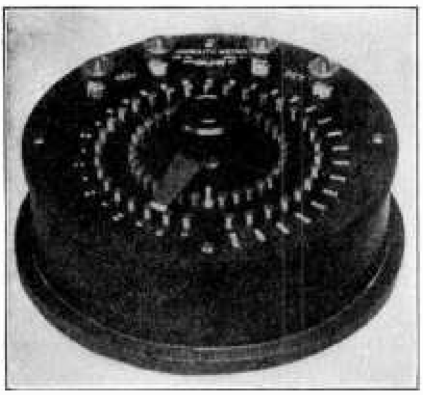

Photo by courtesy of General Radio Co.

An Audibility Meter.

For measurements with an audibility meter, the following shunt formula is used:

$$K = \frac{s+t}{s}$$

Where s is the *impedance* of the *shunt* resistance and t the impedance of the phones, then K is the audibility constant. In general practice a *series* resistance is devised to compensate for the reduction in resistance of the shunt circuit, this keeping the impedance of the plate circuit constant.

AUDIO AMPLIFIER—An *amplifier* used to increase the volume of signals of *audio frequency* (*q. v.*). Audio amplifiers are connected in the circuit of the detector in place of the phones (input) as shown in Fig. 1. This is the standard two stage audio amplifier. The separate stages each consist of a *vacuum tube, a transformer, socket* for the tube and a control *rheostat*. If desired one rheostat may be used for both amplifier tubes as the *filament* current (*q. v.*) can be the same if the tubes are of a similar design. This is known as "transformer coupled amplification." Another much used method is known as "resistance coupled amplification."

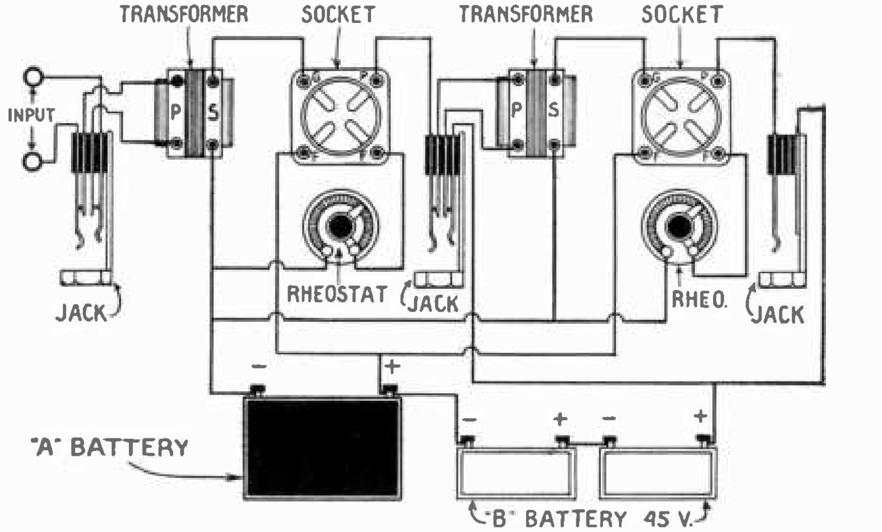

Fig. 1. A standard two stage Audio Amplifier employing phone jacks for detector, first stage, and second stage Audio Amplifiers.

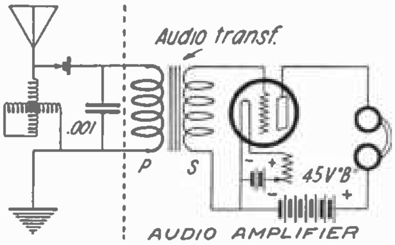

Fig. 2. A one stage Audio Amplifier connected to a crystal receiving set.

Fig. 2 shows one stage of audio frequency amplification connected to a crystal receiving set. There are numerous variations of audio amplification. (See *Push-Pull Amplification,* also *Resistance Coupled Amplifier,* and *Power Amplifier.*)

AUDIO FREQUENCY—A frequency corresponding to normally audible sound waves, i.e., between 40 and 10,000 per second. The limits of audibility are given variously from 16 to 20,000 cycles, but for ordinary usage may be taken as from 40 to 10,000 cycles per second. In audio frequency amplification as used in conjunction with the tuning and detector apparatus of the radio receiving set, the volume of the received sound is amplified or increased over that of the originally rectified sound waves. (See *Radio Frequency;* also *Amplifier.*)

AUDION—The name given by Dr. L. De Forest to a *vacuum tube detector* which possesses a glowing *cathode* and has a steady E. M. F. (*Electromotive force*) permanently applied between *anode* and hot *cathode* and two cold *anodes.* (See *Vacuum Tube.*)

AUSTIN, Louis Winslo, Ph.D.—Born in Ordwell, October 30th, 1867. Graduated at Middlebury College and studied at Clarke University and the Universities of Strasburg and Berlin. Noted for the fact that he is head of the U. S. Naval Telegraphic Laboratory, Washington, D. C., and for his work in measuring high frequency currents.

AUTO-COHERER—A coherer having automatic action to release the particles that cohere when circuit is established. Now obsolete. (See *Coherer.*)

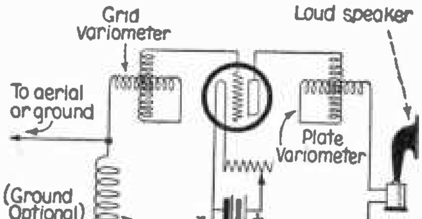
AUTODYNE RECEPTION—See *Self-Heterodyne Reception.*

AUTO INDUCTIVE COUPLING—See *Coupling.*

AUTOMATIC INTERRUPTER—A vibrating electro-mechanical device to make and break an electric circuit by using the energy passing through it. The most common example is that of a *spark coil.* An interrupter may be used for several purposes. In the case of a spark coil it is used to produce sparks for transmission of signals. In another form it may appear in a mechanical battery *charger,* in this instance being used to interrupt the *alternating current* and permit passage of the current in one direction only. A *buzzer* uses a type of interrupter—a vibrating device producing a buzzing sound having a pitch dependent on the rapidity with which the vibrations take place.

AUTOMATIC TRANSMITTER—An apparatus for operating a sending *key* mechanically. (See *Wheatstone Transmitter.*)

AUTOPLEX—A type of radio receiver employing one vacuum tube, operating along the lines of the *Super-regenerative* principle and designed to operate a Loud-speaker. The circuit comprises two standard variometers, a 1500 turn duo-lateral coil, and the usual vacuum



Circuit of the Autoplex radio receiver.

tube, socket, batteries, etc. It is extremely critical in operation, but if carefully assembled will give excellent volume under good conditions. Illustration shows the circuit diagram of the Autoplex receiver.

AUTO-RECEIVER—A device for the automatic reception and recording of radio signals. It is essential in the reception of signals transmitted by an Automatic transmitter (see *Wheatstone Transmitter*) as the speed is too high to permit reception by ear. There are three general classes of automatic receiver: a *resonance intensifier* in conjunction with an inking arrangement; a *phonographic recorder* and a recorder using *photographic means.* In the latter method, a powerful beam of light is projected on to a mirror which is arranged to respond to the signals in approximately the same manner as a mirror *galvanometer.* In the phonographic type, the signals are reproduced on a drum. (See *Resonance Intensifier*, *Photographic Recorder*, also *Phonographic Recorder.*)

AUTO TRANSFORMER—A device for changing voltage in a circuit carrying alternating currents. A form of *transformer* having but one winding, any part of which may be used as the *primary* and any part as the *secondary.* In Fig. 1 the two windings P and S are continuous, although different sizes of wire may be used according to the purpose for which intended. In this case the voltage taken from the secondary D E will be less than the voltage impressed at A B, because the secondary has fewer turns of wire than the primary. Now in Fig. 2, this conditions is reversed, and as the primary has only a few turns of wire and the secondary has a comparatively large number, the voltage obtained from D E will be greater than that impressed at A B. The voltage ratio is approximately proportional to the ratio of wire turns. Thus, if the primary has 100 turns of wire and a pressure of 100 volts is placed at A B, then the voltage at D E would be within certain limits about equal to the number of turns of the secondary. In other words, if the number of turns on the secondary is one-third the number of turns on the primary, then the voltage at D E will be approximately one-third that impressed at A B. The main advantage of the autotransformer is that a saving is accomplished by having the primary and secondary windings combined. The chief disadvantage is that where extremely high voltages are used there is always danger of the two windings becoming crossed or shorted. (See *Short.*) For this reason they are used mainly for comparatively low voltages. One of the most common forms is the step-down type, known as a "bell-ringing transformer." These are used to cut down the voltage of an electric light line to suitable value for use with small toys or bells. If the transformer is used to increase the voltage, it is known as a "step-up" transformer. (See *Transformer—Radio, Audio.*)

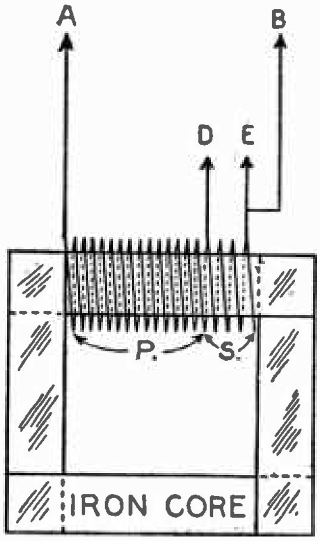


Fig. 1.

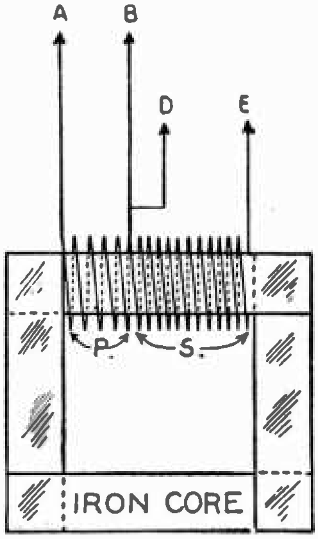

Fig. 2.

AUTO TRANSFORMER COUPLING—See *Coupling.*

B

B—Abbreviation for Baumé, the scale used in a *hydrometer* (*q.v.*)

B. A. AMPERE—The standard ampere fixed by the British Association for the Advancement of Science.

BACK COUPLING—See *Reactance Coils.*

BACK ELECTRO-MOTIVE FORCE—An *Electromotive force* (E.M.F.) which opposes the original electromotive force. The more common term is "*Counter E. M. F.*" In many arrangements of electrical circuits there will be an electromotive force set up in such manner as to oppose the impressed voltage or force. This will be true in the case of a *choke coil* in which any variation in the pressure or electromotive force applied to the coil will result, under proper conditions, in the production of a back or counter-electromotive force that will oppose the change in the original force.

This phenomena is frequently found in electrical circuits; at times introduced for a purpose and at others self-introduced, and therefore demanding consideration in design of apparatus. The rotation of the *armature* of a motor creates a counter E. M. F. opposed to the impressed E. M. F. and upon which the driving power of the motor depends. When an external E. M. F. is impressed on a circuit in which there exists a local E. M. F., the flow of the current through that portion of the circuit containing the local E. M. F. will result in an increase or decrease of energy depending on whether the local E. M. F. is opposed to, or in the same direction as, the external E. M. F. (See *Counter Electromotive force.*)

BACK OSCILLATION—When the *condenser* of a transmitting circuit of the spark type discharges across the *spark gap* some of the *high frequency* current may flow back through the secondary of the transformer instead of taking its normal path across the gap. This back flow is usually referred to as *Back oscillation* or kick back, and is apt to break down (see *Breaking Down of Insulation*) the insulation of the transformer if not prevented or controlled. Back oscillation is retarded ordinarily by means of coils of wire having a certain arbitrary *inductance* value. When the high frequency discharge from the condenser has any tendency to break through, the *reactance* of these coils becomes so great that they act in effect as insulators. As the capacity and inductance of these coils might create an *oscillatory circuit* of the same *natural period* as the primary oscillator, they are shunted with non-inductive carbon resistances. These coils are termed "*choke*" coils.

BAKELITE—An insulating material having widespread use in radio. It possesses great strength and has a high *dielectric* (insulating) value together with the ability to withstand high temperatures. This material is furnished in many forms and under a variety of trade names, being considered one of the best of the insulating compounds.

Chemically known as *Oxybenzylmethylenglycol anhydride.* It is produced by the union under heat and pressure of phenol and formaldehyde together with a small percentage of some alkaline agent. Is heat resisting up to about 500 degrees Fahrenheit—disintegration setting in somewhere above that point.

BALANCED CIRCUIT—An electric circuit arranged in such manner with relation to adjacent or neighboring circuits as to do away with the effect of *mutual induction* (*q.v.*).

BALANCED DETECTORS—A term applied to an arrangement of opposed rectifying *detectors* for reducing the effects of strong *strays* in receiving apparatus. The detectors must be balanced for violent *electro-motive forces*, but not balanced for the moderate E. M. F.'s due to the signals. Actually, a method of eliminating stray impulses in reception.

BALANCED METALLIC CIRCUIT—A circuit through conductors (wire or any metal) in which the total resistance is the same on each side of the circuit. (See *Circuit.*)

BALANCED ROTARY CONDENSER—A variable condenser having some arrangement for keeping the plates accurately balanced in rotation at all points. Fig. 1 shows a form known as the "balanced plate" type. In this case the plates are so arranged that half the movable plates are on one side and half on the other side of the shaft.

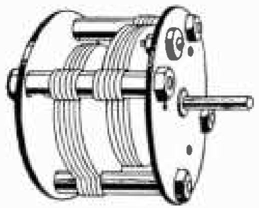

Fig. 1. A "Balanced-Plate" type Rotary Condenser.

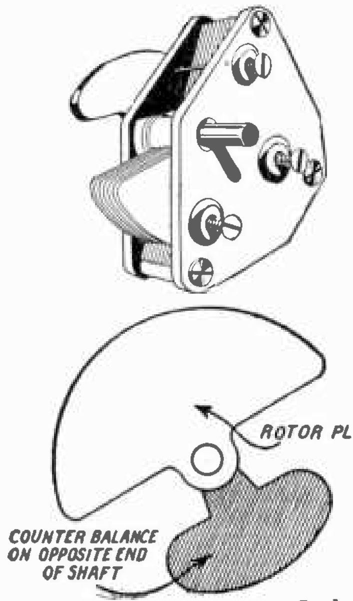

Fig. 2. A Counter-Balanced Rotary Condenser and illustration showing how the counter balance is attached to shaft.

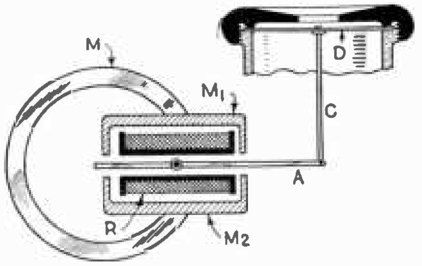
This maintains the balance of the part. Fig. 2 shows another method known as "counter-balanced." The weight of the balance is the same as that of the movable plates and its position on the other side of the shaft serves to maintain balance. The idea is to prevent the plates slipping due to lack of balance and thus keep the setting at the desired point after adjustment.

BALANCING—Any method of eliminating interference by reducing the *amplification* of the undesired signals while permitting full amplification of the desired signals. (See *Interference Eliminator.*)

BALANCING AERIAL—An aerial system designed to permit reception of signals from distant points without interference from a powerful nearby transmitter. The system involves the use of two aerials, one for balancing, the other for receiving. The receiving aerial is tuned to the wavelength of the desired signals, while the balancing aerial is tuned to the wavelength of the nearby station (the interfering signals).

In operation the receiving circuit is coupled to each aerial *electro-magnetically*, and is acted on by both series of *oscillations* (distant and nearby waves). By careful adjustment of *coupling* and phase relation of the *induced currents*, the interfering wave may be balanced out in effect and the desired oscillations received.

BALDWIN RECEIVER—Perhaps the most sensitive type of telephone receiver thus far developed. It employs what is known as a "balanced armature," the signals being produced by the vibrations of a *diaphragm* which is not acted on directly by the magnets. The illustration shows the general plan of a receiver of this type. The *armature* (A) is of soft iron and is pivoted between two U-shaped soft iron pieces (M1, M2) mounted on the ring-shaped horseshoe magnet (M) as indicated. The armature is acted on by the magnets in response to incoming signals and the movement of this element in turn acts on the mica diaphragm (D) by means of a fine brass wire (C). The usual windings (R) are placed between the two pole pieces, the armature being mounted in a central slot. These receivers are much used both for headphones and for loud-speaker units. In the latter case the mica diaphragm is generally made heavier to handle the more powerful vibrations due to the *amplification* of the signals.



Principle plan of the Baldwin Receiver unit.

When no fluctuating impulses (signals) flow through the windings (R), there is no *magnetic stress* on the armature (A), because this member is suspended centrally between the pieces (M1) and (M2), the magnetic attraction of which are equal. Now when a fluctuating impulse flows through the windings (R) it produces a magnetic flux which combines with the flux of the permanent magnet (M) and the total flux is distributed asymmetrically or unevenly on both sides of the armature. The result is a rocking vibratory movement to this member which is in turn communicated by the juncture wire (C) to the diaphragm (D), producing the audible signals. (For a comparison of this action with the conventional telephone receiver action, see *Telephone Receiver.*)

BALKITE BATTERY CHARGER—An electrolytic battery charger which makes use of a sulphuric acid solution and tantalum as the valve metal. Used for charging *storage batteries* from *alternating current.* See illustration.

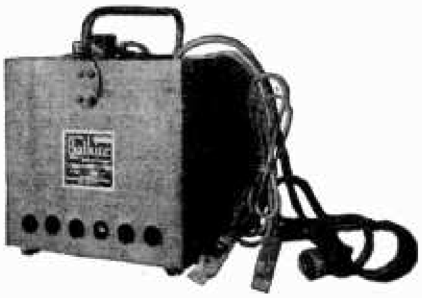


Photo by courtesy of Fansteel Products Co.

A Balkite Battery Charger.

Note: The name Balkite is derived from the name of the man who perfected the process of extraction of tantalum from its ores.

BALLAST TUBE—An automatic means of regulating the *filament current* of vacuum tubes. The device is enclosed in a glass tube and is arranged to permit passage of a certain fixed amount of current. The ballast element is a wire whose *resistance* changes with the current through it, due to the change of resistance with the temperature of the wire. When the *electromotive force* increases beyond normal, the increased current raises the temperature and hence the resistance, so that the current is held to the normal value.

B. and S.—Abbreviation for Brown and Sharpe Gauge (*q.v.*).

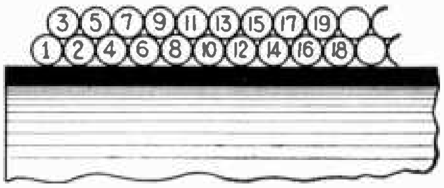
BAND OF FREQUENCIES—A continuous range of *frequencies* extending between two frequencies. (See *Band of Wavelengths;* also *Band Pass Filter.*)

BAND PASS FILTER—A *filter* arrangement designed to permit passage of all *frequencies* extending between two definite frequencies but excluding all other frequencies. (See *Band of Frequencies.*)

BAND OF WAVE-LENGTHS—A continuous range of *wave-lengths* extending between two definite wave-lengths. For example, the usual broadcast band of wave-lengths is approximately 250 meters to 550 meters.

BANKED BATTERY—A *battery* that has its *cells* connected in *parallel.*

BANK WINDING—A form of winding for coils in which the turns are staggered so that two or more layers may be used without having large distributed capacity losses. The illustration shows method of bank winding for two layers. Note that in this form the *electrostatic capacity* between any two turns is only that between adjacent turns, representing only a small part of the total winding, whereas on the usual form of winding the adjacent turns would represent a good portion of the total *inductance* and hence the effect of distributed capacity would then be much greater. (See *Distributed Capacity.*)



Method of hank winding wire on a coil form.

BARRETER—A receiving instrument consisting essentially of a small mass of conducting material that is heated by the passage of an *oscillatory* current, and arranged so that the consequent alteration of electrical *conductivity* affects an indicating instrument, such as a telephone receiver or *galvanometer.*

BASKET COIL—Variometers—couplers, etc. (See *Basket Wound.*)

BASKET WOUND—A method of winding coils, such as variometers or variocouplers. The winding is a latticework of wires in skeleton form, the object being to save weight and eliminate large losses such as occur in the types using a great deal of solid insulating material. The illustration shows a popular form of basket variometer.

A Basket Wound Variometer.

BATTERY — In the electrical field, a group of *primary or storage cells, dynamos*, or *condensers* grouped together to form a single unit. The term is often used incorrectly to refer to a single cell—as "dry battery," the correct name for which is "dry cell." Thus a group of condensers joined together as one unit is termed a battery, also a number of dynamos arranged as a single unit for the production of electrical energy. (See *Dry Cell*, also *Battery of Alternators, Storage Battery, "A," "B" Battery*, etc.)

"B" BATTERY—An appliance for obtaining electricity of sufficient voltage to supply the plate of a *vacuum tube*.

There are two types of "B" batteries, viz., the *dry cell* type and the storage types. In order to obtain the high voltage required for vacuum tube plates, many small cells are connected in series. The usual method is to connect them together and seal in a square package. Often taps are brought out so that various voltages may be obtained for *critical* vacuum tubes. The most popular voltages which dry cell "B" batteries give are 22½ and 45 volts. The storage "B" battery is similar to the ordinary storage battery with the exception that the cells are much smaller, but contain more cells in series. These can be charged in the same manner as the "A" or *storage battery*. In Fig. 1, we have a popular type of "B" battery. This is tapped in order that different voltages may be obtained.

Fig. 1-B. A "B" Battery showing the contents of small cells.

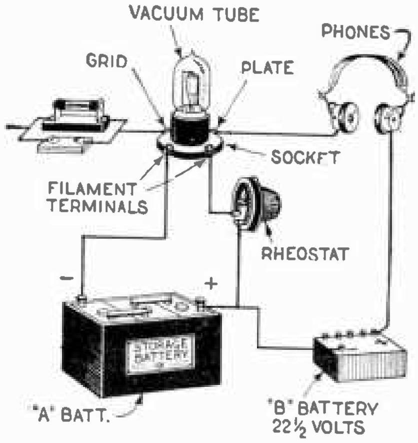

Fig. 2. Manner of connecting a "B" Battery in the circuit of a vacuum tube detector.

The manner of connecting up the "B" batteries in radio receiving is shown in Fig. 2. Here one battery of 22½ volts is used. In Fig. 3, three batteries are connected in series so that 67½ volts are obtained.

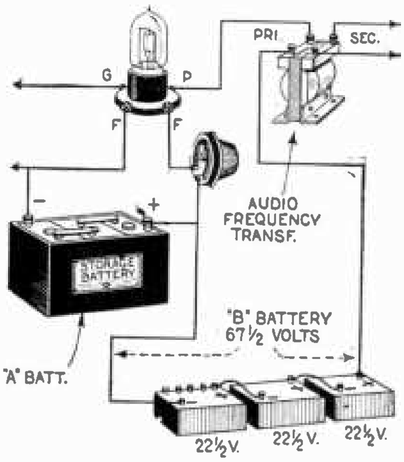

Fig. 3. "B" Battery of 67½ volts connected in an amplifier circuit.

A common "B" battery may be used for the detector tube and the amplifier as shown in Fig. 4.

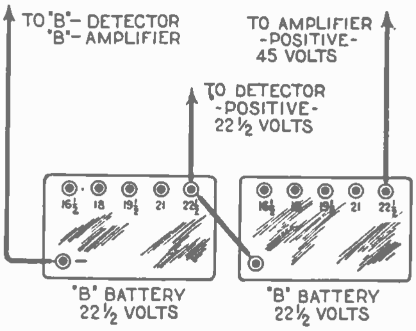

Fig. 4. How a common "B" Battery may be used both for detector and amplifier.

If separate batteries for each tube are desired, the circuit should be connected as in Fig. 5. This lengthens the life of the "B" battery as the drain on the battery is much less, i.e., only one vacuum tube is operated on each battery.

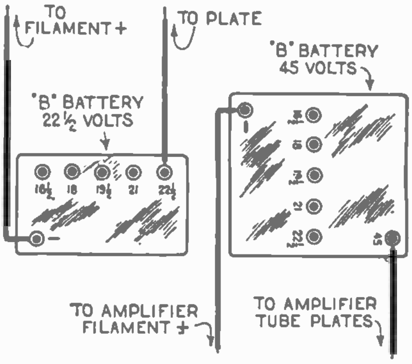

Fig. 5. Method of employing separate "B" Batteries for the detector and amplifier.

BATTERY OF ALTERNATORS — In ordinary electrical work such as house lighting, several *alternators* for the production of alternating current may be used together as one source of power. Also in high-power radio transmission, several *high-frequency alternators* may be used together to produce added power. (See *High-Frequency Alternator*.)

BATTERY TESTING INSTRUMENTS —The various devices used for determining the condition of batteries used as radio apparatus. (See *Ammeter, Voltmeter*, also *Hydrometer*.)

BEAT FREQUENCY—The *frequency* or number of vibrations per second of a series of *oscillations* representing the difference between two other series having different frequencies. It is numerically equal to the difference between the original two series of oscillations. Thus, if we have a series of oscillations having a frequency of 100,000 *cycles* per second, and combine it with another series having a frequency of 90,000 or 110,000 cycles, the *beat frequency* will be 10,000 cycles or the difference between the other two frequencies.

X. The frequency of recurrence per second of either maxima of addition or minima of opposition of two superposed periodic phenomena having the same nature but of different frequencies. The time measure of vibration of a beat or heterodyne. (See *Heterodyne*, also *Beats*.)

BEATS—When two sets of *oscillations* of different *frequencies* occur in the same system, the difference in the frequency or rapidity of vibration causes a new set of oscillations having a frequency equal to the difference between the original two sets. This may be accidental as in the case of certain types of receivers such as the *regenerative* type, in which case the beat oscillations are undesired and cause interference or disturbances in the set. Then again a beat frequency may be purposely introduced as in the case of the *Super-Heterodyne receiver*. Here we have the natural incoming oscillations from the antenna combined with a series of oscillations produced locally in the system. The result is a new set of oscillations where the incoming series and the locally produced series are not of the same frequency. (For more complete explanation see *Super-Heterodyne Receiver*.)

X. Where two *periodic phenomena* are *super-posed* or run together and the frequencies differ, the gradual change in *phase difference* produces a condition wherein the *amplitudes* are in opposition at one instant and in concurrence at a later instant with the various intermediate stages during the interval. (See *Heterodyne*, also *Beat Frequency*.)

BEG OHM—A *resistance* of one billion *ohms*. (See *Megohm*.)

BELIN, EDOUARD—French scientist, the inventor of what is considered the first practical system of radio transmission of photographs. The device can be used for sending photos by cable or telephone lines as well as radio. (See *Transmission of Photographs by Radio*.)

Brown photo.

Edouard Belin.

BELL, Alexander Graham (1847-1922)—Scottish scientist. Born in Edinburgh, March 3rd, 1847, he was educated at the High School and University and graduated as a doctor of medicine. In 1870 he went to Canada, and in 1872 became professor of vocal physiology in the University of Boston. In 1876 he exhibited his apparatus for the transmission of sound, afterwards developed into the telephone. Bell was experimenting with an electric invention by means of which he hoped to make speech visible to the deaf. A delicate metal reed was caused to vibrate by spoken speech and to transmit an electric current to the opposite end of a wire, where the vibrations of the first reed were reproduced in a second reed by a magnet. He found that it was possible to transmit not merely vibrations of the original reed, but to reproduce the sound itself in the vibrations of the second reed. In 1878 he invented the photophone, to enable sound to be transmitted by variations on a beam of light, and later a phonograph. Bell was the author of many scientific papers, was awarded the Albert Medal of the Royal Society of Arts in 1902 and the Hughes Medal of the Royal Society in 1918. He died Aug. 2nd, 1922.

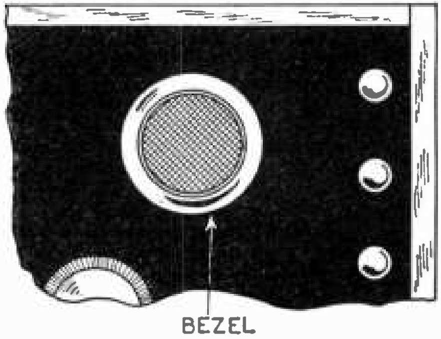
Alexander Graham Bell.

BELLINI, Dr. Ettore—Born in Foligno, Italy, April 13th, 1876. Educated at the University of Naples. Noted as Electrical Engineer to the Royal Italian Navy, and chief of the Naval Electrical Laboratory at Venice. Joint inventor with Captain Tosi of the "Radiogoniometer" (*q. v.*), a device for finding the direction of transmitted radio signals.

BELLINI-TOSI AERIAL—See *Goniometer*.

BELLINI-TOSI DIRECTION FINDER—See *Goniometer*.

BEZEL—In mechanics, generally a groove and flange made to receive a beveled edge. In its adaptation to radio some liberty was taken with its real meaning. Its significance in this sense is a small metal ring having a wire mesh or glass center. It is fitted into a circular hole in the panel of a radio receiver and used as a peep hole to enable the operator to know at all times the conditions of the tubes, whether or not they are properly lighted.



A Bezel on the panel of a radio receiving set.

BILLI CONDENSER—A variable *condenser* of low *capacity*, consisting of two brass tubes, one of which is arranged to slide in and out of the other for the purpose of varying the capacity. Such condensers were much used before the days of broadcasting, in conjunction with any circuit using a crystal and battery for detector. This type of condenser has long been obsolete in the United States.

BINDING POST—A screw and nut arrangement used on electrical units and radio apparatus to make convenient connections from an external source to the desired point within the apparatus. Binding posts are provided, for instance, to make handy connections from batteries to the set and from the aerial and ground leads. The illustration shows a popular type of binding post.

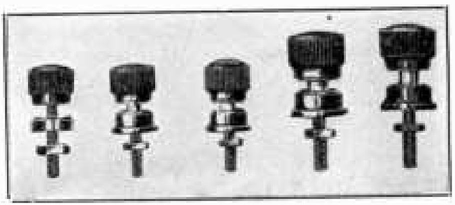


Photo by courtesy of The H. H. Eby Mfg. Co.

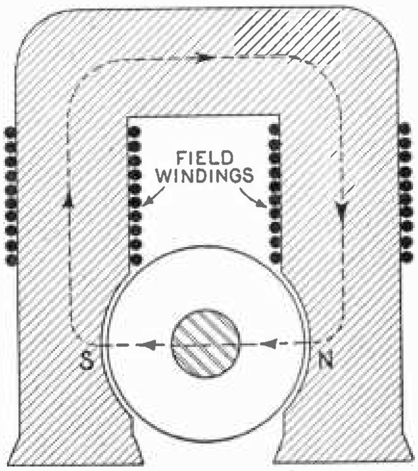
A group of Binding Posts as used on electrical and radio apparatus.

BI-POLAR—Having two *poles*. Usually a *dynamo* or motor whose *armature* rotates between a *field magnet* having only two poles. The most modern types are of the Multi-polar variety. (See *Bi-polar Magnetic Field*.)

BI-POLAR ARMATURE WINDING—An *armature* wound in a manner to permit its use with a dynamo having a bi-polar magnetic field.

BI-POLAR MAGNETIC FIELD—The magnetic field (*q.v.*) created between two magnetic poles. The illustration shows a common form of bi-polar magnet for a dynamo. Bi-polar magnetic fields are now used as a rule only for direct current machines of low power, such as those under 5 *Kilowatts*. (See *Dynamo*, also *Generator*.)



A Bi-Polar Magnet of a dynamo.

BI-TELEPHONE RECEIVER—A headset with two receivers or phones as generally used in radio. In the early days of radio transmission it was the custom to use only one phone.

BLONDEL, Andree—French electrical expert. Born at Chaumont, France, in 1863, he graduated at Paris University, and studied electric waves, on which subject he early contributed a number of papers to various scientific journals. In 1893 he invented the *oscillograph*, an instrument somewhat similar to a mirror *galvanometer*, for showing curves of *oscillating* or *alternating currents*. This invention opened up a fresh field in the study of alternating currents. In the same year Blondel explained for the first time mathematically the effect of inertia in the shunting of *alternators*. He is responsible for a system of acoustically syntonic wireless telegraphy, and for directed waves produced by a double aerial. In 1902 he patented a method for producing electric oscillations for wireless telephony, and has written many papers on microphonic control for transmitters, wireless telephony, the singing arc, etc.

BLONDLOT, Professor Prosper Rene—French wireless expert. Born at Nancy, France, in 1849, studied at

Paris, and became professor at the faculty of sciences, Nancy, and afterwards Honorary Professor and Correspondent of the Institute of France. Professor Blondlot is famous for his studies of electro-magnetic waves, particularly with regard to their speed, and the laws of *propagation* of wireless waves in various media.

BLOWER MOTOR—A motordriven fan used to deliver a high pressure blast at the *spark gap* to prevent *arcing*. (See *Spark Gap*, also *Spark Discharger*.)

BLOWOUT—See *Magnetic Blowout.*

BLUE GLOW—A condition within a *vacuum tube* when the vacuum has become poor. After continued use a tube will often hold a small percentage of gas, which causes a blue glow when current is passed through it. A tube in this condition is a poor *detector* or *amplifier* and should be replaced. The condition should not be confused with the glow often caused by an excessive voltage. In this latter case decreasing the voltage to the normal value will generally permit the tube to be operated efficiently. The blue glow in this case is due to *ionization* of the residual gas by the excessively high *potential* impressed across the elements of the tube.

BOARD OF TRADE UNIT—B.O.T. 1,000 Watt Hours. One and a third Horse Power.

BODY CAPACITY—The effect of the human body when tuning a radio receiving set. The hand when placed on or near the controls very often throws the receiver out of balance with the incoming signals. In the case of very *sharp tuning* this effect is more in evidence and is likely to cause howls due to *self-oscillation.* The howling is due to the production of an audible *beat frequency* in the system, caused by the combination of the local *oscillations* with the incoming signal oscillations. The remedy may be to shield the panel with metal foil or in some cases to merely alter the direction of the leads from the *tuning condenser.* The experienced operator seldom pays much attention to the phenomena, as a little practice enables the listener-in to compensate for the effect. To make this more clear, if, when tuning the set, the withdrawal of the hand from the dial *detunes* the set or throws it out of balance, it is due to the fact that the hand has acted as a certain amount of *capacity* in the circuit, and naturally its withdrawal is equivalent to a change in the condenser setting. A simple system is to turn the control beyond the point of maximum volume, then when the hand is withdrawn the capacity will drop to its proper value. This can be mastered very readily. If the tuning condenser is connected across the secondary, i.e., one side to the grid, and the other to the grid return, the stator plates of the condenser should be connected to the grid of the tube. If metal foil or thin copper sheeting is used for shielding it should be connected to the ground post of the set.

The tendency of the human body to insert an arbitrary capacity in the circuit. The phenomena is especially noted where maximum volume is obtained only by very critical control close to the oscillating point, in which case the circuit may be thrown out of *resonance*.

BOLITHO CIRCUIT—A *super-regenerative circuit* patented in England in 1919 by Captain J. B. Bolitho. The circuit was originally intended to operate a relay device. The circuit has been adapted to use as an *amplifier* for radio reception.

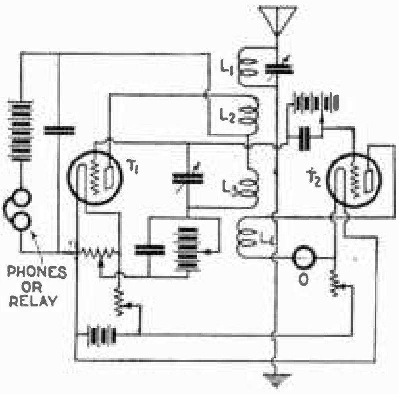


Diagram of the Bolitho Circuit.

In the illustration the phones may be replaced by a loud speaker or relay. In operation, T1 is held at a point just below that where *oscillation* sets in by means of T2 which is excited by an oscillator O in the plate circuit and coupled by means of coil L4 to the tuned grid circuit through L2 and L3, the coupling, as explained, being so arranged that the tube is always just below the oscillating point. A *reaction coil* L4 is placed in the plate circuit of T2 in such manner as to oppose the magnetic linkage between coils L2 and L3. The *frequency* of the generator O is lower than that of the received signals. As indicated, the grids of both tubes T1 and T2 are joined together and the tube T2 maintains the circuit in a receptive condition when tube T1 is tuned just below the oscillating point.

The oscillator O makes the *plate* of T2 alternately *positive* and *negative* with the following effect: When the plate of T2 is negatively charged there is no current in coil L4, this coil therefore not affecting coils L2 and L3, and permitting tube T1 to build up self oscillation. When the plate is made positive by the action of the oscillator, current flows through coil L4, and as it is coupled in opposition to coils L2 and L3 it neutralizes the coupling between L2 and L3 and prevents transfer of energy between the grid and plate circuits of the tube T1. This tends to stop the self oscillation and makes the circuit receptive to the energy (signal) produced by outside signals in the aerial coil L1. The frequency, of course, is determined by the frequency of the oscillator O. The system is especially adapted to the reception of continuous wave signals. (See *Super-regenerative circuit,* also *Feed-back* and *Regenerative circuits.*)

BOLOMETER—Type of *Wheatstone Bridge* having an easily heated *resistance,* such as a very fine wire in one arm. (See *Wheatstone Bridge.*)

BOOSTER—An expression signifying a small *dynamo* used in conjunction with main dynamo to temporarily raise, when necessary, its normal *pressure.* It is generally driven by a motor supplied with energy from the main generator and thus becomes in effect a *continuous current transformer.* Frequently used for charging *accumulators* of a generating plant. The term "Boost" is also used to denote increase or a stepping-up of any electrical quantity. (See *Amplification.*)

BORNITE—A *crystal rectifier* much used in radio reception. It is a natural sulphide of iron and copper, having a metallic blue lustre. This mineral is used in combination with zincite or copper pyrites as a crystal detector. Such combinations are generally known as "crystal to crystal" detectors to distinguish them from the ordinary variety using one mineral and a wire contact.

BORON—A non-metallic chemical element used in radio as one of the electrodes for the *T. Y. K. Arc.* Chemical symbol B, atomic weight 11.0, specific gravity 2.6.

B. O. T.—The customary abbreviation for *Board of Trade Unit.* The unit represents 1,000 *watt hours.* (See *Board of Trade Unit.*)

BOX AERIAL—A term occasionally applied to loop aerials. (See *Loop aerial,* also *Frame Aerial.*)

BRADFIELD INSULATOR—A particular form of *Lead-in Insulator,* consisting of an ebonite tube provided with zinc cone and ebonite spark discs, for breaking up continuous streams of rain running down outside which might cause the aerial to become grounded. The whole is held in position, half way through roof of operating room, by means of a stuffing box. The aerial is led in by means of a conducting rod through center of tube. (See *Petticoat insulator.*)

BRANLY COHERER—Early form of *Marconi Coherer.* (See *Coherer.*)

BRANLY, EDOUARD—French radio expert. Born at Amiens, France, Oct. 23rd, 1844. He was educated at Paris and afterwards became Fellow of the University, doctor of physical science, and doctor of medicine. Branley early made a study of electro-magnetic waves, and in 1890 and 1891 patented methods of operating a local relay circuit from a distance by means of wireless waves. In 1900 he was awarded the Grand Prix by the International Jury of Superior Precept Instruction for his exhibition of radio-conductors.

In 1890 Branly published an account of his very extensive series of observations on the electrical conductivity of loosely packed metal filings, and he made the extremely important observation that an electric spark at a dis-

Edouard Branly.

tance had the power of suddenly changing the electric *conductivity* of loose masses of powdered *conductors*. To Branley is due the *coherer* named after him.

BRAUN, FERDINAND—Professor at the University of Strasburg, and one of the leading world authorities on Radio transmission. As early as 1899 Braun was granted a patent for *closed oscillating* systems with an *inductively coupled* antenna. The system was claimed by Braun to possess a much greater efficiency than the directly coupled systems. The Braun transmitting set, as manufactured by Siemens and Halske, consisted of a large coil worked into an *electrolytic interrupter*, a set of *Leyden jars*, enclosed *spark gap*, *oscillation transformer* wound with insulated wire placed in oil, and for the receiving set the standard type of *coherer relay* and Morse register. In 1899 Braun established communication between Cuxhaven and Heligoland, using aerial wires 90 feet high, and the inductive coupled aerial connection for transmitting. In 1903 Braun joined with Slaby, von Arco, and Siemens to form the Telefunken system of transmission. Professor Braun was awarded the Nobel prize with Marconi in 1900, for his work in wireless. Braun has devised a method of directional wireless which depends upon the interference of *electric waves* travelling in the same direction but different in *phase*. Three simple vertical wire aerials are set up in positions corresponding to the angular points of an equilateral triangle, and *oscillations* are created in these which differ from one another in phase. In 1897 Professon Braun published a description of his cathode ray tube, and afterwards pointed out, in 1902, how such a tube could be used to trace the forms of alternating current waves.

BREAK or BREAKER—See *Circuit Breaker.*

BREAKDOWN POTENTIAL or BREAKDOWN VOLTAGE—The voltage necessary to *break down* or puncture a *dielectric.* The ability of any *insulating* material to resist breakdown is an important matter. An insulator or dielectric material is usually given a certain rating or point above which it is likely to fracture. Thus, a condenser may have a breakdown rating of 500 volts. That is to say that voltages up to 500 and slightly over may be handled with safety, but any large increase above that figure may result in puncture of the material by the excessive potential or voltage. The relation between dielectric strength and breakdown voltage is shown in the following formula:

$$V = cd^{2/3}$$

Where d is the thickness of dielectric in millimeters

V the potential difference in volts

c-a constant representing the potential difference required to cause a dielectric breakdown of a sample of the material 1 mm. thick. (See *Dielectric Strength.*)

BREAKING DOWN OF DIELECTRIC—In a *condenser*, the gradual weakening of the *dielectric* or insulating sheets which eventually causes them to permit direct passage of the current. For example, if a force of 1000 volts is applied for a considerable period to a condenser that has been designed for a maximum of 500 volts, the insulating material between the plates would probably be punctured by the current. (See *Break-down Potential.*)

BREAKING DOWN OF INSULATION—The same effect as referred to under *Breaking Down of Dielectric.* The insulation weakens and permits the ready passage of electric currents. (See *Break-down Potential.*)

BRIDGES—See *Capacity Bridge*, also *Wheatstone Bridge.*

BRIDGING—A term occasionally used for *shunt* (q.v.) connections. Thus, a grid condenser is generally shunted or bridged by a *grid leak.*

BROADCAST—Transmission of music, news and other matters of general interest and entertainment by means of *radio telephony.* (See *Broadcasting, General Treatise on Methods.*)

BROADCASTING, GENERAL TREATISE ON METHODS—The application of radio telephony to the transmission through the ether of musical programs, speech or any form of news or entertainment, in such manner that it can be readily received by anyone possessing a radio receiver sufficiently sensitive and capable of being tuned to resonance with the particular waves being sent out. While broadcasting in its present world-wide scope is a comparatively new enterprise, it has actually been used to a more or less degree since the practical development of the wireless telephone. As near as records can be determined, the first actual broadcasting was done in 1912. It was, however, not until after the world war that it began to develop into an industry of prominence. Now it occupies a place of very definite importance in everday life; carrying news and entertainment into the remote corners of the earth, far removed from telephone or telegraph communication.

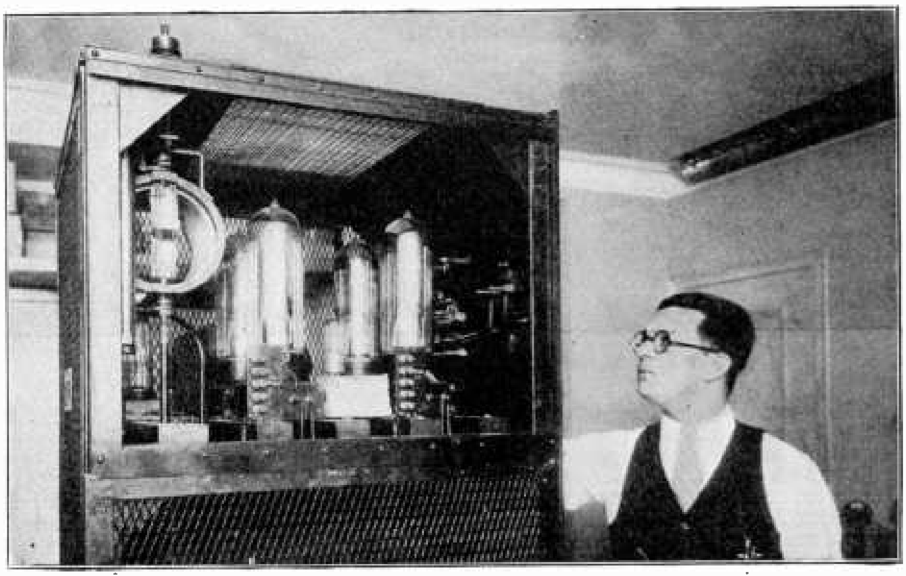

Fig. 1. A bank of 250-watt transmitting tubes in a Radio Broadcast Station. Note the small receiving tube for comparison of size.

The fundamental principles of broadcasting are essentially those of radio transmission, with the addition of means of combining the speech or music vibrations with the regular radio waves. First we have to consider the radio waves of high-frequency—alternating current that changes in direction many thousands of times each second. These high frequency waves are known as the carrier waves. The frequency of these waves varies according to the length of the waves (wavelength), in the case of American broadcasting stations, being between 250 and 550 meters in most cases, which means a frequency range of approximately 550,000 to 1,200,000 cycles.

Now by means of a microphone, a device similar in principle to the mouthpiece of an ordinary telephone, but designed to handle large currents, the air pressure waves, i.e., speech or music, are converted into variations of electric current. By use of suitable amplifying apparatus, the strength of the electric waves radiated from the antenna is varied to correspond electrically to the acoustic or sound variations due to the speech or music being impressed on the microphone. The speech or music waves are low frequency waves, generally ranging between 100 and 4000 per second. Thus, while the carrier wave oscillations are of high frequency, the variations in it are low frequency, corresponding to the ordinary speech or music vibrations.

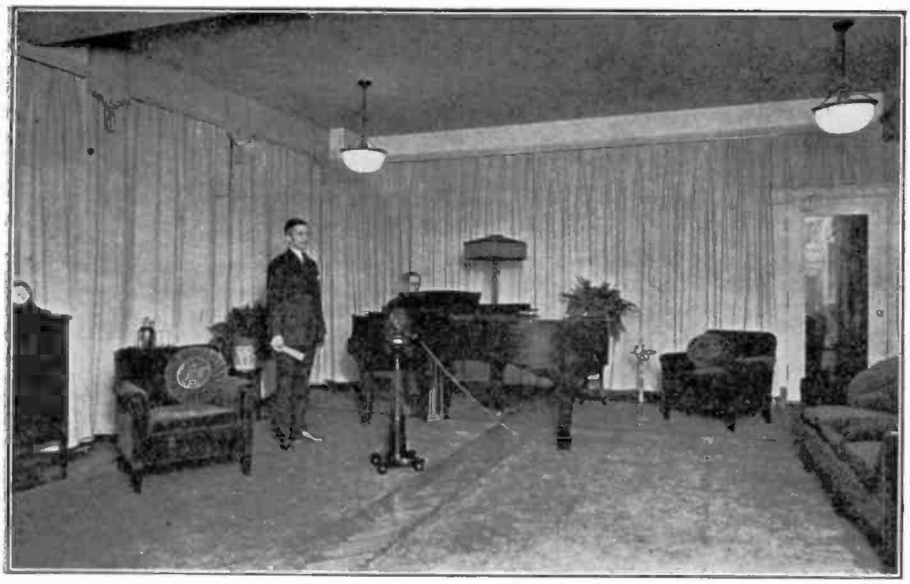

Fig. 2. Studio of a modern Radio Broadcast Station.

The process of varying the radiated wave in accordance with the sound waves is known as *modulation.* This adjustment is of the utmost importance, as defects here result in distorted or improperly modulated sound waves and the reproduction cannot be perfect. The reception of broadcast programs is essentially the same as that of ordinary radio signals, with the exception that care must be used at the receiving end to preserve the form of the original vibrations. When dot and dash signals are received, the tone is of comparatively little importance, whereas with voice or music it is essential that the tone quality be retained.

In broadcasting the high frequency oscillations are produced by means of a tube or group of tubes, practically identical with those used for reception, but designed to handle large currents and voltages. The majority of American stations use vacuum tubes of 250 watts power rating, one or more of them being used to obtain the total power required. These tubes are shown in the illustration, Fig. 1.

When a program is being broadcast, the action is somewhat as follows: The artists are disposed before the microphone with due regard to the effect of certain instruments. That is to say, one type of instrument may be placed near the microphone, while another must be placed farther away, owing to the differences in tone and volume. This is done to prevent any one tone or range of tones from predominating. These speech or music currents are converted into electrical variations by the microphone and then increased many times in power or amplitude by means of a speech amplifier system, comprising vacuum tubes and the necessary associated circuits.

These amplified currents are applied to the grid of a control tube or bank of tubes and result in large variations in the plate current of the tubes. (See *Theory of Vacuum Tube.*) The control tubes are supplied with filament current from storage batteries or special low voltage D. C. generators, and the high voltage applied to the plates of the tubes is furnished by generators. This power will vary in most cases from about 1,000 to 5,000 volts. In some broadcasting stations, the power is obtained through high voltage direct current generators, while in others, the alternating current supply is stepped up or transformed through high voltage transformers and then rectified by means of special vacuum tubes.

The high frequency waves are applied to the antenna system tuned circuits and carefully modulated in accordance with the variations of the speech or music being transmitted. The action of the transmitter and the effect of the modulation must be carefully observed at all times during the transmission of programs. (See *Harmonic Suppressor,* also *Oscillograph.*) Fig. 2 shows the studio of a modern broadcasting station. It is interesting to note that these studios are very carefully arranged and the walls cushioned to prevent troublesome acoustic effects. There must be no reverberation—echoes—or the transmitted program would be distorted by the additional or repeated tones. Fig. 3 shows the main control panels. Fig. 4 illustrates the power generating system of a typical broadcasting station.

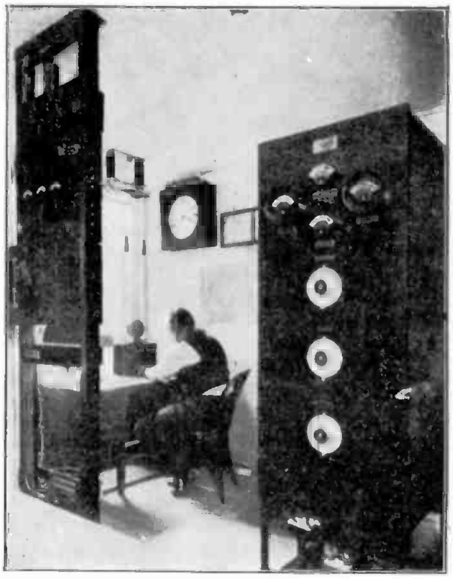

Fig. 3. Main control panels of a Radio Broadcast Station.

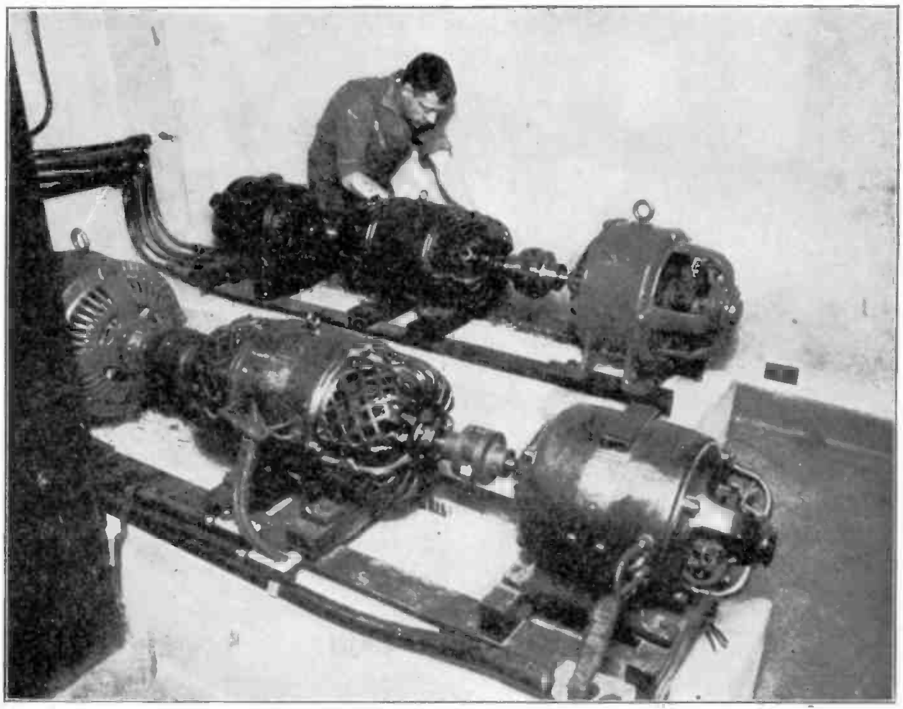
The radio waves generated and radiated from the broadcasting station travel away from the antenna at tremendous speed—that of light waves, or about 186,000 miles per second. These waves radiate off into space in



Photos by courtesy of Station WRNY (New York)

Fig. 4. A section of the generator room with power plant in a Radio Broadcast Station.

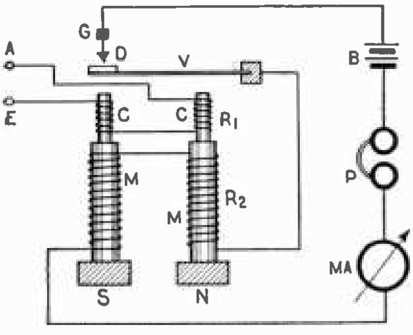
much the same manner as light waves, but a certain portion apparently follow the curvature of the earth. When these waves impinge on a receiving aerial they follow the path of least resistance, and being then in the nature of electrical impulses, they follow the aerial and lead-in wire to the receiving set, and thence to the ground. The receiver is arranged in such fashion that it corresponds electrically to the antenna circuit of the transmitting station. That is to say, the receiver is placed in resonance with the particular signals desired. The usual system of detecting, either with a simple crystal or by means of vacuum tubes, may be followed by special amplification which will make the signals audible on a loud speaker. In many cases the signals are amplified in their original form (radio frequency amplification), then rectified by the detector and further increased in volume at audio frequency. (See *Modulation*, *Speech Amplifier*, *Electromagnetic Waves*, *etc.*)

BROAD TUNING—A term used to designate the lack of *selectivity* in reception or in transmission, the use of several *waves* rather than a sharp, pure wave. If a receiving set is of such a nature that it is difficult or impossible to receive the desired signals without hearing any other, the set is said to be "broadly tuned." (See *Tuning*, also *Selective Tuning*.)

BROKEN CIRCUIT—See *Open Circuit*.

BROWN AMPLIFYING RELAY—An arrangement whereby the comparatively weak signals received by a *crystal detector*, usually of the *carborundum type*, may be *amplified* or increased in intensity, either to allow a recording machine to be used or merely to make the signals more readily audible in the ear phones. The device consists essentially of an arrangement for controlling and stepping up the vibrations in conjunction with a small *battery* or *dry cell*.

One example of such a relay is shown in the illustration. In this case the soft iron *cores* cc are *magnetized* by the *permanent magnets* mm, the poles of which are marked n and s. R1 is a fine wire winding such as is ordinarily used in ear phones and R2 is a larger winding placed over the main magnets mm. Directly above the soft core cc with the windings R1 is placed a steel vibrating tongue V having a contact D which touches lightly contact G. Contact G is of a special alloy of osmium and iridium and the contact D is a carbon button, which in contact with G forms a *microphone*. The winding R2 is joined with the telephone P and the battery B, all in series with the microphonic contact. When current (signal current) enters the leads A—E through the windings R1 the result is a change of *flux* in the core of the magnet which vibrates the tongue V. This in turn varies the current of the battery B and causes correspondingly greater sounds in the ear phones P. Several of these relays may be connected together to permit a much greater *amplification* of the original signals.



The Brown Amplifying Relay Circuit.

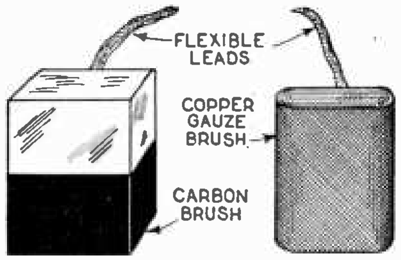
BROWN & SHARPE GAUGE—The American wire gauge adopted as standard for wires for electrical purposes. Commonly known as B. & S. The various sizes run from 40 to 0000, 40 having a diameter of .00314 inch, and 0000 being .46 inches in diameter. We refer to wire having a diameter of .00314 inch as being 40 B. & S. gauge. (*See page 26 for table.*)

BROWN, Sidney George—Born in Chicago, U. S. A., in 1873, of English parents, he was educated at Harrogate and London University. An early study was made by him of the subject of submarine telegraphy. During these investigations he invented the magnifying relay for cables. Another important invention was the cable drum relay. In the year 1898 he invented the magnetic shunt. Since that time many of his activities have been directed to the solution of problems in telephone and wireless telegraphy.

In particular the radio experimenter will know the telephone receivers bearing his name and the important developments of the *microphone relay*. In the field of land telegraphy and telephony, his activities have resulted in the invention of such items as the carbon telephone relay system, which is largely used on land trunk lines for the transmission and reception of telephony.

He is a Fellow of the Royal Society and Vice-President of the Radio Society of Great Britain. His writings on technical subjects are extensive, and numerous valuable patents have been taken out by him, including the vacuum tube *oscillation generator* in 1916 and ionic electric relays in 1918.

BRUSH—A device for collecting current from the *commutator* (*q.v.*) of a *dynamo* or supplying current to the commutator of a motor. Brushes are made in a great variety of forms, the most common being carbon blocks or brass or copper gauze. The illustration shows two different types.



Two different types of Brushes. At the left is shown a carbon brush, and at the right a copper gauze brush.

BRUSH ANGLE—The angle formed by a brush in its contact with the *commutator*. The angle is usually 45°. If the brushes do not bed properly, sparking is apt to occur.

BRUSH DISCHARGE—A faintly luminous discharge which takes place on the surface of *conductors* charged to *high potential*, due to *ionization*. This effect can be noted at times on the *antenna* of a powerful transmitting station. (See *Corona*.)

BRUSH HOLDER—Metal clamp capable of adjustment which holds the *brush* in position on the *commutator* of a dynamo or motor. (See *Brush*.)

BRUSH LOSS—The loss in *watts* or power due to the friction of the brushes against the *commutator*. This loss is at a minimum when the brushes make perfect contact at the proper angle.

BRUSH PRESSURE—A term used to designate the pressure with which the brushes bear on the *commutator* of a dynamo machine and also referring to the voltage or *electrical pressure* delivered at the brushes.

B. S. G.—Abbreviation for British Standard Gauge of Wire, commonly known as B. S. (See *British Standard Wire Gauge*.)

B. T. U.—Abbreviation for "British Thermal Unit," being the commonly used heat unit. The amount of heat required to raise the temperature of a pound of water one degree Fahrenheit at ordinary atmospheric pressure.

BUCHER, Elmer E.—Born Akron, Ohio, Nov. 11, 1885. Educated at high school and private tutors. An American pioneer, Experimental Engineer with De-Forest Wireless Telegraph Company in 1903; constructed several high power stations in Middle West and Gulf Coast and later for United Wireless, which absorbed the Deforest Company. Organized training school for United Wireless and instituted first radio schools for Y. M. C. A. in New York City. Supervised commercial operations and conducted research work for United Wireless; later instructing engineer Marconi Wireless Tel. Co. Technical Editor "Wireless Age" 1913 to 1917. Appointed Commercial Engineer for newly formed Radio Corporation of America in 1920, and since 1922 has been in charge of general sales for that corporation. Author of numerous standard works on radio, including "Practical Wireless Telegraphy," "Wireless Experimenters' Manual," "Vacuum Tubes in Wireless Communication," and many others. Holds numerous U. S. patents on radio systems and devices.

BUCKLED DIAPHRAGM—Warping of the *diaphragm* of a phone as used in radio. Excessive voltages if applied direct to the head-phones will often bend the diaphragms. Any such defect may seriously impair the operation of the part and when it is noted that a diaphragm is bent or warped through rough usage or the application of too great voltages, it is best to replace it immediately.

BUCKLING OF PLATES—During discharge of a *storage battery* the plates gradually expand, owing to the fact that lead sulphate has about twice the volume of the same quantity of lead peroxide. Should this expansion or discharge take place too quickly, the plates will bend or buckle. (See *Storage Battery*.)

BUNSEN BURNER—A form of gas burner frequently used in radio construction for heating the soldering iron where electricity is not available. By special arrangement of the parts, the gas is combined with the proper amount of air before it reaches the burning part. This is done by driving the gas through a tube with small holes drilled to allow the air to be sucked in. This method promotes complete combustion and gives a non-luminous flame that heats the soldering iron without

THE BROWN & SHARPE (B. & S.) COPPER WIRE GAUGE—Below is a comprehensive copper wire table, which is the standard one in use in the United States. The resistance and cross-sectional areas of various sizes of conductors are given, so that considerable calculating can be done with the data at hand. A mil means 1-1000 (one thousandth) of an inch. Hence a wire with a diameter of 9 thousandths of an inch could also be stated as having a diameter of 9 mils. The area of cross-section of the wire in circular mils is found by squaring the diameter in mils; thus the 9 mil conductor would have 9 times 9, or 81 circular mils area. This is the end area of the wire, of course, and is used in all electrical figuring. If the resistance per 1,000 feet of a certain size wire is, say, 50 ohms, then 500 feet of the same size wire would have a proportionately less amount of resistance, or ½ of 50 ohms, that is, 25 ohms. The resistance per foot is found by dividing the resistance in ohms per 1,000 feet by 1,000. This wire table is for bare copper wire. Conductors, according to the B. & S. standard gauge, halve their sectional area in circular mils (Cir. Mils) for every 3 gauge sizes smaller wire; and double their sectional area in Cir. Mils for every 3 gauge sizes increase.

Gauge Number.	Size.		Weight and Length.			Resistance.			Carrying Capacity, 2,000 Amperes p. sq. in. section.

depositing soot as in the case of an ordinary luminous flame.

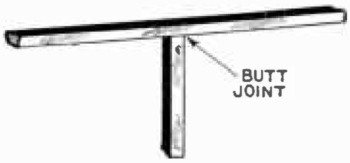
BURSTYN, Dr. W.—Born in Austria, 1877. Educated at Vienna University. Noted as: Developer of the *quenched spark system* in radio transmission, upon which he worked in conjunction with Baron Lepel in 1907 to 1912.

BUS BAR—A single bar, usually copper, which serves as a common connector for a number of pieces of apparatus. Also referred to as Omnibus Bar.

BUS BAR WIRE—Square copper wire, usually tinned, much used in making radio connections. This wire is generally furnished in lengths of two or two and a half feet and is particularly efficient for radio work, as it offers a low *resistance* connection, makes a neat appearance, and is suitable for soldering at joints.

BUSHING—Pieces of insulating material, usually fibre or rubber composition, used to *insulate* parts of radio apparatus or in mounting machine screws or shafts of *condensers* and other devices. The term is also applied to brass or other metal bearings through which the shaft of a piece of apparatus is run.

BUTT JOINT—A method joining two lengths of wire together by placing them end to end or at right angles and soldering the joint. The illustration shows a common butt joint.



Showing how a Butt Joint is made.

BUZZER—An electric call signal device that makes a buzzing noise caused by the rapid vibrations of a contact breaker in a circuit using a small *battery* or *cell*. (See *Testing Circuit.*)

As the *current* flows from the posts A B the *electro-magnets* C and D are energized and draw down the vibrator spring F. This breaks the contact between E and F and as the current no longer flows the magnets release the spring F, which returns to its normal position and establishes the circuit once more. This making and breaking of the circuit takes place so rapidly that the vibrator makes a buzzing or humming sound, the speed with which it vibrates determining the pitch of the note. (See *Frequency*, also *vibration.*)

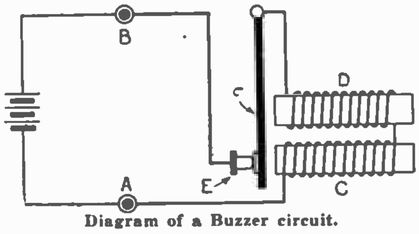


Diagram of a Buzzer circuit.

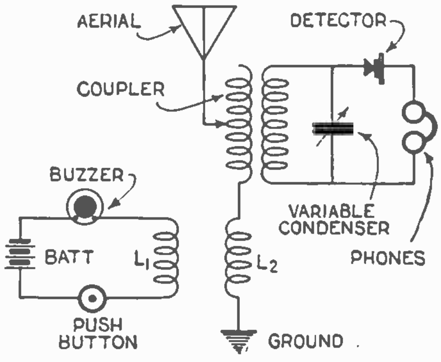
BUZZER EXCITER—A method of using a *buzzer* to produce local signals in a crystal receiving circuit to permit sensitive adjustment of the *detector*. The illustration shows a common method of producing signals to test the receiving set in this manner. In this case a small coil having a few turns of wire is placed in the buzzer circuit as indicated and a similar one is placed in the ground lead of the receiving set. When the button is depressed the buzzer is set in vibration and a transfer of energy takes place between L1 and L2. This causes an *oscillating* impulse (*q.v.*) to flow through the receiver circuit. The detector can then be adjusted to the most sensitive point at which it can be left until outside signals are heard. Another but less efficient method of exciting the circuit is to connect a short length of wire from the contact point of the buzzer to the ground connection of the receiving set. The former system is much more practical and furnishes better test signals.



Buzzer Exciter.

Coil L1 being placed in *inductive relation* to coil L2, which is in the antenna circuit, undergoes a change of *flux* when the buzzer is *excited*. This sets up a *difference of potential* across coil L2 which charges the antenna ground system and produces oscillation at a definite *frequency* according to the adjustment. Now if the secondary circuit is tuned to resonance with the primary circuit, the signals will be audible in the phones when the detector is properly adjusted. Also called *Buzzer Wave Generator*.

BUZZER MODULATION—See *Modulation.*

BUZZER PRACTICE SET—A combination of a *buzzer* and signalling key arranged on a baseboard used for the purpose of practicing signalling.

B. W. G.—The abbreviation for Birmingham Wire Gauge—a system of gauging wire used in England. (See *B & S Gauge*, also *British Standard Wire Gauge.*)

BY-PASS CONDENSER — See *Condenser*, also *Filter.*

C

C—The chemical symbol for carbon. When printed in *italics*, it is also the symbol for *coulomb* in electrical practice. It is the international symbol for *capacity.*

CABLE—A number of wires stranded together, used to carry electrical currents, heavily insulated and often covered by a sheath or outer coating of lead, rubber, gutta percha, or braided silk or cotton. The term is used very often in a broad sense to signify any heavy wire or strand of wires that may be insulated more thoroughly than is ordinarily the case. (See *Conductor*, *Stranded Wire*, etc.)

CADMIUM—A chemical metallic element somewhat resembling zinc. In color, white with a bluish tinge. It is useful in fusible alloys because of its property for uniting readily with other metals, having a low melting point. Its electrical conductivity is about 25% of that of silver. It is very useful in the construction of a crystal detector, the molten metal holding the crystal firmly and as it melts at a low temperature the heat will not affect the sensitivity of the crystal. Cadmium is also used in making cells, notably the *Weston Cell.* (See *Weston Cell.*)

CAGE ANTENNA—An aerial having a number of wires arranged in cylindrical form, suspended either vertically or as a horizontal top. So named because of its resemblance to a cage. (See *Aerial.*)

CALCULATION OF CAPACITY—The mathematical or comparative determination of *capacity.* There are various formulas in use for calculating capacity under various conditions, such as for capacity of various types of condensers, or the capacity of a circuit. Rough approximations of capacity of condensers might be obtained by direct comparison with a known value. Other formulas are used for the calculation of antenna capacity. For determining the capacity of flat condensers, such as fixed condensers used for transmitting or receiving circuits, the following formula is generally used:

$$C = 0.0885\,K\,\frac{S}{r}$$

In this case, C is the capacity in micro-micro farads; to obtain result in the usual units of micro-farads, divide the result by one million. S is the surface area of one plate in square centimeters; r is the thickness of the dielectric in centimeters and K a constant depending on the material between the plates of the condenser. (See *Dielectric Constants.*)

CAL-ELECTRICITY — Electricity produced in the secondary of a transformer due to changes in temperature of the core. This current is in addition to the current normally induced in the secondary. (See *Transformer*, *Core*, also *Core Losses.*)

CALIBRATION — A process whereby instruments such as *galvanometers* *ammeters*, *wavemeters*, etc., are made to indicate certain values. Before such

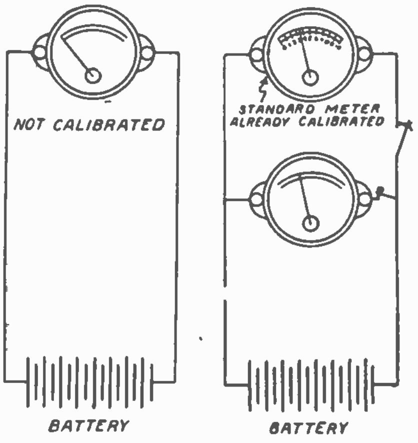


Fig. 1. Fig. 2.

Calibrating a Meter

instruments can be made use of, it is necessary to mark the dials in such a manner that the indicator showing on the dial or scale will have a definite meaning in terms of electrical values. Thus, a voltmeter before calibration is shown in Fig. 1. When it is placed across a battery, the pointer will move to some position on the white space, but without indicating any definite value. Now by testing with another meter which is already marked or calibrated in volts, we find, for example, that when the pointer is at the middle point in its swing, it indicates 10 volts. Similarly various other positions are found to indicate more or less voltage by comparison with the standard. This is shown in Fig. 2. It will be understood that one of the small switches must be open at all times. The reading of the calibrated meter is taken with the other meter out of the circuit (switch open), then the reading is marked on the other meter at the point indicated with the calibrated meter out of the circuit. Such a method would, of course, be inefficient and it is shown only to give a rough idea of the purpose and meaning of calibration. Another example of calibration is in the case of a dial on a receiver. Fig. 3 shows the usual form of dial used in tuning a receiving set. The dial is marked off to scale, from 1 to 100, the numbers having no particular significance. Now if we find that when the tuning dial is set at 20 it is adjusted for a wavelength of 260 meters, we can put that figure in place of the 20. The same procedure can be followed throughout the entire range of the dial, and when thus marked in terms of a definite quantity—wavelength in meters in this case—the dial is said to be calibrated.

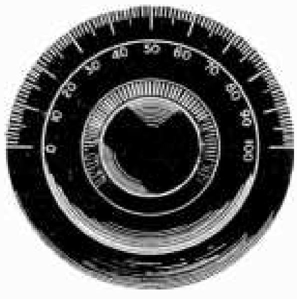

Fig. 3.

A dial as used on radio receiving sets may be Calibrated according to different wavelengths.

The actual method to be followed out in calibrating will depend on the equipment available and the accuracy desired. If a standard of comparison is available, it saves a great deal of work. Thus, a voltmeter can easily be calibrated by means of a standard meter, already calibrated, and a source of steady voltage controlled by a rheostat. An ammeter can be calibrated in the same manner by using a standard ammeter, and a wavemeter can be calibrated from another wavemeter of known values.

Calibration may be done in such a manner that the readings require mathematical solution to determine their value in terms of actual volts, amperes, meters and so on, or it may be *absolute*, in which case the readings are directly in terms of the quantity and require no solution. (See *Voltmeter Calibration, Wavemeter Calibration*, also *Rough Calibration.*)

CALIDO — An alloy containing nickel and chromium with a small percentage of iron. The melting point is very high, about 1550 degrees centigrade. Calido wire is much used as a *resistance*, particularly for heating devices. The chief characteristics are as follows: maximum working temperature 1100 degrees centigrade; microhms per cubic centimeter at 20 degrees centigrade, 100; temperature coefficient per degree centigrade, 0.00034; specific gravity, 8.2.

CALLAND CELL—A primary cell used in French telegraph work. It is a form of gravity cell having a negative electrode of copper and a positive electrode of amalgamated zinc, the electrolyte being zinc sulphate. Crystals of copper sulphate are used as a depolarizer. (See *Gravity Battery.*)

CALORIE — The unit of heat in the C. G. S. (Centimeter-Gram-Second) (q.v.) system. It is equivalent to the amount of heat necessary to raise the temperature of one gram of water from 0° to 1° centigrade. (See *Thermal*, also *C. G. S.*)

CALORIMETER—In electrical practice, an instrument used to measure the heat generated in a conductor carrying an electric current.

CAMBRIC, VARNISHED — Varnished muslin used as an insulating material. Also known as Empire Cloth. (See *Spaghetti.*)

CANAL RAYS—When an electric discharge takes place between the *anode* and a perforated *cathode* in a vacuum tube, fine pencils of light are seen to pass through the perforations in the cathode. These rays are called *canal rays*, and consist of positively charged particles. They produce phosphorescence on the wall of the tube.

Canal rays travel at a lesser velocity and in the opposite direction to the cathode rays. This fact and also the fact that the rays are deflected by powerful electric or magnetic fields in the opposite direction to cathode rays, is taken as proof that they consist of positively charged particles. (See *Cathode Rays.*)

CAPACITANCE — A term very often used as synonymous with *capacity*. Due to the fact that capacity may refer to the current carrying ability of a conductor and also to electrostatic capacity, it has been suggested that capacitance be used to refer only to *electrostatic capacity* of a body or device. Capacity would then refer to *current carrying ability.* (See *Capacity*, also *Electrostatic.*)

CAPACITATIVE REACTANCE—That part of the *reactance* of a circuit carrying alternating current which is due to the *capacity* in the circuit. (See *Reactance* also *Impedance.*)

CAPACITATIVE COUPLING — See *Coupling.*

CAPACITY — Generally speaking, the quantity of electricity in any form which a body is able to store or contain. The term is usually qualified to denote the particular case, such as *electrostatic capacity*, which is a measure of the ability of a condenser to store up energy in the form of electrostatic charges; also *current-carrying capacity* of a conductor, which is considered as the ability of a wire to carry a certain amount of electric current without overheating. The tendency in electrical literature is to use the term capacitance as applying to the electrostatic capacity of a condenser. Thus, a certain condenser may have a capacitance of 2 micro-farads. The unit of electrostatic capacity is the *farad.* This is understood as the capacity of a condenser that will store one *coulomb* of electricty under an electromotive force of one *volt.* When V is expressed in volts, C in farads, and Q in coulombs, $C = Q/V$.

CAPACITY CIRCUIT — An electrical circuit in which the *capacity* is very large compared with the *inductance.* The inductance may be considered negligible.

CAPACITY CONVERSION FACTORS —In the calculation of *capacity*, as the capacity of a condenser, there are several different units. For instance, a *farad* is a large unit of capacity and is equal to one million *microfarads*, or conversely, a microfarad is equal to one millionth of a farad. In the same way a farad is equal to one billionth of an *abfarad.* The four units used in capacity measurement are the *farad, micro-farad, micromicrofarad, statfarad* and *abfarad.* The following table gives the conversion factors for these various units:

$$1 \text{ abfarad} = \begin{cases} 10^{9} \text{ farads} \\ 10^{15} \text{ mfds.} \\ 9 \times 10^{20} \text{ stfds.} \end{cases}$$

$$1 \text{ farad} = \begin{cases} 10^{-9} \text{ abfd.} \\ 10^{6} \text{ mfds.} \\ 9 \times 10^{11} \text{ stfds.} \end{cases}$$

$$1 \text{ mfd.} = \begin{cases} 10^{-15} \text{ abfd.} \\ 10^{-6} \text{ farads} \\ 9 \times 10^{5} \text{ stfds.} \end{cases}$$

$$1 \text{ stfd.} = \begin{cases} 1/9 \times 10^{-20} \text{ abfd.} \\ 1/9 \times 10^{-11} \text{ farad} \\ 1/9 \times 10^{-5} \text{ mfd.} \end{cases}$$

$$1 \text{ mmfd.} = 10^{-6} \text{ mfd.}$$

In the table above, farad is abbreviated Fd.; abfarad is shown as abfd.; microfarad is mfd., micromicrofarad is mmfd. and statfarad is stfd. In dealing with large figures containing many ciphers the amount is shown as 1,000,000 is 10^6 and $\frac{1}{1{,}000{,}000}$ is 10^{-6}, etc. (See *Capacity, Farad*, also *Unit.*)

CAPACITY EARTH or CAPACITY GROUND—A substitute for the usual ground connection where the wires or plates are buried beneath the ground or attached to a water or steam pipe. It is in effect a second aerial, and is placed either under the regular aerial or to one side. It is more used in radio transmission than in reception. (See *Counterpoise.*)

CAPACITY ELECTROSTATIC — See *Capacity* also *Electrostatic Capacity.*

CAPACITY FREQUENCY FACTOR—The relation between the apparent capacity of a condenser and the *electrostatic capacity.* (See *Capacity, Condenser* also *Electrostatic.*)

CAPACITY OF CONDENSERS IN PARALLEL—When several condensers are connected in parallel the resultant capacity is the sum of the individual capacities. It is written:

$$\text{Capacity} = C_1 + C_2 + C_3, \text{etc.}$$

It will be evident that the resultant capacity of condensers connected in parallel is just the reverse of case for resistances, where the total resistance is less than that of the smallest individual resistance in the parallel connection. (See *Resistance Measurement* also *Capacity of Condenser in Series*, also *Condensers in Series* and *Condensers in Parallel.*)

CAPACITY OF CONDENSERS IN SERIES—When several condensers are connected in series with each other the resultant capacity is always less than the capacity of the smallest condenser in the group. The capacity of condensers in series is given as follows:

$$\text{Capacity} = \cfrac{1}{\cfrac{1}{C_1} + \cfrac{1}{C_2} + \cfrac{1}{C_3}, \text{ etc.}}$$

The resultant capacity is thus the reciprocal of the sum of the reciprocals of the several capacities. (See *Condenser, In Series.*)

CAPACITY MEASUREMENT OF ANTENNA—A simple method for the measurement of the capacity of an antenna as given by Austin follows: The illustrations show the general arrangement. The inductance L in Fig. A is a coil that will increase the wavelength (natural) of the antenna system 4 or 5 times; C is a calibrated variable condenser and W a standard wavemeter. In operation the coil L is connected in the antenna circuit, the buzzer is used to excite the antenna circuit and the wavelength is measured by w. The coil L is then taken out of the antenna circuit and shunted by the condenser C. The condenser C is then varied until the wavelength of the combined coil L and condenser C is the same as that obtained before with the coil in the antenna circuit but without the variable condenser. The capacity of the condenser now will be approximately that of the antenna, ignoring the distributed inductance of the antenna system. Fig. A shows the first operation, the measurement of the antenna with the coil in the circuit, and Fig. B shows the measurement of the wavelength of the coil and condenser. (See *Mutual Capacity, Wavemeter, Natural Wavelength,* also *Distributed Capacity.*)

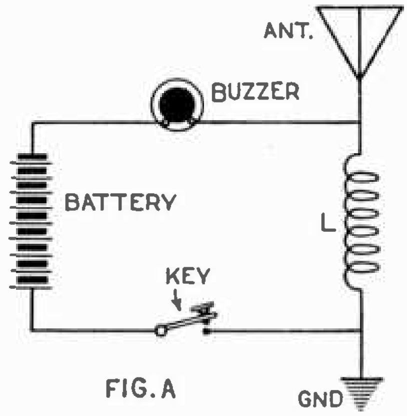

FIG. A

The first operation in the measurement of the antenna. The wavemeter is shown below.

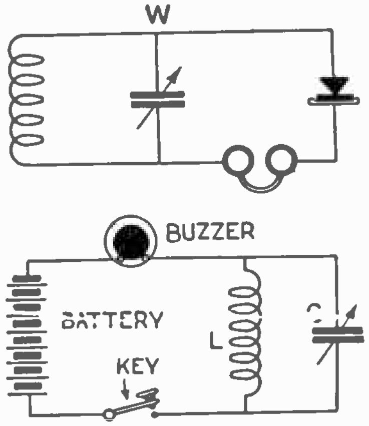

FIG. B

Circuit for the measurement of wavelength of coil and condenser.

CAPACITY MUTUAL—See *Mutual Capacity.*

CAPACITY RESISTANCE—The resistance to alternating currents offered by a body possessing electric capacity. (See *Capacity,* also *Resistance.*)

CAPACITY SWITCH—Any switch used in a circuit to introduce or cut out capacity (condenser).

CAPACITY (UNIT OF)—The unit of capacity is the farad. A condenser has a capacity of 1 farad when 1 coulomb is required to raise its potential from zero to 1 volt. Since the farad is very large, its millionth part, or the microfarad is generally used.

CARBON—A non-metallic chemical element used for many purposes in electricity and radio. It exists in three forms, two crystalline and one non-crystalline. The first two are diamond and graphite, the third charcoal. Carbon is used as an electrode in electric arcs, as one of the poles in certain types of primary cells, as a material in place of wire for various forms of resistance, and as brushes in motors and generators. (See *Diaphragm, Carbon.*)

CARBON RHEOSTAT—A rheostat or variable resistance using carbon in place of the customary wire. In its simplest form a carbon rheostat may be merely a piece of carbon having a sliding contact. This is shown in Fig. 1. Owing to the relatively high resistance of carbon used in this manner, such a controlling resistance will generally be termed a *potentiometer* (q.v.) and used as such.

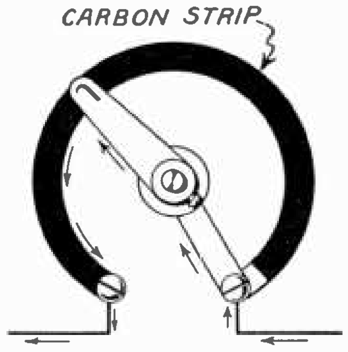

Fig. 1.—A carbon rheostat with a rotary sliding contact.

The most practical form of a carbon rheostat is known as a carbon pile rheostat. This type uses a number of flat pieces of carbon of relatively low resistance placed together and arranged with a knob and screw in such manner that the pressure can be varied. This change in pressure alters the resistance of the mass and allows control of the current for vacuum tubes. The same principle is used for very high resistances as well as for low values. The principle will be seen from the illustration Fig. 2.

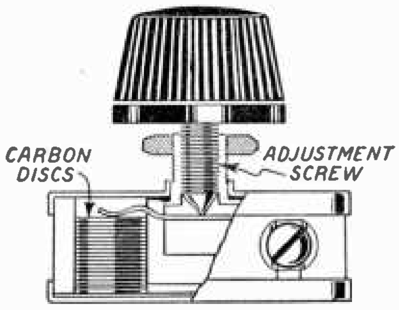

Fig. 2.—A carbon pressure type rheostat.

CARBORUNDUM—An abrasive material, a product of the electric furnace, composed of silica and carbon. It is used in radio as a crystal rectifier, although the strides of radio have practically rendered it obsolete, many other better crystals being in use. The chief difficulty with its use as a rectifier or crystal detector was the fact that for efficient operation it required a cell or battery and potentiometer to regulate the current flowing through it. The simple crystal circuit using a carborundum detector is shown in the illustration. C is a tuning coil, D the carborundum crystal and contact, P a potentiometer and T the head phones. (See *Rectifier,* also *Detector.*)

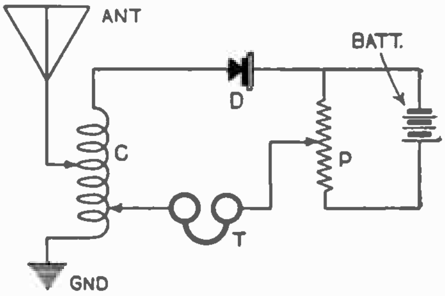

Diagram of a radio circuit employing a carborundum crystal detector.

CARDBOARD TUBING—Tubing made of laminations of paper pasted together. They are used for home made coils of all descriptions, and while not as efficient as the composition tubing, can be used for many purposes without any great loss. As a general rule it is better to use some of the numerous compositions, such as bakelite or rubber compounds.

CARPENTIER, JULES—French radio expert. Born in Paris, in 1854, he joined the Ecole Polytechnique in 1871, and in 1876 was appointed principal stores engineer of the Lyons Railway Company, making a special study of electricity. For his work in electricity he obtained in 1881 the cross of Chevalier of the Legion of Honor. One of the early pioneers of radio in France, he founded the Compagnie Generale Radiotelegraphique, afterwards absorbed in the Compagnie Generale de Telegraphie sans Fil. Carpentier is a member of the Academie des Sciences, Commander of the Legion of Honor, and President of many scientific societies.

CARRIER WAVE—The *continuous wave* (q.v.) of radio frequency generally thought of as carrying the voice or music waves from the radio broadcasting station. Actually it is a radio wave of high frequency, which is altered in amplitude by the music or speech transmitted. In action, this continuous wave has another wave super-imposed on it. This other wave having wave form and amplitudes determined by the voice or other sounds being transmitted. The illustration shows the carrier wave, the waves representing speech or music and the combination of the two. This effect of varying the amplitude or strength of a continuous wave by means of some sort of program is known as *modulation.* (q.v.) The wave representing the speech or music is imposed on the carrier wave resulting in the combined wave which reaches the listener and is translated by suitable apparatus into approximately the same sounds that are transmitted. (See *Modulation, Broadcasting*, also *Speech Vibrations*.)

CARRYING CAPACITY—See *Current Carrying Capacity.*

CARTRIDGE FUSE—A fuse in which the fuse wire is surrounded by some non-inflammable substance, enclosed in a cartridge-like tube and having brass lugs soldered to caps at ends. Used to prevent the hot wire from "flying" when fused. (See *Fuse*.)

CASCADE—A term applied to pieces of apparatus connected together in series, particularly vacuum tubes. In this case, the arrangement would be such that each vacuum tube would amplify the signal output of the preceding tube. The tubes will be so connected that the output of one is introduced as input to the next and so on the total result being greatly increased signal strength from the output of the last tube. This term may apply to either radio frequency or audio frequency amplification. (See *Amplifier, Radio Frequency*, also *Audio Frequency*.) A simple cascade arrangement is shown in the illustration. Fig. 1 is a circuit with two stages of cascade radio frequency amplification, and Fig. 2 a circuit using two stages of audio frequency amplification with the usual detector tube in each case. A combination of both radio frequency and audio frequency stages of amplification might also be used, the term cascade amplification also applying here.

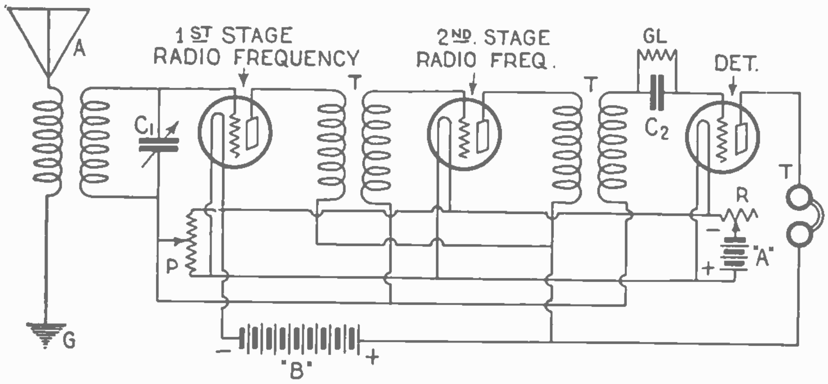

Fig. 1.—Circuit diagram showing two stages of cascade radio frequency amplification and detector.

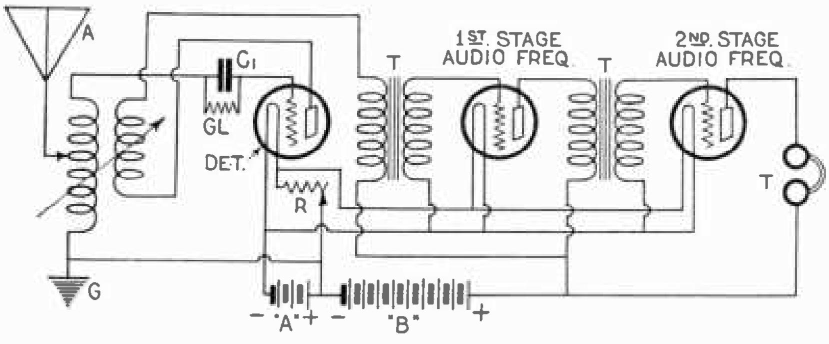

Fig. 2.—Diagram of detector and two stage cascade audio frequency amplifier.

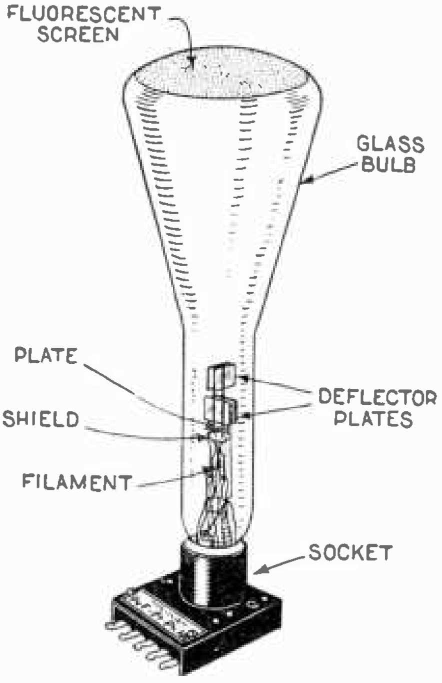
CATHION or CATION—The charged particles which appear at the cathode or move toward it through the electrolyte of an electrolytic cell. (See *Anode*.)

CATHODE or KATHODE—A *negative electrode*. The term is often applied to the filament of a vacuum tube to distinguish it from the anode or plate. (See *Cell, Electrolysis*, also *Anode*.)

CATHODE RAY TUBE—A vacuum tube having a high vacuum, that is from which practically all air has been exhausted, used in the production of cathode rays. These tubes in their modern form are used for many purposes in studying the nature and form of electric waves. The illustration shows one of the latest types of tube, known as the *Cathode Ray Oscillograph*. This tube is used for the following purposes: examination of the wave forms of various rectifiers, study of wave forms of different types of generators, study of vacuum tube characteristics, examination of the characteristics of X-ray and other types of tubes, examination of radio frequency waves modulated as in broadcasting, measurement of hysteresis and dielectric loss in various materials, study of phenomena in arcs and sparks, together with numerous other associated effects. The development of this tube is one of the marvels of science, enabling the research engineer to virtually see the electric wave, and to study exhaustively, electric phenomena otherwise invisible.



A cathode ray tube with socket.

The Western Electric modification of the Braun Cathode ray tube or oscillograph, is a three electrode glass tube about 30 centimeters (about twelve inches) long, in the form of a cylinder an inch and three-quarters wide, spreading out in conical shape, the tube being about three and a half inches wide at the top. The *cathode* is a filament coated with active oxides and arranged to emit the number of electrons required for the cathode rays, at a dull red heat. The *anode* or plate is a small platinum tube set very near the filament. Between the filament and the anodes is a small circular screen having a hole just a little smaller than the circular filament. A battery of several hundred volts is connected between the filament and plates with the positive terminal connected to the plate. The electrons emitted from the hot filament are controlled by this field in the same manner as in an ordinary vacuum tube. A small portion of these electrons pass completely through the tubular anode and constitute the *cathode* rays. These rays are passed between two pairs of deflecting plates set at right angles to each other, and fly against the large end of the tube. This end is covered with a fluorescent mixture which renders the rays visible. These rays are deflected in various ways. For example, if an alternating current is applied the visible spot on the screen will be drawn out into a line. (See *Electron, Vacuum Tube*, also *Wave Analysis*.)

CATHODE RAYS—The stream of electrons or electrical particles sent out from the *cathode* or filament of a vacuum tube. These rays are negatively charged. (See *Cathode, Electrons, Vacuum Tube* also *Oscillograph*.)

CAT-WHISKER—The fine wire used with certain crystal detectors to make contact with the crystal. Usually a springy metal such as phosphor bronze wire.

"C" BATTERY—One or more small cells having a voltage generally between 2 and 10 volts, used in the grid

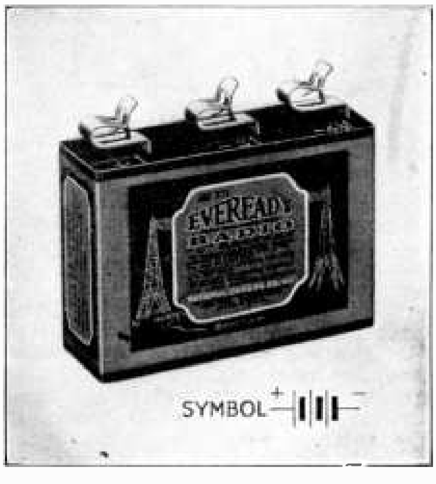


Fig. 1.—A 4½ volt "C" battery. This type of battery has a common positive terminal and is tapped at negative terminals for 3 and 4½ volts.

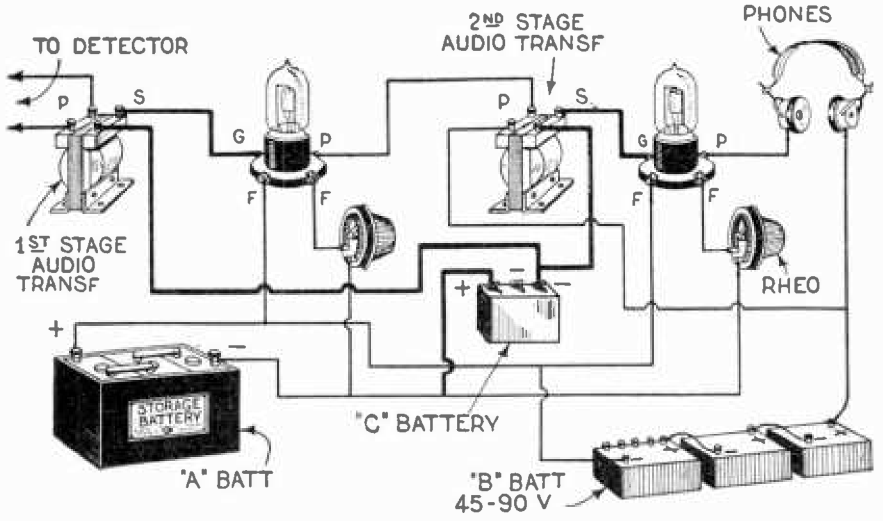

Fig. 2.—A diagram showing how the "C" battery is connected in the audio frequency amplifier.

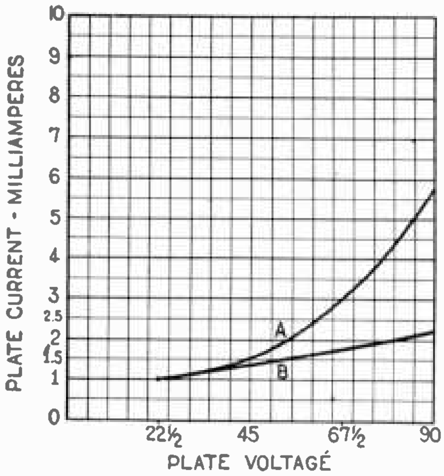
circuit of an amplifier tube for the purpose of impressing a negative potential on the grid of the tube. The method of connecting it in the circuit is shown in Fig. 2. Fig. 1 shows a typical 4½ volt "C" battery. (See also *Grid Bias* and *"C" Battery Curve.*)

"C" BATTERY CURVE—In order to show the effect of a "C" battery on the consumption of current from the "B" battery in an audio amplifier, a *curve* (q.v.) may be drawn as in the illustration. In this case the test was made with a type UV 201A tube used as a one stage *audio frequency amplifier* in



Test conducted on UV201A tube using single stage audio amplifier with conventional circuit. Plate Voltage—Abscissae. Plate Current in milliamperes—ordinates. A—Consumption curve without "C" Battery. B—Consumption curve with "C" Battery. (Note: 1.5 ma. at 45v plate rising to 5.75 ma. at 90v plate without "C". With "C" Battery consumption maximum is 2¼ ma. at 90v.)

a conventional circuit. It is readily apparent on referring to the lines A and B that when the "C" battery is in use the consumption of current by the plate is much less than without it.

CELL—A cell is one of the four chief sources of electric energy. In a cell the energy is created by an *electrochemical* process, using in its simple form two unlike metals immersed in a dilute acid or alkaline solution. In the illustration Fig. 1 the common form of electric cell is shown. C is a strip of *carbon* and Z a strip of *zinc.* These are placed in the jar in a conducting solution of sal ammoniac. If the exposed terminals from the carbon and zinc strips are connected together by a piece of wire, current will flow from one side of the cell to the other through the wire. The current flows from the carbon or *positive* pole to the *negative* or zinc pole through the wire, completing the circuit through the solution from zinc to carbon. (See *Current, Direction of Flow.*) The cell described is known as a *primary cell.*

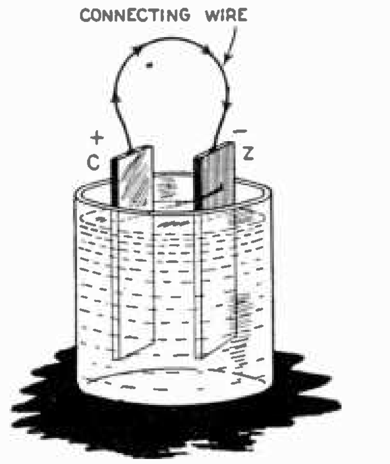


Fig. 1.—Common form of electric cell.

In Fig. 2 a simple *storage cell* or *secondary cell* is shown. In this case there are two lead plates immersed in a dilute solution of sulphuric acid. A source of primary current (primary cell) may be connected to the secondary cell in the manner shown in Fig. 3 and after being connected for a certain length of time it will be found that the energy of the primary cell has been transferred to the secondary cell and stored in it. This process of placing electric charges in a secondary cell is known as *charging*, and the current stored up in it is known as the *charge.* Now, if the wire is connected from one terminal to the other it will be found that electric energy can be withdrawn in a similar manner to that of the primary cell. A secondary cell may contain several plates and several of these cells may be connected together to form a storage battery. (See *Storage Battery, Current, Production of,* also *Anode* and *Cathode.*)

PEROXIDE OF LEAD THIS PLATE BECOMES THE POSITIVE POLE OF CELL

Fig. 3.—Primary cell connected to secondary or storage cell.

CELL, SECONDARY—When a *primary cell* is connected to a *storage* or *secondary cell,* the current from the primary cell flows into the secondary cell and in effect deposits energy in that cell. Then when the charging source (the primary cell) is withdrawn, the secondary cell can be used in practically the same manner as the primary cell. A wire connected from one terminal to the other will permit passage of current. The action of storing up energy in a storage cell is approximately as follows: When the charging current flows from plate to plate through the solution in the secondary or storage cell, the plate connected to the *positive* (+) *pole* (carbon or copper) of the primary cell, receives a brown coating of *peroxide of lead.* At the same time the other plate becomes spongy or porous. Now as one plate has received a coating while the other remains unchanged as far as its surface is concerned—it acts as a primary cell if the charging source is taken away and the two terminals connected. It now has all the essentials of an ordinary chemical cell. As long as the coating of peroxide of lead remains on the surface of one of the plates, the cell will be capable of delivering current.

When the coating has been worn off or eaten away the cell is said to be in a discharged condition. It will then be necessary to go through the same process of connecting a primary source to the terminals in order to again deposit peroxide of lead on one plate. It will therefore be evident that when the *storage cell* is charged, *current* is not actually stored in it, although in effect it has received potential energy. What has actually occurred is that the current supplied to the cell during the charging process has produced electrochemical changes, making the plates dissimilar and thus producing a difference of potential. (See *Current, Production of*). The *voltage* or *electromotive force* of primary cells varies from .06 to 1.5 volts according to the nature of the elements used and the grade of the *electrolyte* (q.v.). Secondary or *storage cells* of the lead plate type produce from 2.1 to 2.6 volts. (For more complete explanation of the theory and action of a secondary cell, see *Storage Battery.* See also *Electro Motive Force, Current* and *Voltage.*)

CELL, THEORY OF PRIMARY—It has been explained under the heading *Cell*, that a primary cell produces electrical energy by chemical action. More specifically the action of a simple cell is as follows: When the copper and zinc, or carbon and zinc placed in a cell are connected together by a conductor, (wire or other conducting object) the acid in the case of a sulphuric acid solution, attacks the surface of the zinc plate and forms a compound known as zinc sulphate. While this sulphate is being formed some of the hydrogen contained in the sulphuric acid is liberated in the form of bubbles which appear on the copper plate. Some of these bubbles escape into the surface of the solution, but others cling to the surface of the copper plate and gradually cover it with a film of hydrogen. It may be said here that the decomposition of the zinc plate in the acid solution furnishes the *electro-motive force* required to cause the flow of current between the plates, through the solution and through the conductor. Now, hydrogen is a non-conductor, and as the hydrogen gradually covers the copper plate, the surface of the plate in contact with the solution gradually decreases. The flow of *current* from zinc plate to copper plate in the solution is thus gradually diminished, until eventally we can imagine the copper plate as being entirely covered with hydrogen and no longer in contact with the solution. In addition to this insulating action of the hydrogen, it tends to set up a current within the cell in the opposite direction to the normal flow of current produced by the chemical action. A cell in this condition is said to be "polarized," and various means have been used to cut down or eliminate the *polarization effect.* The purpose of these various means is to prevent the hydrogen bubbles clinging to the surface of the copper plate, thus allowing them to escape to the top of the solution and thence into the surrounding air. (*See Polarization, Current, Voltage, also Storage Cells.*)

CENTIMETER—A measure of length in the metric system. It is one hundredth part of a meter, or approximately .3937 inch. It is used as the unit of length in the Centimeter Gram Second System (q.v.).

CENTIMETER GRAM SECOND or C. G. S. A system of units of measure employed in practically every branch of engineering, particularly in electrical practice. It is a decimal system, the centimeter being the unit of length, the gram the unit of weight and the second the unit of time. All other units are derived from these three. When the magnitude of a quantity is spoken of, it refers to the relative magnitude of the quantity when compared with some other quantity of the same nature. The magnitude used as a standard of comparison is termed a unit. Thus, if the length of a body is measured in feet, as for example, ten feet, it means that the magnitude of the body is ten times unity or ten times one foot. Similarly a *current* of ten *amperes*, is a current of magnitude ten times as great as the unit quantity—one ampere. Now an ampere is the practical unit of rate of flow of electric current. The unit has a certain definite value. (See Ampere.) The magnitude of any other similar quantity measured in amperes will mean a value equal to a certain number of units. In addition to the C. G. S. system of units, there is a practical system. This is commonly used for ordinary calculations. Under this system, the following are the main units: The *volt* is the practical unit of *electro-motive force;*—the force required to maintain a flow of current of one ampere through a resistance of one ohm. The unit of *current strength* or rate of flow of current is the *ampere;*—the strength of current maintained by a force of one volt through a resistance of one *ohm.* The unit of *resistance* is one *ohm*, and is the resistance of a *conductor* or *circuit* that will permit the passage of a current of one ampere under the force of one volt. The unit of *quantity* is the *coulomb*, which is the quantity of current flowing in a circuit when one ampere passes a given point during one second of time. The *watt* is the practical unit of *electrical power*, being the power of a current of one ampere flowing in a circuit under the pressure of one volt.

It will thus appear that the practical system is actually based on the C. G. S. system. Calculations of an involved nature necessarily make use of the C. G. S. system, and when multiples or sub-multiples are used they are expressed in Greek and Latin prefixes. For example, a million ohms is 10^6 ohms and is expressed as a *meg-ohm.* "Meg" being derived from *mega millian.* Similarly a millionth of an ampere is expressed as a *micro-ampere* or 10^{-6} AMPERE. The various units under the C. G. S. and practical systems are taken up in detail under the respective headings, as *JOULE. ERG, DYNE* and so forth. (See also *Inductance (Unit of); Capacity (Unit of); Electrostatic Units and Electromagnetic Units.*)

C. E. M. F.—The abbreviation for *counter electromotive force* (q.v.).

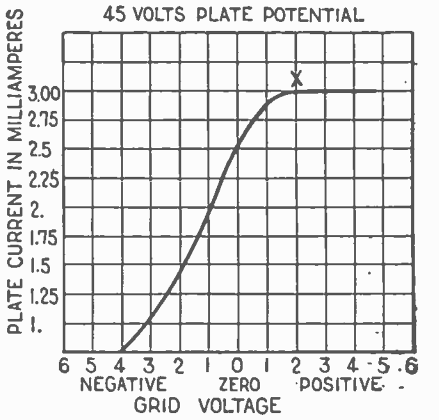
C. G. S. UNIT OF CURRENT—The absolute *electromagnetic unit of current.* It is the current which when passed through a conductor bent into a circle of one centimeter radius will attract or repel a unit magnetic pole placed at its center, with a force of one *dyne* (q.v.).

CERUSITE—A kind of mineral used as a rectifier in some types of *crystal detectors.* It is a carbonate of lead having a whitish-grey color. This mineral is not as good a rectifier as some of the others, but has the advantage of more uniform sensitivity over practically its entire surface. (See *Crystal Detectors.*)

CHALCOPYRITE—A crystal used in a *pericon detector*, which is composed of zincite and chalcopyrite in contact with each other. It is a combination detector suitable for use where it is subject to jarring, since it has nearly uniform characteristics over its entire surface. It works without the aid of an electric battery.

CHARACTERISTICS—A term broadly applied in electricity to refer to any distinguishing feature in electrical apparatus. In radio usage the term is generally applied to *vacuum tubes.* The characteristic of a tube is understood as the relation between the potential (voltage) at the *grid* (q.v.) and the resulting current obtained from the *plate.* (q.v.) It may also occasionally refer to other features of a tube, such as its current requirements or amplifying quality as distinct from the ratio of *grid voltage* to *plate current.* (See *Characteristic Curve, Vacuum Tube Characteristics;* also *Plate Current.*)

CHARACTERISTIC CURVE—A diagram showing graphically in the form of a curved line the relation of changing values. Thus, in the case of a *vacuum tube*, a change in the *grid* voltage produces certain changes in the *plate* current (q.v.) and these changes may be plotted as curves. The temperature of a wire carrying current increases with increase in the *current* passing through it, and this increase may be shown by a curve. (See *Vacuum Tube Characteristics.*)



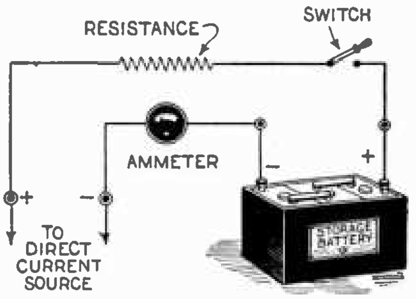
Characteristic chart of vacuum tube grid and plate voltage.

CHARGE—The presence of electricity in a body. Is usually defined as an excess or deficit of *electrons* (q.v.) on an insulated body. In the case of a *condenser* (q.v.) after it has accumulated electrical energy it is said to be in a charged condition, or to have an *electro-static charge.* The charge in a *condenser* is measured in *coulombs.* (q.v.) A *storage battery* is said to contain a charge when it has been connected to a source of direct current for a length of time, and the hydrometer test shows the electrolyte at proper specific gravity.

CHARGE, SPACE—See *Vacuum Tubes*, also *Space Charge.*

CHARGED BODY—Any body that has accumulated electrical energy. (See *Charge.*)

CHARGER, STORAGE BATTERY—Any means of controlling the current delivered from a primary source for the purpose of charging *storage batteries* or other *secondary cells.* Chargers are made in many forms and are designed for either direct or alternating current. Direct current chargers consist of certain resistances, with the necessary meters and switches. A simple form of direct current charger is shown in the illustration. In constructing a direct current charger there are several important details that must be



Charging storage battery from direct current source.

taken into consideration. The plates of a storage battery require certain charging rates in amperes, depending on the size and number of the plates. That is to say, the manufacturer specifies that when charging, a certain number of amperes must be passed to the battery from the charging source for a definite number of hours. This figure may be decreased but not increased. As an example, some storage batteries will take a charge of five amperes without injury to the plates, which rate would be ruinous for other batteries. Now the question of obtaining the proper amount of charging current arises. The majority of house lighting systems have a voltage of from 110 to 125 volts. (Reference is now made only to direct current systems, alternating current chargers being taken up later on.) According to *Ohm's Law* (q.v.) the current flowing in a circuit is directly proportional to the *voltage* and inversely proportional to the *resistance*. Voltage is the product of resistance times the current, the resistance in ohms and the current in amperes. Therefore if we desire a current of five amperes from a source of 110 volts, it is necessary to have a resistance of a value in ohms which, when multiplied by the current in amperes,—five in this case—will produce 110. Conversely, we can divide the voltage—110 by the current—5 to obtain the correct resistance. This would indicate a resistance of 22 ohms. There is another factor which enters into the problem however, the back pressure, or Counter Electromotive Force exerted on the charging source by the battery. In the case of a six volt storage battery, this will be six volts. This must be subtracted from the voltage of the charging source to obtain the effective value. Thus, the effective value in this case would be 110 — 6 or 104 volts. Then as explained before, dividing the voltage by the current required, we find that it is 104 ÷ 5 or approximately 21 ohms. Then by placing a resistance of 21 ohms in the circuit, as shown in the illustration, and connecting the battery as indicated, a charge of five amperes can be applied to the battery. The same result can be obtained by placing an ordinary electric lamp in series in place of the resistance. (See *Lamp Bank.*) The *internal resistance* of the battery is very small compared to that of the line resistance, and can be ignored. A point to remember is that the voltage of the charging source must always be higher than that of the storage battery, because, as explained above, the back or *counter electromotive force* of the battery, must be subtracted from the voltage of the charging source to indicate the effective voltage. Thus, if the battery exerts a counter electromotive force of six volts and the charging source is only six volts the counter force would be equal to the charging force and there would be no charging current. When *direct current* is not available and *alternating current* is used to charge the battery, it will be necessary to change it to direct current. For this purpose it is essential that some form of *rectifier* be used. This rectifier may be of a chemical, mechanical or electrical type. These various forms will be taken up under their separate headings. (See *Rectifier, Balkite, Tungar, Rectigon, Electrolytic Rectifier, Tube Rectifier.*)

CHARGING—The act of expending electrical energy to place a charge in or on a battery or body. The term is used generally to indicate the process of impressing electrical energy on the *storage battery* elements for the purpose of making the battery a secondary source of electricty. (See *Charger, Chemical Rectifier* also *Tube Rectifier.*)

CHARGING BOARD—A term used synonymously with *charging panel* to denote an arrangement for controlling the current used for charging *storage batteries.* It generally consists of an insulated panel with various *switches, fuses* and *resistances* thereon to limit the amount of current delivered, and at the same time furnish a ready means of connecting and disconnecting the various circuits connected through it. The fuses act as safety devices and break the circuit when too great a current is delivered. (See *Fuse, Switch, Charger.*)

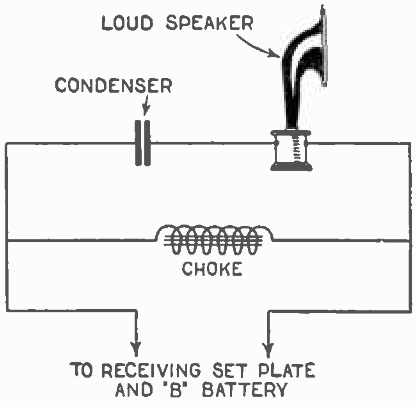
CHEMICAL RECTIFIER—Device for changing alternating current to direct current. (*See Electrolytic Rectifier.*)

CHLORIDE BATTERY A type of storage battery for heavy duty operation. The positive plate is made of lead with a number of holes pierced in it and each filled with a coil of pure lead. This coil is forced into the holes during manufacture and is said to enable the battery to withstand heavy discharge without damage to the plates. (See *Storage Battery.*)

CHLORIDE CELL—A cell (q.v.) which uses in most cases, a positive plate having lead as the active material, the negative plate being made of metallic zinc. A solution of chloride of zinc is used, from which the name is derived. (See *Chloride Battery.*)

CHOKE OR CHOKING—The action of a device in a circuit wherein it tends to choke, or hold back, certain forms of current or certain *frequencies* while permitting others to pass freely, or to oppose fluctuations in the strength of the current passing through it in the circuit.

CHOKE COIL—A coil of wire possessing considerable *self-inductance* and relatively little *resistance.* These coils are used in various ways and for a variety of purposes. When connected in a direct current circuit, and possessing the proper value, they have a tendency to prevent any fluctuations in the current and thus keep the current smooth. An example of its use is with a *loudspeaker.* A *condenser* will permit passage of *high frequency* (*alternating*) *currents* such as we find in radio reception, but will effectively block direct currents. On the other hand a choke coil will pass direct current without offering any appreciable resistance, but will retard the *modulated currents* (q.v.) It will be apparent then that by a proper combination of the two (Choke Coil and Condenser) as in the illustration, the direct currents can be shunted around the loud speaker and thus prevent injury to it, while the necessary modulated currents are allowed to pass through without difficulty. Another use for the Choke is in a circuit carrying alternating currents. In this case the choke will limit the current in the circuit without loss, whereas an ordinary resistance, while it would limit the current, would dissipate a certain amount of energy. Chokes may be made with iron cores of the open or closed type, for *low frequency currents*, or may only have air for the core when used in *high frequency* circuits. The closed core type is the more common form. The formula most commonly used in determining the inductance of a choke coil in *henries* is as follows:



Method of using choke coil in connection with loud speaker.

$$L = \frac{1.257 \times \mu \times A \times N^2 \times 10^{-8}}{l}$$

Where L is the inductance in henries.

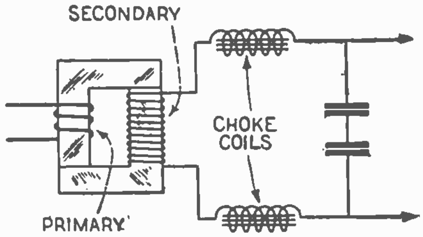
μ is the permeability. (This varies from about 1000 to 2000 in most cases).

A is the effective area of iron cross section (square centimeters).

N is the number of turns of wire.

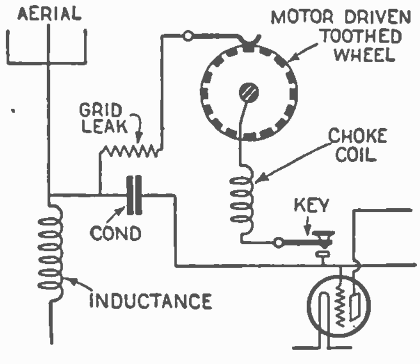
l is the length of iron path (in centimeters).

CHOKE, HIGH FREQUENCY — A choke coil of high *self-inductance* (q.v.) used in transmitting circuits to prevent puncture of the secondary windings of the *transformer* (q.v.). When the condensers in a transmitting circuit are charged or discharged, a back pressure is exerted on the windings of the transformer supplying the high voltage. The illustration shows the position of these choke coils in the transmitting circuit. (See *Back Oscillation.*)



Position of choke coils in transmitting circuit.

CHOPPER—A device used in the aerial circuit of a *continuous wave* (q.v.) transmitter to break up the continuous trains of waves into separate groups and thus permit them to become audible. In the case of reception of ordinary *damped waves* (q.v.) the head phone produces signals that have a frequency of vibration equal to the number of wave trains per second. When the transmitted waves are con-



Showing how chopper is used to interrupt signals from continuous wave transmitter.

tinuous there is obviously no interval, that is, there are no groups of waves and they are therefore inaudible in the usual receiving apparatus. The *chopper* is only necessary when *crystal detectors* are used for reception. (See *Ticker, Beat Reception and Continuous Wave Transmission.*)

CIRCUIT—The path followed by an electric current passing from its source through a wire conductor or series of such *conductors*, and back again to its starting point. A *closed circuit* is one that is continuous and will permit the passage of current. An *open circuit* is one that is not continuous and, being broken or open at some point, will not permit passage of the current. The term is used very commonly, and broadly covers any system for the conducting of electric current from its source, through some electrical instrument or appliance and back to the starting point.

CIRCUIT BREAKER—Generally speaking, any device for automatically breaking or opening a circuit and thus preventing flow of current through the circuit. More specifically, it may be a device similar to a *switch*, used to automatically open the circuit when the current falls below a certain point, or rises above a certain fixed value. Thus an *overload circuit breaker* is an arrangement which will automatically open the circuit if the current becomes too great. This is shown in Fig. 1. It is a simple form and consists of an *electro magnet* which requires a certain force to operate it. When the current in the circuit reaches a certain point, the magnet operates, pulling down the bar "A" against the action of the spring "P," and thus breaking the circuit. As long as the current is not more than that fixed by the requirements of the circuit—the magnet being arranged in accordance with the particular requirements — the current flows, the breaker operating to open the circuit only when more than the desired current is introduced into the circuit. In the illustration we can consider "S1" and "S2" as the source of current, "M" as an electro-magnet in series with the motor "D," and "A-B" a switch, in which "A" has attached to it a piece of soft iron. Now if the current required for the motor is ten amperes, the magnet can be so designed that it will not act on the bar "A" until 15 amperes flow through it. Thus, as long as the current is less than this, the circuit is continuous, but if the current is increased to 15 amperes, the magnet operates and attracts the bar "A," breaking its contact with "B" and thus opening the circuit. In Fig. 2 a simple *underload breaker* is shown. In this case the operation is the reverse of that of the *overload breaker*. Here the bar "A" is held down in contact with "B" by the magnet "M" thus keeping the circuit closed through the motor "D". Now assume that the motor requires ten amperes and the magnet requires the same amount to hold the bar "A" in place against "B". If then the current in the circuit falls below ten amperes, the magnet can no longer hold the bar "A" against the action of the spring "P" and it rises, breaking the contact between "A" and "B" and thus opening the circuit. These circuits are of course only assumed for the purpose of illustrating the theory of circuit breakers. Actually the system is generally much more elaborate. Circuit breakers are used for many purposes—chiefly to prevent any sudden increase or decrease of current in a circuit, and to control the flow of current for charging batteries. (See *Charger-Storage Battery.*)

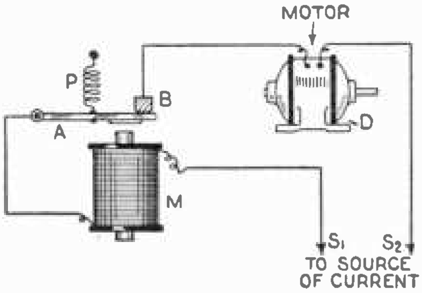


Fig. 1. Overload Circuit Breaker.

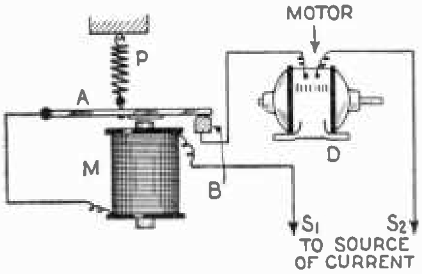

Fig. 2. Underload Circuit Breaker.

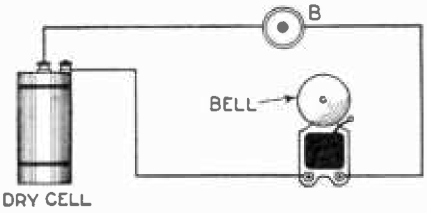
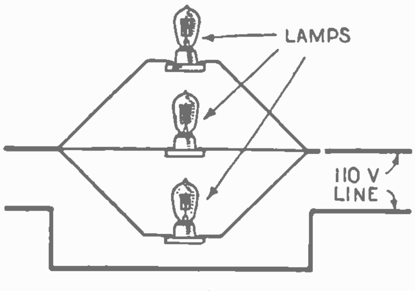
CIRCUIT, BROKEN—A circuit that is not continuous, having been opened either purposely, or due to some defect in the circuit. The term is usually applied where the circuit is opened by the breaking of a wire, or through a faulty contact.

CIRCUIT, OPEN — A circuit which is open and through which current cannot flow, or a circuit which is normally open but which can be closed at will by pressing a key or button. A common example of open circuit is in the case of an electric bell circuit. The illustration shows such a circuit. Normally it is open and current does not flow to the bell, but on pressing the button B, the circuit is closed and current passes to the bell. (See *Circuit*, also *Closed Circuit.*)



Open circuit which can be closed by pressing button "B".

CIRCUITS, PARALLEL — Circuits starting at a common point and ending at a common point. The illustration shows three *parallel circuits*. Actually each one is a part of the whole circuit. (See *Parallel Resistances.*)



Three parallel circuits.

CIRCULAR MIL—The cross-sectional area of conductors (wires) is usually designated in terms of circular mils. A circular mil is the area of a circle having a diameter of one thousandth of an inch. Thus a wire having a diameter of one quarter of an inch is said to have an area of 250 circular mils. (See *Square Mil.*)

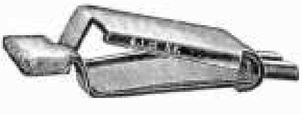
CLEAT—A form of porcelain *insulator* used in house wiring. They are generally arranged in two parts, with corresponding grooves in which the wire is held, and are nailed or otherwise fastened to the wall. Cleats are about the cheapest form of insulator and where the voltages used are low, are quite as effective as the more elaborate types. Cleats are much used in radio work, both for insulating lead in wires coming from the aerial, and for insulating the aerial itself.

CLERK-MAXWELL, JAMES—Born at Edinburgh, Scotland, in 1831, and educated at Edinburgh and Cambridge University, he became Professor of Natural Philosophy at Aberdeen, 1856-69, and Professor of Physics and Astronomy at King's College, London, 1860-65. In 1871 he became the first holder of the new chair of experimental physics at Cambridge, where he died, November 15, 1879. Clerk-Maxwell was recognized in his later years as one of the greatest authorities on physics of his time, and his fame has been steadily increasing since his death. Radio owes Clerk-Maxwell a deep debt. Electricity was the chief study of his lifetime, and his first important paper on the theory of *electromagnetism* was communicated to the Royal Society in 1867. In 1873 he published his "Electricity and Magnetism," a work on the subject which has never been surpassed. In it he formulated his famous *electro-magnetic theory* of light and his theories on electric waves, which developed into the modern system of wireless telegraphy and telephony through the experiments of Hertz.

James Clerk-Maxwell.

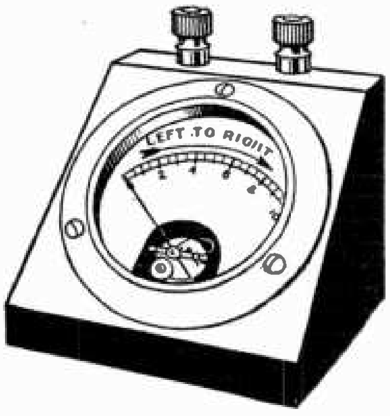
CLIMAX—A high resistance nickel steel alloy, used extensively in *rheostats* (q.v.). It is one of the cheapest and most practical alloys for low-temperature resistance wire. Its chief properties are as follows: Maximum working temperature 540 degrees centigrade, resistance in microhms per cubic centimeter at 20 degrees centigrade, 87.2; temperature coefficient per degree centigrade, .00054, and having a specific gravity of 8.14.

CLIPS—A clamp connector used for various purposes in radio receiving and transmitting circuits. (See *illustration.*) In a receiving set a clip may be used at the end of a flexible wire for the purpose of varying the connection to the various "B" battery taps; clips are very frequently used in making the connections to the storage "A" battery, and for many other purposes about the receiving set. One of their principal uses in the transmitter is in connection with the leads to the oscillation transformer. Flexible leads with clips attached come from the other units of the transmitter and are clamped at will along the various turns of the oscillation transformer until the point giving the desired wave length or highest radiation reading is found.



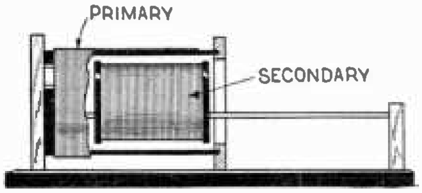
Type of clip in general use.

CLOCKWISE—A term used to indicate that the rotating part of an electrical machine or instrument moves from left to right (when facing it), or as the hands of a clock. In the illustration the needle or pointer of the meter moves in a clock-wise direction. In an electrical measuring instrument this is always true where the zero point is at the left part of the dial. The opposite is known as *counter-clockwise*. When looking at the *armature* of a motor or generator, if the rotating part moves from left to right it is said to have a clock-wise motion.



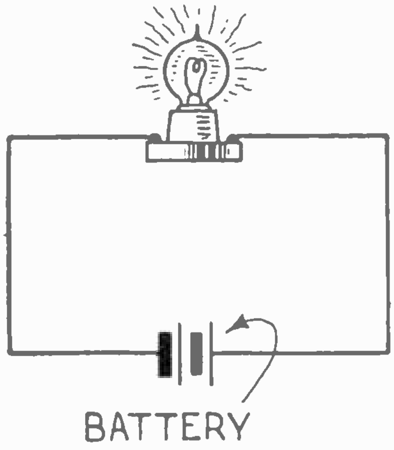
Indicator needle moves from left to right in clockwise motion.

CLOSE COUPLING The arrangement of two coils acting as *primary* and *secondary*, placed close together in such manner that the coupling or electrical relation between them is close. In the illustration the secondary coil is shown entirely within the primary. In other words the transfer of energy will be large in this case as the coupling is close. If the secondary is withdrawn a certain distance from the primary, the effect is referred to as loosening the coupling, and the coils are then said to be *loose coupled*, the transfer of energy from one to the other being considerably less than in the case of close or *tight coupling*. (See *Coupling*.)



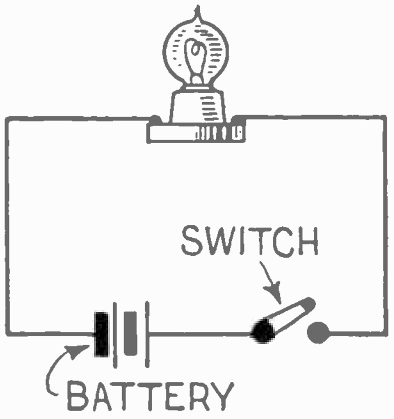
Loose coupler with secondary placed to produce close coupling.

CLOSED CIRCUIT—A circuit which permits the continuous flow of electricity. The illustration shows an ordinary dry cell connected in circuit with a small lamp. In Fig. 1A the circuit is closed and current is permitted to flow to the lamp. In Fig. 1B the circuit is open and no current can flow. A closed circuit is therefore an electrical circuit that is continuous. (See *Circuit*, also *Open Circuit*.)



-1A-

Circuit closed.

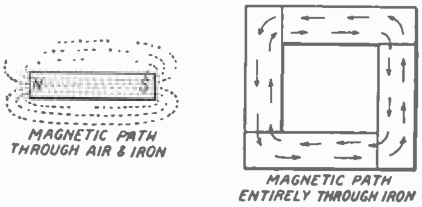


-1B-

Circuit open by means of switch.

CLOSED CIRCUIT CELL—A cell that can be used in a closed circuit for a considerable length of time without the impairing effects of *polarization* (q.v.) An *open circuit* cell is one that can only be used intermittently, as for example, with an electric bell where the circuit is only closed for a brief period. If an open circuit cell is used in a circuit that remains closed for some time, polarization sets in and ruins the cell in a very short time. An open circuit cell might be used with the *test buzzer* (q.v.) because in this case the circuit is closed intermittently as the key is depressed. (See *Cell.*)

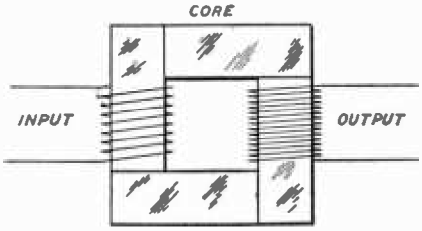
CLOSED CORE—A core (q.v.) used in *transformers*, *chokes*, etc., which is continuous, forming a *closed magnetic path*. The illustration shows the difference between a closed core and an open core. In the open core type, one end is the north pole, the other the south pole, whereas in the closed core, there are obviously no poles. The closed core type is occasionally referred to as a *non-polar* core. (See *Core*, *Transformer*, also *Choke*.)



N
S
MAGNETIC PATH THROUGH AIR & IRON
MAGNETIC PATH ENTIRELY THROUGH IRON

Open core above on left, closed on right.

CLOSED CORE TRANSFORMER—A *transformer* (q.v.) having a *closed core*. In the illustration the magnetic path, or core, is continuous, being made of strips of uniform size. This form of core is known as *"laminated."* An efficient transformer is generally made with a closed core. A transformer may be for a variety of purposes, such as *step-up, step-down, audio frequency* or *radio frequency*. (See *Transformer*.)



Closed core transformer.

C. M.—Abbreviation for circular mil. (q.v.)

Cm.—The abbreviation for *centimeter*, the unit of length in the C. G. S. system (q.v.).

COCKADAY CIRCUIT—A popular radio receiving circuit devised by the American experimenter, Lawrence M.

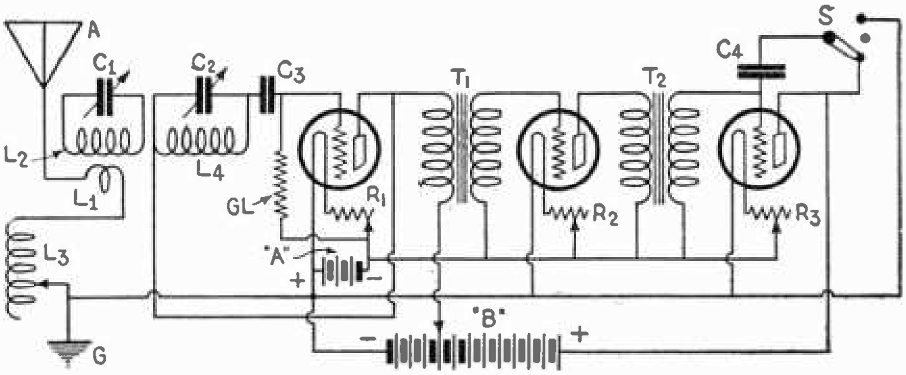


Fig. 1. Original 3 tube Cockaday Circuit.

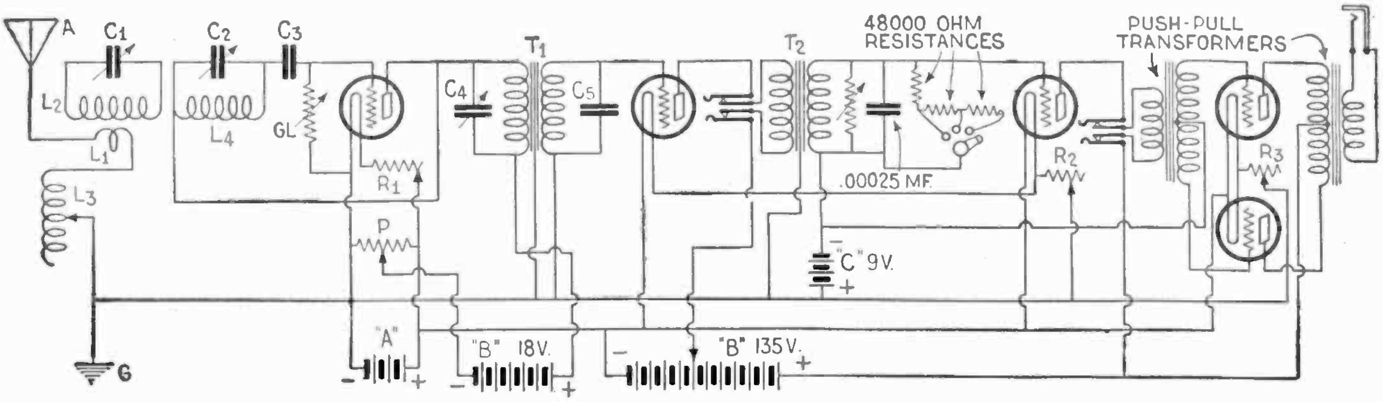

Fig. 2. Cockaday Circuit with push-pull amplifier.

Cockaday. It includes several radical features not found in the usual systems. Receivers using this circuit are generally made in three, four or five tube types. The chief value of this circuit lies in its extreme selectivity. It is usually referred to as a four circuit receiver, owing to the addition of a sensitizing circuit to the regular three circuit regenerative system. The diagram for the three tube receiver is given in Fig. 1. Here the primary or aerial tuning circuit is seen to have a single turn of wire, L1, wound around another coil L2, which is shunted by a variable condenser C1, thus forming a separate closed, tunable circuit, coupled very loosely with the antenna circuit. The primary, or antenna circuit, has in addition to the single turn, a bank wound coil L3 connected in the ground side of the open circuit and tapped to permit coarse tuning. Thus, the primary is coupled inductively to the separate closed circuit, which in turn is inductively coupled to the grid or secondary circuit containing a coil L4 shunted by the condenser C2, allowing tuning.

The tone of the music is varied by means of the novel arrangement using a condenser C4 connected to a three point switch. When the switch is placed in the center position the condenser is eliminated from the circuit and the wiring is standard. With the switch on the top tap, the grid of the tube is connected to the ground, thus by-passing a portion of the oscillations and giving a smooth soft tone with a certain loss of volume. With the switch arm on the bottom tap, the grid of the last tube is connected to the plate circuit, thus producing a different note due to the added grid-plate capacity. Coil L2 in the grid circuit is tuned by means of C1, which is a variable condenser of .0005 mfd. capacity.

A peculiarity of the circuit is that the length of the antenna has no bearing on the tuning. This is due to the *semi-aperiodic primary* and the fact that the sensitizing or pick-up coil is only one turn of wire, the inductance of which, compared to the whole inductance of the aerial circuit, is so small that any change in the over-all inductance has little, if any, effect.

This circuit, while originally having three tubes, has been arranged in conjunction with a standard *push-pull audio amplifier*, as shown in Fig. 2, making a five tube set with great power and possessing the characteristic of the original circuit with increased amplification. (See *Push-pull, Cockaday Coil* also *Regenerative Receiver.*)

COCKADAY COIL—The coil used in the *Cockaday circuits.* It comprises four windings, i.e. tapped primary, separate closed circuit coil, grid or secondary winding and a single turn looped around the closed circuit coil. (See *Cockaday Circuit.*)

CODE—Telegraph codes consist of characters formed by combinations of dots, dashes and spaces which represent letters, numerals, and punctuation marks. These characters are sent out by the radio operator with the aid of electrical impulses, and by using suitable receiving apparatus the receiving operator hears the incoming signal and is thus able to interpret the various combinations of dots and dashes and reproduce the original message. The Morse Code of characters came into general use in wire telegraphy shortly after the establishment of that means of communication. In this system, which is also called the "American Morse Code," some of the characters are made up with so-called spaces which are part of the group signal, and are necessary in distinguishing those characters. The International Morse code is a modified form of the American Morse code, and no spaces are used in the characters of the International Code. The International Morse Code is used all over the world for radio telegraphy, and for wire telegraphy in almost every country except the United States, Canada and parts of Australia. The American Morse, owing to the fact that there are fewer dashes in the characters, is about

Morse and Continental Codes.

5% more rapid than the International Morse. The American Morse and International (Continental) Codes are given herewith.

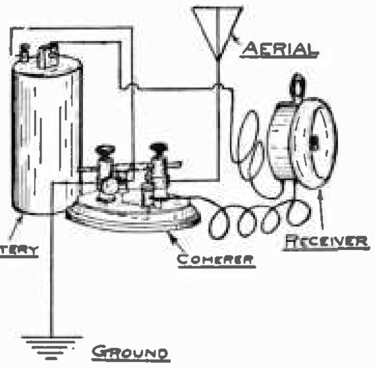
COEFFICIENT—In algebra, a number or multiplier of a *symbol*. Thus in the expression 5Y, the coefficient is 5. In electricity, and in its radio application, it is a number expressing the relation or ratio between quantities, one of the quantities generally being unity (1) as a basis or standard for the coefficients. For example, let us assume a copper wire is carrying an electric current, the *resistance* of the wire at 32 degrees Fahrenheit being one *ohm*. If we consider the resistance of the wire at 32 degrees to be unity, or one, then its resistance at any other temperature will be some number or coefficient times one.

To make this clearer, let us take the ratio of an inch to a foot. An inch is one-twelfth, or approximately .0833, of a foot. Any number of inches multiplied by this fraction will give another number in feet. Therefore we say that the coefficient, or multiplier, of an inch as compared to a foot is .0833. A coefficient is thus any number by which a quantity must be multiplied to give another quantity.

In radio the most common cases of coefficients are the following. The *coefficient of coupling* is the ratio between the *mutual inductance* (q.v.) (between the two coils, *primary* and *secondary*) and the square root of the product of the total *self-inductances* (q.v.) in the two circuits containing the coils. Similarly, the coefficient of amplification is the ratio of the effect produced with an *amplifier* (q.v.) to the effect produced without an amplifier. (See *Mutual Induction Coefficient*, also *Self-induction Coefficient*.)

COHEN, LOUIS, Ph. D.—Born in Russia, Dec. 16, 1876. Educated at Armour Institute of Technology, University of Chicago and Columbia University. Noted for his formulae and tables for the calculation of alternating current problems. He has written a book on the subject. Has evolved many formulas for the measurement of inductance and capacity. Has secured a number of patents on radio apparatus.

COHERER—A device formerly employed for detecting *radio waves*. In its original form it consisted of two metal rods separated by a narrow space in a glass tube and the gap between the rods filled with nickel and silver filings. It was found that when the *electromagnetic waves* or signals were passed through the coherer the particles of filings clung together and became *conductors*. Then by using some device such as the tapper hammer of an electric bell to strike the glass tube, again separating the particles after each signal, it was possible to keep the coherer constantly in a state of change between a *conductive* and a *non-conductive* condition, thus making the signals audible. There were many variations of this type of *detector*, which, however, is now obsolete. (See *Marconi Coherer*.)



Coherer used in radio receiving circuit.

COIL—A term having very broad application in electricity and radio. It may be used to designate any arrangement of a number of turns of wire, usually copper, and used for almost any purpose in the production of electric and magnetic effects or phenomena. The most common significance of a "coil" in radio is in reference to a number of turns of insulated wire wound on various forms and used for *tuning* (q.v.). The term *inductance coil* is generally used, although actually, any coil of wire will have inductance. Coils come in countless numbers and variety for many purposes. A coil may be used not alone for tuning—that is to adjust a receiver or transmitter to resonance with incoming or outgoing signals; it may be used to connect two circuits, in which case it is known as a *coupling coil*; it may be used with a *core* (q.v.) of iron wire, or laminated pieces, as a *choke coil* (q.v.) or it may be used in connection with *high frequency* apparatus, such as used by physicians. Coils are generally referred to by individual names indicating their construction or use. (See *Inductance*, *Tuning Coil*, *Vario-coupler*, *Choke Coil*, *Honey Comb Coil*, *Pancake Coil*, *Spider Web Coil*, *Lorenz Coil*, *Duo Lateral Coils*.)

COIL ANTENNA—Or Loop Aerial. An antenna (aerial) constructed by winding the wire around a square form. The coil (or loop) antenna, because of its comparatively small size, is often mounted on a frame work which may be rotated. If one end of the coil is pointed toward the broadcasting station, the antenna (aerial) will pick up its signals with maximum intensity, but if the coil is rotated from that position the signals from that station grow weaker, until when the plane of the loop is at right angles with the intercepted signals no sound will be obtained. It is a part of the radio compass used at sea. (See *Loop-Aerial*.)

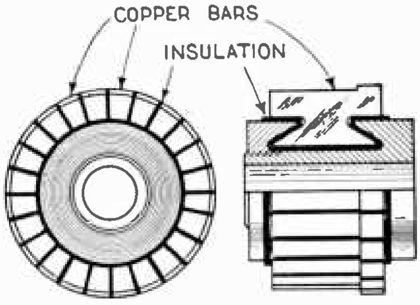
COLLECTOR RINGS—Insulated metal rings attached to the *armature* (q.v.) of an *alternator* (generator of alternating current) in such fashion that the alternating currents can be collected and communicated to the *brushes* without change, these rings are used to collect alternating current from that type of generator and brushes are used to collect direct current from a direct current generator.

COLLODION—A solution used by surgeons to cover slight abrasions or wounds, forming a protective coating similar to skin. It has been adapted to radio use as an insulating coating and is used as a binder on coils of various forms. It has been found more efficient than shellac for this purpose. A solution of pyroxylin or soluble guncotton in ether, with a certain amount of alcohol, depending on the purpose for which intended. When used as a coating for coils it serves as an insulator and also to hold the coils in place, but it should be sparingly applied.

COMBINATION DETECTOR—A detector composed of two different crystals in contact, instead of one crystal with a fine wire to search out the sensitive spots. Some combination detectors are composed of silicon and antimony; zincite and bornite; lenzite and cerusite, and zincite and chalcopyrite. These detectors all function without a battery and are simple to operate.

COMMON CONNECTIONS—A term often applied to a connection that joins several points. For example, in most radio receivers the binding posts for battery connections are arranged so that the "B—" and the "A+" or "A—" are connected to the same point. That is to say the post is a common connection for these leads. The term is also applied to a battery, as a *"B" battery*, which is used for both *detector* and *amplifier*. It is then known as a common "B" battery. The other method would, of course, be to use separate batteries for the detector and amplifier.

COMMUTATOR—In general electrical use, a device for reversing the direction of electric currents in a circuit. A *commutator* as used with a *generator* usually consists of a number of pieces called *segments*, mounted on a circular form but carefully insulated from each other. The illustration shows a common form. In the case of an ordinary motor, the commutator is employed to distribute the current to the windings and in a direct current generator it serves to furnish a direct current to the brushes although the current collected from the windings of the *armature* is alternating.



Front and side view of Commutator.

COMPASS, RADIO — See *Direction Finder*, *Goniometer*, also *Bellin-Tosi Direction Finder*.

COMPONENT—A part of the whole. In mechanics it is one of the parts of a stress or strain (mechanical force). In electricity, *component currents* are the several currents into which a single current may be assumed to be separated, so that if assumed to be acting together they would produce the equivalent effect of the actual current. Thus also, component *E. M. F.'s* (*electro-motive forces*) are understood as the several components into which any electro motive force may be divided. *Impedance* (q.v.) is said to consist of two components, the actual resistance and the apparent resistance present in the opposition offered to the flow of current termed the *reactance* (q.v.) by a circuit. For instance, the total current in the plate circuit of a vacuum tube responding to high *frequency grid voltages* may be considered as made up of two components, viz., a steady or constant current and a high frequency component superimposed on it.

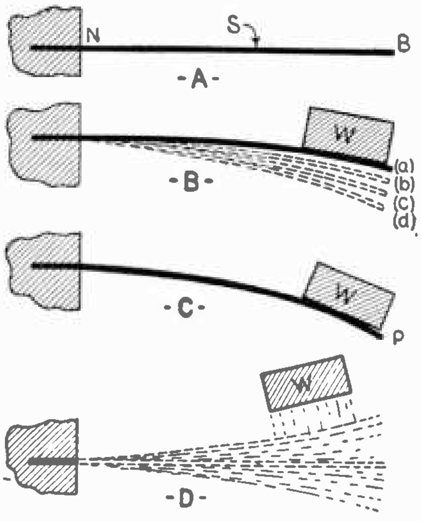
COMPRESSED AIR CONDENSER—A condenser which uses compressed air as the *dielectric* or insulating material between the plates. This type of condenser is used chiefly in transmitting circuits. (See *Condenser*.)

COMPOUND MAGNETS—A combination of several *permanent magnets*. (See *Magnets, Compound.*)

COMPOUND WOUND—A *dynamo* or *motor field magnet* wound with two *field windings*, one of which is connected in series, the other in parallel with the *armature* (q.v.).

CONDENSER—In electricity or radio practice a *condenser* consists of two or more conducting surfaces placed in relation to each other and separated by an insulating medium such as air, impregnated paper, mica, etc. The conducting surfaces are generally referred to as *plates* or *electrodes* (q.v.) and the insulating material is known as the *dielectric* (q.v.). Condensers are used in radio for a variety of purposes, their broad use being to allow tuning. In action, a condenser permits charges of electricity known as *electrostatic charges* (q.v.) to be stored up and released periodically, according to the frequency desired. They may also be used to exclude certain types of energy. (See *Condenser, By Pass,* also *Filter.*) The action of a condenser may be compared to that of a spring when placed under a mechanical strain. In the illustration Fig. 1A a flat spring S is shown in a normal position, NB. In 1B a weight W is placed on the surface of the spring. This weight will force the spring down from its normal position to one of the positions (a), (b), (c) or (d), according to the force exerted and the strength of the spring. If a heavier weight is then placed on the spring it will depress still further until we can imagine a point P in Fig. 1C at which the elasticity of the spring is used up and the opposition is such that it will no longer depress and comes to rest. When the weight is removed the spring will fly back into normal position, Fig. 1D, and in doing so will vibrate back and forth a number of times, thus producing, or rather, returning the energy that was stored in it during the moment of stress.

Considered as analagous to a *condenser*, in the above case the weight can be likened to the electrical charge applied to the condenser, the *resistance* of the spring may be considered somewhat similar to the *capacity* of the condenser, or the power returned on release of the spring may be regarded as the electrical power released by the condenser when the charging force is removed. The capacity of the condenser then will be seen as the ability to store up energy placed in it.



Spring analogy of a condenser.

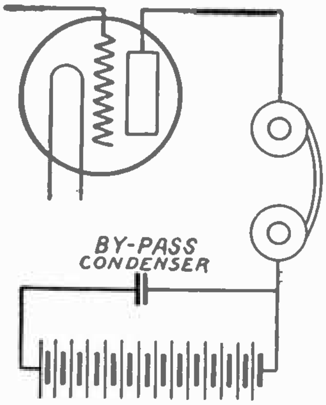
In the case of the spring, if too great a force is exerted, it may break down or as would actually happen, the elasticity would be lost. The same applies in the case of a condenser. If the charging force is too great, it may exceed the dielectric strength of the condenser and result in puncturing the insulating material between the plates. (See *Breaking Down of Dielectric.*) The energy obtainable from a charged condenser will be equal to the charge placed in it providing there is no leakage or other loss. In a well-designed condenser the leakage will be so negligible that it need not be taken into consideration.

The relation between the charge in a *condenser*, the *voltage* applied and the *capacity of the condenser* is expressed as Q = C × E, where Q is the quantity of the charge in *coulombs*, E the potential in *volts* and C the capacity in *farads*. (See *Capacity, Condenser, Variable; Condenser Fixed; Condenser Transmitting,* also *Condenser Curves.*)

CONDENSER, AIR—See *Air Condenser.*

CONDENSER, ANTENNA—See *Aerial Tuning Condenser.*

CONDENSER, BY-PASS—A condenser, usually of the fixed (q.v.) type arranged in a circuit in such manner that currents of a certain frequency will pass freely around any obstructing object, as, for instance, a high resistance element necessary to the circuit. An example of the use of a condenser in this manner is shown in the case of a "B" battery where the battery has a high internal resistance. A fixed condenser is placed across the terminals of the battery without injury to it and offers a path of low resistance for the high frequency radio currents.



By-pass condenser across "B" battery.

CONDENSER CURVES—Curves showing the relation of variations in wavelength, frequency, and capacity with rotation of the dial of a variable condenser. Three types of condensers are shown here, the *compression*, Fig. 1, the *straight line capacity*, Fig. 2, and the *square law*, Fig. 3. In Fig. 1A is shown the relation of capacity and wavelength changes when the dial of a sample compression condenser was rotated. The condenser was shunted across a fixed coil. It will appear that the increase in capacity is gradual at the lower part of the range but increases very rapidly at the upper ranges. This is due mainly to the relation of the curvature of the upper plate to the lower plate as will be seen from the illustration, Fig. 1. These condensers are very satisfactory on about the lower two-thirds of their range, but through the remainder of their range a very slight adjustment of the knob causes an extremely large change in capacity, making them very difficult to handle near their maximum capacity. Fig. 2 shows the shape of the variable plates in the straight line capacity condenser and Fig. 2A illustrates the relation of wave-length and capacity changes with rotation of the dial. Here the capacity depends upon the overlapping area and is therefore proportional to the angle of rotation of the movable plates. The capacity curve appears as a practically straight line running diagonally across the chart. The wave-length, however, changes rapidly at the lower range and very gradually at the upper range as indicated by the wave-length curve. Fig.

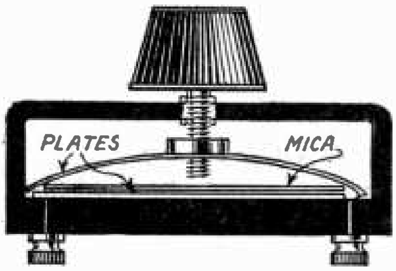


Fig. 1. Compression type condenser.

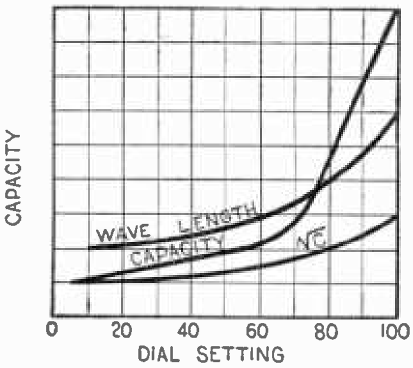

Fig. 1A. Curve for compression type condenser.

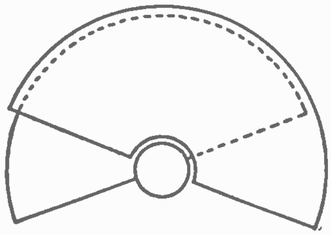

Fig. 2. Straight line condenser.

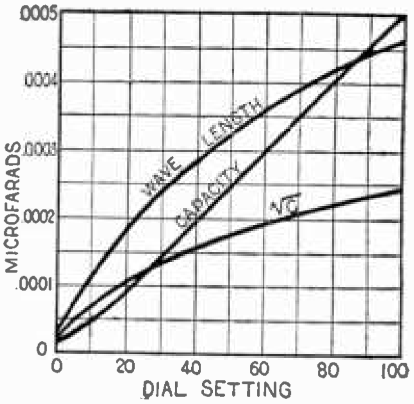

Fig. 2A. Curve for straight line condenser.

3 shows the shape and disposition of rotor and stator plates of a condenser so designed as to read directly in wavelength from the settings of the dial.

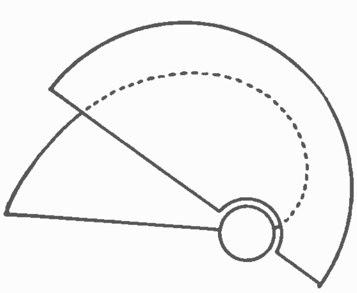

Fig. 3. Square law condenser.

This is known as a square law condenser, and the relational curves are shown in Fig. 3A. Here we find the wave-length curve a straight line and directly proportional to the angle through which the dial is turned. The line indicating the square root of the capacity √C is a straight line, and as the wavelength is the product of the square root of the capacity multiplied by a constant (varying with the individual condenser) the wavelength curve must also be a straight line.

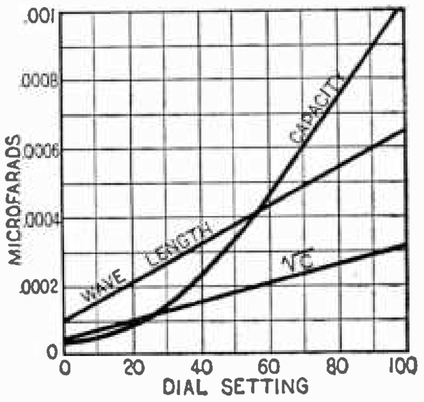

Fig. 3A. Curve for square law condenser.

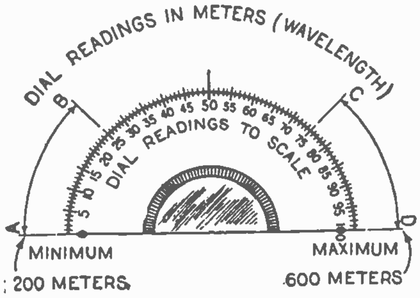

Fig. 3B. Showing effect of straight line condenser on dial reading.

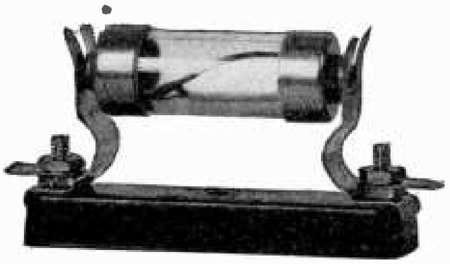
Such condensers are much used in wave meters (q.v.). Condensers are also made so that the frequency curve is a nearly straight line, varying more or less directly as the angle of rotation of the plates. Fig. 3B illustrates the result when an ordinary straight line capacity condenser is arranged with a dial calibrated directly in meters. It appears that the readings are bunched at the lower range (A to B) and spread out at the upper ranges (C to D). The reason for this can readily be seen by glancing at the curve Fig. 2A.

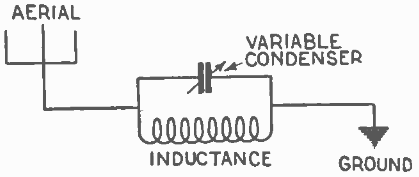
CONDENSER, FIXED—A *condenser* which has a fixed or constant capacity, allowing no variation of the value. (See *Condenser*, also *Condenser, By-Pass.*)

CONDENSER, GRID—A condenser, generally of low capacity, of the fixed or variable type, used in series with the grid of the *detector tube* to prevent excessive charges from affecting the *grid*. These condensers generally have a capacity between .00025 and .0005 *micro farads*. Due to the blocking action of these condensers, a high resistance, known as a *grid leak* (q.v.) is placed across the condenser or from the grid to filament, thus allowing the accumulated charges to leak off the grid of the tube in time for the grid to be free for the succeeding electric charge. The grid leak may be considered as a valve controlling the amount of energy that the detector can efficiently take care of without overload. (See *Grid Leak.*)



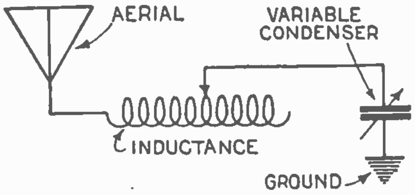
Grid leak and condenser.

CONDENSER, IN PARALLEL—A condenser arranged in a circuit in such manner that the current is divided between it and the other condenser or coil with which it is connected. The illustration shows a *variable condenser* connected in parallel with a coil, both placed in series between aerial and ground and forming a tuned primary or aerial circuit. (See *Parallel Connections.*)



Coil and condenser in parallel.

CONDENSER, IN SERIES—A condenser connected in a circuit with other condensers or coils in such manner as to form a continuous path, allowing the current to pass through each unit without dividing. The illustration shows a condenser connected in series with a *tuning coil*, aerial and ground, thus forming a tuned primary or aerial circuit. (See *Condenser, in Parallel*, also *Series Connections.*)



Coil and condenser in series.

CONDENSER, MICA—A condenser, usually of the fixed type, employing sheets of mica as the dielectric or insulating material between the plates. The condensers of small capacity used in receiving circuits are generally made with mica as a dielectric, but owing to its cost and thickness it is seldom used in low-power, high-capacity condensers. Mica is also used in condensers for high-power work such as transmitting, when the capacity is low. (See *Condenser.*)

CONDENSER, PHONE—A fixed condenser of comparatively low capacity used across the *telephone receivers* to allow a by-pass for a certain portion of the currents and thus prevent undue strain on the phones. (See *Condenser, By-Pass.*)

CONDENSER, TRANSMITTING—See *Condenser, Mica.*

CONDENSER, VARIABLE—Any condenser so arranged as to allow variation of its capacity. This may be accomplished in many ways, the usual method being to have the plates divided so that one series is movable with respect to the others, the capacity changing with the rotation of the variable plates. (See *Condenser.*)

CONDUCTANCE—Sometimes called the conductivity. The quality of a given conductor in virtue of which it facilitates the flow of an electric current. A *conductor* (q.v.) is a body having large *conductance* and an *insulator* (q.v.) is one having negligible conductance. *Conductance* is thus the opposite of *resistance*. The unit of conductance is the *mho*, the reciprocal of *ohm*. The symbol is obviously derived from ohm, reversed. It is the conductance of a column of mercury 106.3 cm. (centimeters) long, 1 square mm. (milimeter) in cross-sectional area and of a weight of 14.4521 grams.

CONDUCTIVE COUPLING—The association of one circuit with another by means of inductances (coils) mutual to both circuits.

CONDUCTIVITY, SPECIFIC—The reciprocal of Specific Resistance; being a standard of reference for comparing the conductances of different substances. (See *Specific Resistance, Conductance.*)

CONDUCTOR—Any substance that offers small *resistance* to the passage of electric currents may be termed a *conductor.* This term is the opposite of *insulator*, but there is actually no line of demarcation between the two, since any insulator will permit the passage of current when sufficiently high voltages are used. For all practical purposes, however, a conductor is considered as material that presents little difficulty to the passage of current. The most common conductor is copper, usually in the form of wire. An idea of the relative conductivity (power of carrying electric current possessed by various substances, pure copper being taken as standard) of various substances can be gained from the table following. The materials on the left are comparatively good conductors given in the order of their conductivity, while those on the right are poor conductors and generally used for resistances. (Note: A *resistance* is used to retard the flow of electricity without necessarily stopping it entirely, whereas an insulator is used to stop the passage of current.)

Silver
Copper
Brass
Gold
Aluminum
Zinc
Platinum
Iron
Nickel
Tin

German Silver
Platinum Silver
Manganin
Mercury
Graphite or carbon

There are, of course, many other substances that can be classed as good conductors, or as poor conductors, but the above are more generally known and used. It is a peculiar fact that while good conductors become less conductive as their temperature is raised, insulators lose a certain amount of their insulating properties as their temperature is raised. As too great current in a conductor will cause heat, and as explained above, cause lessening of conducting ability, it will be obvious that for the fullest efficiency a conductor will necessarily be arranged to carry the required current without undue heating. It is understood also that conductors in any part of a radio circuit should be carefully gauged as to size and the effective cross-section of the conductor determined, in order to offset the losses due to heating. It must not be assumed from the foregoing that the larger the wire the greater the efficiency—in fact a large wire is often less satisfactory than a small one in high frequency circuits.

When the conductor is to carry direct current the only consideration is to have the wire large enough to prevent heat losses and at the same time not be too bulky. Where the conductor is to carry *high-frequency* (q.v.) currents there are other factors to consider. High frequency currents are said to travel only on the outside of the wire (see *Skin Effect*) and therefore it is possible to use very fine wire for this purpose when the very low current values obtaining in reception are in question. A phenomenon that must be given attention, however, is that of *distributed capacity* (q.v.). (For more complete explanation of this subject see *Low-loss Coils*. See also *Bus bar.*)

CONNECTING UP or HOOKING UP—These general terms are used in radio to refer to the process of wiring a receiver or any particular part of a receiver or other circuit.

CONSTANT—A quantity or magnitude, which does not vary, derived from actual experiment, which is included as a factor in most formulas for the purpose of bringing theoretical calculations into agreement with experience. Constants are much used in radio calculations. As an illustration, different dielectric or insulating materials used in a condenser have different constants which must be taken into consideration when calculating the capacity of the *condenser*. Thus, as a dielectric, air at ordinary pressure is taken as the standard, the constant being stated as 1. Flint glass has a high dielectric value, its constant being stated as 10.10, other materials varying according to their comparison with air as a standard. (See *Dielectric.*)

CONSTANT CURRENT—An unvarying *current*. The term "constant" is applied to *voltage* when it is steady and unchanging, to *resistance* when it is fixed and unvarying, or to almost any value that does not change.

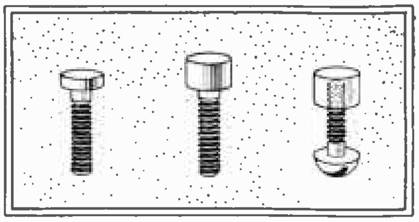
CONSUMPTION, CURRENT — The term usually employed to denote the current required or consumed by any part of an electrical circuit or by the circuit itself. A resistance in a circuit consumes a certain amount of energy because it dissipates it as heat energy. A filament in the case of a vacuum tube, requires a certain amount of current to heat it to brilliancy. If the filament thus requires one-quarter of an ampere we say its current consumption is one-quarter ampere. (See *Plate Consumption.*)

CONSUMPTION, PLATE—The current required to energize the plate of a vacuum tube. (See *Plate Consumption.*)

CONTACT BREAKER—A contrivance for quickly and automatically making or breaking an electrical circuit normally existing between two contacts. (See *Circuit Breaker.*)

CONTACT DETECTOR—A form of crystal detector in which a small wire, or "catwhisker," as it is called, makes contact with the crystal in the detector and acts as a *rectifier* of the *high frequency waves* received from the broadcasting station. (See *Crystal Detector—Theory of Operation.*)

CONTACT POINTS, or SWITCH POINTS—Generally refers to a small flat-headed machine screw used as a contact point for a *switch*. The illustration shows the types mostly used.



Various contact points.

Leads from various points of a tapped coil may be connected to the several contacts in order to permit variation of the *inductance*. A "contact point" may also mean any point in an electrical circuit at which contact is made to close the circuit.

CONTACT RECTIFIER—See *Contact Detector.*

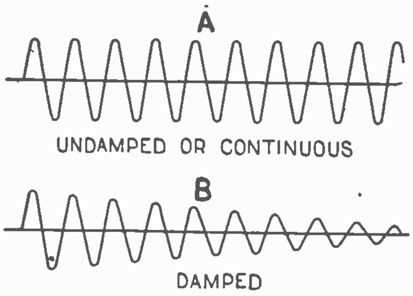
CONTACT RESISTANCE—When two connecting surfaces in a circuit carrying electrical energy do not make absolute or perfect contact, a certain amount of *resistance* (q.v.) results. In any part of a radio circuit where two wires or *conductors* are joined to form a circuit, it is essential that they make a positive contact. The wires used for connections in a radio receiver are generally soldered or fastened tightly by nuts or bolts, or machine screws in order to form a good contact. If this is not done, energy may be wasted, due to the resistance at the point of contact.

CONTINUOUS OSCILLATIONS—Each oscillation or vibration being of the same amplitude as the preceding one. (See *Sine wave.*)

C. W.—Abbreviation for continuous wave (q.v.).

CONTINUOUS DIRECT CURRENT—A *direct current* which flows steadily without interruption or reversal. The current supplied from a battery for radio use is continuous direct current, while that portion of the *high frequency alternating current* which is rectified by a *vacuum tube* detector is called *pulsating direct current*, as there is an interval of time between the rectified half of each incoming wave, due to the other half not being rectified. (See *Current, Pulsating Direct, Pulsating Current,* also *Rectification.*)

CONTINUOUS WAVES—Also called *Undamped* or *Sustained waves* and usually referred to as *C. W. Electromagnetic waves*, the separate oscillations (each vibration) of which are of constant or unvarying amplitude. In Fig. A a series of *oscillations* (q.v.) are shown. It will appear that one oscillation or *cycle* is of the same amplitude as the preceding one—the amplitude (q.v.) being considered as the height of the wave above the straight line representing time or its depth below that line. Each loop above the line or below it represents an *alteration* (q.v.) (the increase in current to maximum and back to minimum in either direction)—the loops above the line being considered as *positive alternations* and those below the line as *negative alternations*. Now it is evident from the sketch that each succeeding alternation has the same strength (amplitude) as that preceding it, and the same is true of the complete cycle, consisting of one alternation in each direction. Thus the waves are continuous, or constant, as far as amplitude is concerned. Now in Fig. B the amplitude is not constant—it decreases with each succeeding alternation and hence with each succeeding cycle (two alternations). After a comparatively few oscillations the current has decreased to zero, that is, the oscillations have died out completely. In this case the percentage of decrease in amplitude from one cycle to another is known as *decrement* or *damping*. Thus continuous waves may be considered as waves in which, with any train or group of oscillations, each succeeding oscillation has the same amplitude as that preceding it.



Series of undamped and damped waves.

CONTINUOUS WAVES—KEY MODULATED—Continuous waves (q.v.) which have been broken into dots and dashes of the telegraphic code by means of a *telegraphic key*, these signals being made audible at the receiving end by the use of an oscillating receiver.

CONTINUOUS WAVES—MODULATED AT AUDIO FREQUENCY—The process of variation of the frequency (vibration) of waves radiated by a broadcasting station in accordance with the sound waves is known as modulation. Frequencies from 10,000 down to about 32 are audible to the human ear and are known as audio frequencies. Hence continuous waves which are modulated at *audio frequencies* are waves which have been modulated (varied) by having the voice or music impressed on the *microphone* at the broadcasting station, which in turn causes the strength of the radiated electric wave to vary so as to correspond electrically to the sound vibrations at the microphone.

CONTINUOUS WAVE SIGNALS—See *Continuous Waves.*

CONTINUOUS WAVE TRANSMISSION—System of radio telegraphy using waves as described under "Continuous Waves."

CONVECTION CURRENTS—When a hot and a cold body are separated by a fluid which is free to circulate, heat is transferred from the hot to the cold body by currents of the fluid itself flowing from one to the other; similarly, all parts of a fluid which is being heated quickly come to approximately the same temperature. This transfer of heat by currents of the fluid itself is called "convection." In electricity "Convection Currents" are currents arising from the motion of charged particles thrown off in electrified streams, i.e., the flowing of charged air particles in streams from the pointed end of a highly electrified conductor, sometimes called "electric wind."

CONVENTIONAL—This term is much used in radio to denote a form established by custom. A conventional circuit for some particular purpose is understood as a circuit which has been generally used and which is generally considered as standard. Broadly, the most common form or use of anything. The conventional method of amplifying signals of *audio frequency* is by means of *audio frequency transformers*. Any other means is unconventional, although it may produce similar results.

CONVERSION FACTORS—A numerical factor which gives relation between the magnitude of a quantity expressed in terms of one system of units, and the same quantity expressed in terms of any other system of units. For example, the yard is regarded in the United States as 3600/3937 meter (a meter is approximately 39.37 inches). We say, therefore, that the conversion factor between the yard and the meter is 3600/3937 because any number of yards multiplied by this figure or factor will give the result in meters. (See *Capacity Conversion Factors.*)

CONVERTER—A term applied generally to any mechanical, electrical or electro-chemical device which will convert or change one form of energy to another. More specifically in electricity the term is used in reference to (1) a dynamotor designed with two *armatures*, mounted on one shaft, one being a motor armature driven by the original current, the other armature generates new current; this is also called a "motor-dynamo" and it can transform continuous (direct) current to higher or lower voltages, or, (2) a rotary electrical device used to change direct to alternating current or vice versa. (See *Rotary Converter.*)

COORDINATES—A thing of the same rank with another thing may be termed a coordinate. For example, lines by means of which the position of any point as of a curve may be defined with respect to certain fixed lines. In the illustration Fig. 1 lines known as axes of coordinates are shown. Such a system as this will be the basis for curves (q.v.) showing the relation between varying values. If we assume the horizontal line X as the axis of abscissas, all distances measured parallel to this line will be known as abscissas; distances measured parallel to the vertical line Y being referred to as ordinates. The line A-B is parallel to the axis of abscissas X and is therefore an abscissa. The line B-C is parallel to the axis of ordinates and is referred to as an ordinate. Now if we place a number of lines parallel to each axis (ordinates and abscissas) and assign to each of them a certain value, such as amperes, to each abscissa, and volts to each ordinate, a line can be drawn through a number of points to represent the various values of each quantity as related to the other. Thus, in Fig. 2 we have a purely hypothetical curve representing the assumed value of current in amperes under assumed voltages. In the example, the curve at point A shows approximately three amperes under a pressure of ten volts. This imaginary curve is, of course, shown merely for the purpose of illustrating the meaning of coordinates, ordinates, abscissa, etc. (See *Abscissa, Characteristic curve*, also *Graph.*)

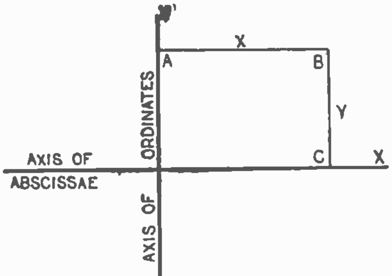


Fig. 1. Axis of coordinates.

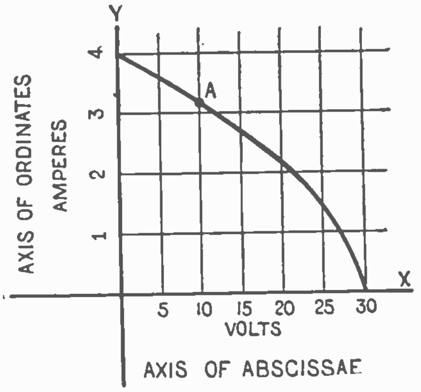

Fig. 2. Curve showing assumed value of current in amperes under assumed voltages.

COPPER PYRITES—Sometimes referred to as *Chalcopyrite*. It is used in radio reception as one of the elements of a *crystal rectifier* (detector) generally in conjunction with zincite or tellurium.

COPPER SULPHATE—A salt of copper. Also known as blue vitriol or copperas. A copper sulphate solution is sometimes used as a preservative for wooden aerial masts. It is used in certain forms of primary cells (devices for transforming chemical action into electric current) and also produces sulphuric acid when subjected to *electrolysis* (q.v.).

CORD, PHONE—The cord or flexible wire used to connect a *headset* (phone) or *loudspeaker* to the terminals of a receiver. Phone cord is usually copper tinsel wrapped around a cotton cord, the whole covered by braided silk or cotton threads. It cannot be used to carry high currents, but is efficient for the comparatively low currents flowing through the phone circuit of a radio receiver. Some phone cords are also formed of a number of fine copper wires covered with a suitable insulating material.

CORE—The central portion of a piece of certain electrical apparatus. Thus the center of a coil will be the *core*, irrespective of its nature, whether air or iron. The core of a *choke coil* (q.v.) is usually made of a bundle of soft iron wires or strips of iron. The core of the closed type is called a *laminated core*, being made up of laminations or layers of the core metal. (See *Choke or Choking Transformer, Closed Core.*)

CORE LOSSES—The losses due to the *stray currents* (q.v.) set up in an iron core while under the stress (strain) of a *magnetic field* (q.v.). Also losses due to *hysteresis* and *eddy-currents*. (See *Magnetic flux, Eddy current*, also *Hysteresis.*)

CORE TRANSFORMER (Iron)—A transformer having the wire wound over an *iron core*, the iron forming a path for the *magnetic lines of force*, as distinguished from a *transformer* in which there is no iron core—called *air core*. (See *Transformer.*)

CORONA—The Latin word meaning crown, originally applied to the crown shaped lights occurring in the *aurora borealis*. In electrical parlance it refers to the luminous discharge which occurs along high tension transmission lines or the aerial wires of a high power radio transmitting station. (See *Brush Discharge;* also *Corona Loss.*)

CORONA LOSS—The energy loss due to corona discharge. (See *Corona;* also *Brush Discharge.*)

CORRECTION FACTORS—A formula for the measurement of certain values is generally made by using certain conditions or types of apparatus as a standard. For example a formula for calculating the inductance of a coil is made by using a particular type and shape of coil as the standard. Therefore the formula will be essentially correct for this type of coil, assuming that its shape and other characteristics are the same. If, however, the nature of the coil to be tested differs from that of the standard coil in some way not covered by the formula, a system of correction must be used to adjust the formula to the particular case. Thus, the formula for inductance of coils takes into consideration the size of the wire or the number of turns, the length of the coil, its diameter and so on. However, it does not take into consideration the ratio between the length of the coil and its diameter. For this purpose a correction factor (necessary consideration) is needed to correct the result of the formula to fit the individual occasion. This correction factor is generally referred to as a *constant* (q.v.), its value being determined generally from a chart prepared to cover various ratios of length to diameter.

CORROSION—Chemical action which causes destruction of the surface of a metal. In the case of iron it is generally rust, corrosion of copper being due to oxidation, or perhaps the action of stray currents causing *electrolysis* (q.v.). This effect is very often noted in the case of an aerial wire where the wire is necessarily exposed to the action of the atmosphere, rain, etc. The effect is particularly important and undesirable where the lead in wire is joined to the aerial.

If the two wires are not soldered securely or at all, corrosion may set in, which will produce in time a high resistance connection and waste the valuable energy of the incoming signals. This is the main point of danger in an aerial system and the best protection is to solder the joint carefully. As a matter of fact the remainder of the wire may corrode to a considerable extent without disastrous effect. In the case of copper, the wire very quickly corrodes when exposed. For this reason insulated wire is sometimes used for the aerial. As the current received by an aerial travels only on the outer surface of the wire (see *Skin Effect*), and a corroded surface is not a particularly efficient conductor, there seems to be some basis for the use of insulated wire for this purpose. Another instance of corrosion is in a soldered joint within a receiving set. All soldered joints should be carefully wiped to remove any trace of *acid flux* (q.v.), which may remain to produce a destroying chemical effect on the wire and cause loss of energy. (See *Electrolysis*, also *High Resistance Joint.*)

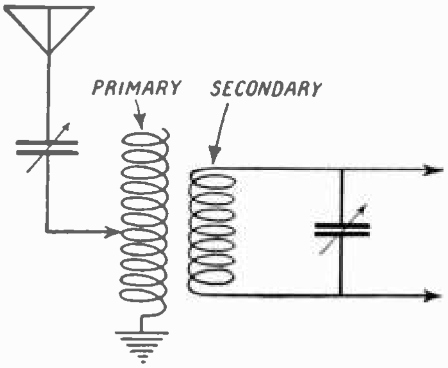
COULOMB—The practical unit for electrical quantity. It is defined as the quantity of electricity delivered by a current of one *ampere* flowing for one second. Therefore a *coulomb* of electricity will pass each second in a circuit having one *ohm* of resistance and a pressure of one *volt.* It is also used to express the quantity of electricity which a condenser having one *farad* of capacity will absorb when placed under a pressure of one volt. (See *Capacity, Electro-static, Volt, Ampere Hour, Practical Units, CGS Units.*)

COUNTER ELECTROMOTIVE FORCE—Commonly known as *Counter E. M. F.* It is an opposing electromotive force which tends to resist or act against the original electromotive force. It may be introduced in a circuit to prevent any fluctuation of the original force. (See *Back Electromotive Force*, also *Choke Coil.*)

COUNTERPOISE—A *counterpoise* is generally a second aerial suspended either below the main aerial or to one side of it. It is used more often in transmitting stations in place of the usual ground connection, but is occasionally also used in reception where it is impossible to obtain an efficient ground. (See *Aerial.*)

COUPLE, THERMO ELECTRIC—See *Thermo-Couple.*

COUPLED CIRCUITS—The term generally used to refer to circuits that are joined by *coupling.* (q.v.) In the illustration the *primary circuit* (the aerial ground and tuning devices) is coupled or joined to the *secondary circuit* by *inductive* coupling. That is to say, the signals impressed on the *primary circuit* are transferred to the *secondary circuit* by means of *inductive coupling;* when the lines of magnetic force around the primary coil cut the secondary coil, a voltage is set up in this coil which causes a current to flow in the secondary circuit, and it is then said the coils are "inductively coupled", there being no connecting wires between them. Signals might be transferred to the secondary circuit by any of several means, but in each case the method of joining the two for the purpose of effecting a transfer of energy is referred to as "coupling the circuits." (See *Coupling.*)



Circuit in which primary and secondary are joined by inductive coupling.

COUPLER—See "Coupler—(Loose)" and "Coupler—(Vario)".

COUPLER—(LOOSE)—A tuner used in a radio receiver, consisting of a primary and secondary coil so constructed that the secondary coil slides on rods in and out of the primary coil. When the secondary is entirely within the primary the coupling is said to be "tight," and as the secondary is withdrawn from the primary the coupling becomes "loose," depending upon the distance which the coils are separated.

COUPLER—(VARIO)—Form of tuner used in a radio receiver, having primary and secondary coils arranged in such a manner that the secondary rotates on a shaft within the primary. The degree of coupling is governed by the variation of the angle between the axes of the two coils.

COUPLING—The relation of one coil of wire carrying alternating currents to another in which energy is set up by the first coil. It is used to define the intimacy between the primary and secondary windings of various types of *oscillation transformers, couplers* and *tuning devices.* This transfer of energy may be produced in several ways, as by *inductive coupling, conductive coupling* or *electro-static coupling.* The more common method is to place the primary and secondary coils in close proximity and produce the energy in the secondary through induction. The illustration Fig. 1 shows a simple two slide tuning coil which is divided into a primary and secondary by *conductive* coupling. Here the transfer of energy from the aerial and ground, or primary circuit, to the secondary circuit (detector and phones) is accomplished with little loss of energy as the circuit is through wire conductors. This is also known as *direct coupling.* Now in Fig. 2 a simple form of *loose-coupler* is shown. This device is made in numerous forms, the principle of operation however, being the same in all cases. Here one coil, the secondary in this case, is made to fit into the larger coil which is the primary. The energy flowing in the primary coil induces or sets up a similar current in the secondary by reason of its proximity. The energy in the secondary, however, will not be as great as in the case of Fig. 1 where it is transferred directly through a wire conductor. The coupling shown in Fig. 2 will on the other hand, permit much closer adjustment to the desired signals.

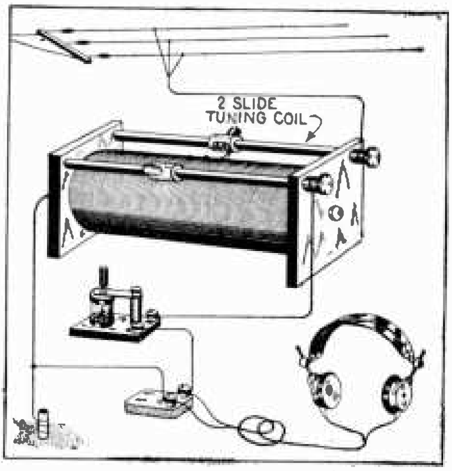


Fig. 1.—Two slide tuner divided into primary and secondary circuits by conductive coupling.

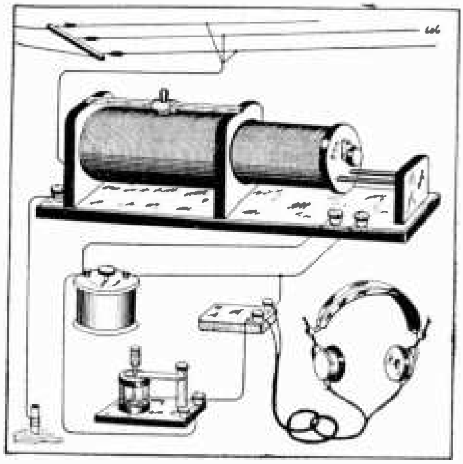

Fig. 2.—Circuit in which primary and secondary are inductively coupled by loose coupler.

The other method is known as *capacitive* or *electrostatic coupling.* This is shown in Fig. 3. Here the secondary coil is not in direct inductive relation to the primary, in fact it might well be almost any distance away were it not for the loss in efficiency due to long connections. The connection between the primary and secondary coils is by means of condensers. The transfer takes place through these and is determined by the setting of the condensers. It will appear that from a standpoint of maximum transfer of energy, the direct or *conductive coupling* system is best. The factor of tuning enters here however, and must be considered. In order to eliminate undesired signals the various systems of coupling are resorted to. It is known that *selectivity*—the ability to tune out undesired signals while receiving the desired signals—is often obtained only at the expense of a certain amount of energy or volume. It is a safe assumption therefore, that if there is any such thing as maximum efficiency in tuning apparatus, it must be a general term covering both selectivity and volume.

Coupling in its various forms is intended to refer not only to receiving circuits but to transmitting circuits as well. Its application in transmitting is covered under the heading *Spark transmission* (q.v.).

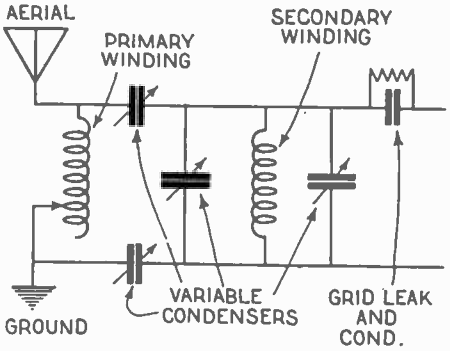

Fig. 3.—Electrostatic coupling between primary and secondary by means of variable condensers.

COUPLING COEFFICIENT — The closeness of *coupling* is specified by a quantity representing the ratio of the *mutual inductance* between two coils to the square root of the product of the two *self inductances.* In its practical sense coupling coefficient refers to the inductive relation of two coils. Coupling coefficient is defined as the ratio

$$\frac{X_m}{X.\ X_2}$$

Where Xm is the mutual or common reactance X is the total inductive or capacitive reactance in the primary circuit and X_2 the similar reactance in the secondary circuit. (See *Coupling, Mutual Inductance.*)

COUPLING, DEGREE OF—The extent of relationship between coupled circuits. In a great number of circuits the coupling is arranged so that it may be adjusted either close or loose, as the requirements of the reception may be. Variable coupling may be obtained either by varying the distance between the two coils of a *loose coupler*, or by changing the angle between the coils of a *variocoupler*. (See *Coupling.*)

COUPLING TRANSFORMER—(OSCILLATION TRANSFORMER) — This is the "tuner" of the transmitting circuit. It consists of primary and secondary windings usually of flat strips of copper, or copper ribbon, instead of wire, in order to reduce losses due to *skin effect* (q.v.). The primary coil receives the energy in the form of alternating currents from the generating device; these currents set up lines of force which interlink with the windings of the secondary coil connected in series with the antenna system, and in this manner the energy of the oscillation (alternating) current is transferred to the radiating system (aerial and ground) and thence into space. The purpose of the oscillation transformer is to produce a sharp wave which is readily tuned at the receiving end and causes a minimum of interference. The greater the distance between the primary and secondary coils the more sharp the wave becomes.

A device serving the same purpose in a receiving set, i.e. to enable the receiver to separate sharply the received signals, is sometimes called a receiving transformer, although commonly known as a tuner, coupler, vario-coupler, etc.

C. Q.—Abbreviation of inquiry made in code by a radio telegraph station desiring to communicate with another station. (See *Abbreviations.*)

C. Q. D.—The original Distress Signal (q.v.) established in 1904 by the Marconi Company. The origin of this signal is said to have developed from the use by telegraphers on land lines sending the C. Q. call when they wished everyone on their circuit to listen to the message being transmitted.

The signal C. Q. D. is now obsolete, having been replaced by S. O. S. at the International Radio Telegraph Convention held at Berlin, Germany, in July, 1908.

CRITICAL—A term often used in reference to the tuning qualities of a radio set, and, less frequently, to indicate a *vacuum tube* that *oscillates* too freely. If a receiving set is not critical in adjustment it is said to tune broadly, that is to say, not sharp in tuning. A critical set has a very narrow margin of control in tuning—the particular signals being receivable within only a very few points on either side of their true wave setting on the tuning dials. If a set is difficult to tune it is termed "too critical". This means that it tunes too sharply and it is difficult to get proper results, due to the possibility of passing by signals unnoticed when turning the dials. Obviously there is a middle point wherein a set may be selective and yet not too difficult to tune. If a vacuum tube goes into *self-oscillation* (q.v.) too readily it is said to be critical. This effect is not desired in a tube except in rare instances. (See *Resonance*, *Tuning*, *Broad, etc.*)

CRITICAL CURRENT—The current required to bring about some particular effect in an electrical circuit. In radio use, a common example is the exact amount of current needed by the filament of a vacuum tube to bring it close to the *oscillating point* (q.v.) without actually going into oscillation. (See *Critical.*)

CRITICAL POINT OF CURVE—The peak or point of maximum value in a curve showing the relation of any varying values. The illustration shows the curve indicating relation between voltage and signal strength in two types of vacuum tubes. The points marked "Peak" in each curve represent the critical points of the curves at which maximum audibility is obtained, any further increase in voltage not increasing the audibility. (See *Characteristic Curve*, also *Curve.*)

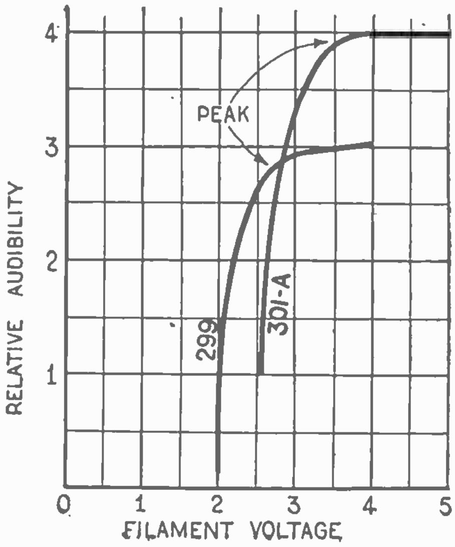

Illustration showing peaks or critical points of curve.

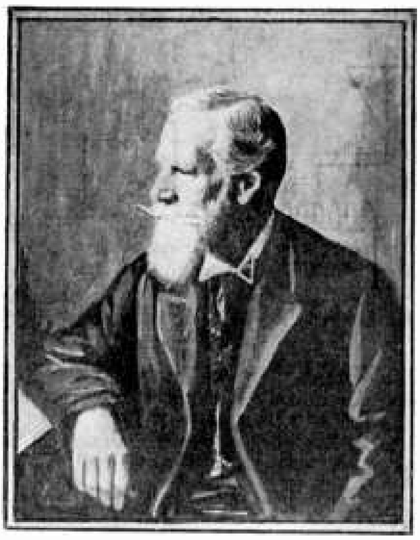
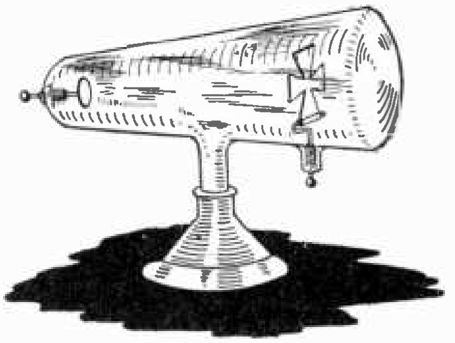
CROOKES, SIR WILLIAM (1832-1919)—English chemist and physicist. Born in London June 17th, 1832, Crookes was educated at the Royal College of Chemistry and afterwards became assistant in the meteorological department of the Radcliffe Observatory, Oxford. In 1855 he obtained a chemical post at Chester.



Sir William Crookes.

Crookes early began that series of brilliant researches which has left its mark on the scientific progress of the nineteenth century. In 1861 he isolated the new element *thallium*, during the investigation of the atomic weight of which he made the discovery of his *radiometer*. This led to his researches on the phenomena of electric discharges through highly exhausted tubes, or *Crookes tubes*. The illustration shows such a tube. When a current is passed through it, cathode particles travel along it. His discoveries on these phenomena led directly to the development by Sir J. J. Thomson of the now generally accepted *electron theory*. (q.v.) In 1883 he began his study of the rare earths, and in 1892 he forecast Radio telegraphy on the strength of Lodge's and Hughes' experiments.



Crookes' tube.

Knighted in 1897, Crookes was awarded the Royal medal in 1875, the Davy medal in 1880, and the Copley medal of the Royal Society in 1904, and the O.M., in 1910. He died in London, April 4th, 1919.

CRYSTAL—A general radio term for a mineral used as a *detector* (q.v.) of radio signals. The Physicist F. Braun noted in 1874 that certain pairs of crystals when arranged so that only a small area of surface was in contact, offered high resistance to the passage of currents in one direction while permitting them to pass readily in the other. This was really the birth of the crystal detector, although radio was not then developed. There are a great many different minerals that will act as detectors for radio signals, some of which operate with a wire, or other metallic contact, others which require a combination of minerals, one in contact with the other. There are also numerous *synthetic crystals* such as *carborundum*. Then again some of the more common natural crystals are subjected to treatment by heat, or other means, to change their nature or to make them more sensitive.

The following crystals are most used in radio reception: *galena*, *silicon*, *molybdenum*, *carborundum*, *zincite*, *bornite*, *chalcopyrite*, and *cerusite*. All of these are taken up under their respective headings. (See *Crystal Detector*, also *Combination Detector.*)

CRYSTAL DETECTOR—A combination of a *crystal rectifier* with contact and supports, used to detect *radio frequency oscillations*. Detectors of this nature are made in a great variety of styles, and use various kinds of crystals. In the more widespread form

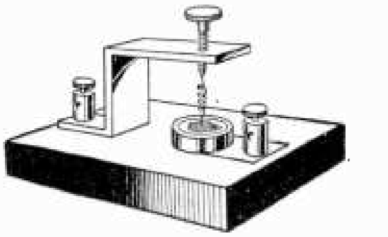


Fig. 1. Crystal detector using contact wire, or "cat-whisker."

the crystal detector consists of a crystal with rectifying properties, held in a cup or spring grip and arranged with a contact wire as shown in the illustration Fig. 1. This may be elaborated upon by supplying a series of flat springs to obtain very fine adjustment of the contact. Fig. 2. shows a combination detector, using two crystals, in contact with each other. This form has several advantages over the wire or *cat-whisker* (as the contact wire is called) type, chief among them the fact that it will withstand severe shocks without losing its adjustment. Fig. 3 illustrates a popular form of fixed crystal detector, in which the contact seldom requires adjustment. This type is of advantage providing it can be made sufficiently sensitive. (See *Carborundum, Vacuum Tube,* also *Crystal Receivers.*)

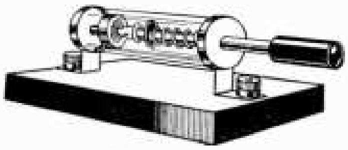

Fig. 2. Combination crystal detector.

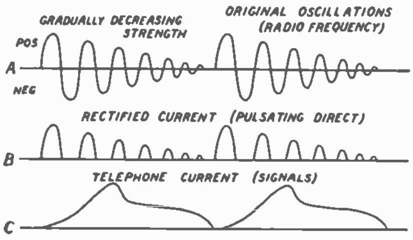
Fig. 3. Fixed crystal detector.

CRYSTAL DETECTOR—THEORY OF OPERATION—Theory of operation of a device used to detect radio waves, usually comprising a crystal in combination with a metallic contact, or, in some cases, two crystals arranged to rest against each other. In action this device serves to rectify the incoming signals, that is to say, it changes their nature from an alternating current to pulsating direct current. The incoming waves or signals consist of a series of alternations, the current flowing first in one direction, then reversing and flowing in the opposite direction along the circuit of the receiver. The changes of direction take place many times each second and would not be audible in the head phones in their original state. The crystal, as used in radio reception, has the peculiar property of furnishing a ready path for the flow of current in one direction while offering high resistance to its passage in the other. Now an *alternation* (q.v.) is a rise in current from minimum to maximum in one direction and back to minimum or zero, repeating the process in the other direction. Two of these alternations, one in a positive direction and the other in the negative direction constitute a *cycle.* (q.v.) If the crystal will permit the passage of current in one direction only, it is apparent that only half of each cycle can pass through; the other half of each cycle being lost or blocked out by the action of the crystal.

The illustration "A" gives a graphic representation of the *radio frequency oscillations* as they move over the aerial circuit. The curves above the line show the current in a positive direction while those below the line show it in the opposite or negative direction. If the signals or waves in this state were sent through a telephone receiver or head phone in a radio receiving set no sounds would be reproduced. Then again if the incoming oscillations were continuous, of unvarying strength, the rectified current would merely act on the diaphragm of the phone and hold it in a certain position as long as the signal persisted. This of course would not create any audible or intelligible sounds. If, however, the incoming oscillations were in the forms of groups or trains of waves, in any one of which the successive oscillations were less than the previous ones, the current would be rectified as shown in B and the result would be a series of pulses in the phone as indicated in C. These pulses would occur as often as the trains of oscillations occur (for more complete explanation of the difference between continuous and damped waves, see Damped Waves, also Continuous Waves). It will therefore appear that a *crystal detector* can only be used to receive *damped waves.* When the rectified portion of a damped wave train reaches the phones, the *diaphragm* is depressed and held until the train has died out, at which point the diaphragm is released until another train reaches it. This creates the audible signals and the number of trains occcurring each second will determine the number of depressions of the diaphragm and hence the pitch of the audible signals. (See *Crystal Receiver, Crystal Detectors,* also *Tickler.*)



Rectifying process of radio signals.

CRYSTAL RECEIVERS—A crystal receiver is the complete set of apparatus for receiving broadcast programs or *spark transmission* (signals), employing a crystal as the *detector* or *rectifier.* The set comprises a crystal detector, tuning device and phones, together with the usual aerial and ground arrangement. In its simplest form it may be merely a crystal detector, coil of wire and phones as in Fig. 1.

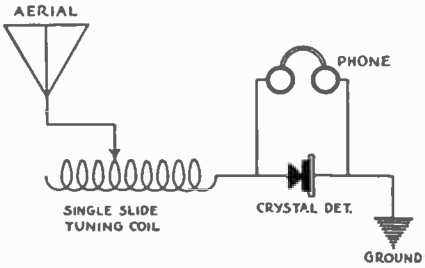


Fig. 1. Simple crystal set with single slide tuner.

Fig. 2 shows a more efficient form, using a two slide tuning coil. This method permits closer adjustment of the receiver to the particular signals desired. A still more efficient form is the *inductively coupled* type shown in Fig. 3. This method allows a very close adjustment and considerably reduces interference. The kind of detector to be used in any of the above types of receiver is immaterial as long as it is sufficiently sensitive. Such an arrangement as shown in Fig. 3 is very inexpensive to construct and when used within ten to twenty miles of the broadcasting station gives excellent results. A very simple arrangement for use with a crystal detector is shown in Fig. 4. This circuit uses a standard *variometer* and eliminates the necessity for a *condenser,* thus having only one control in addition to the adjustment of the crystal.

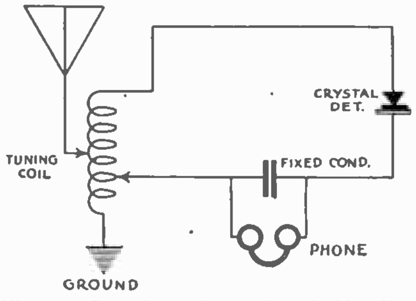

Fig. 2. Crystal receiver using double slide tuner.

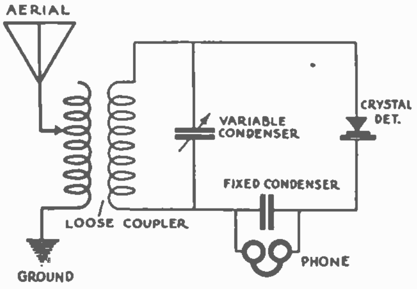

Fig. 3. Selective crystal receiver with loose coupler for tuning.

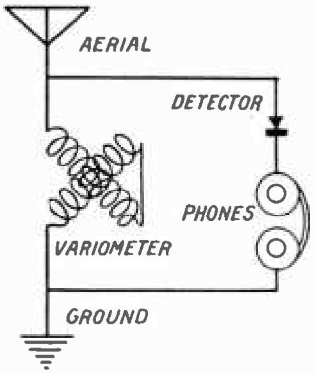

Fig. 4. A variometer is used as the tuning element in this crystal set.

CRYSTAL RECTIFIER—A device for changing an alternating current in a radio receiver into a pulsating direct current. This action is fully explained in "*Crystal Detectors (Theory of Operation).*"

CURRENT—A term used in electrical practise to signify the rate at which electricity flows from point to point in a circuit. The current in a circuit may be likened to the water flowing in a pipe. In this case the water would represent the electricity, the force or pressure represents the voltage, the pipe can be compared to the conductor or wire through which the electricity flows, and the current can be likened to the discharge from the pipe over a given period of time, that is the cubic feet of water per second. For practical purposes the unit of current is considered as the *Ampere.* This is the rate of flow of electricity when one *coulomb* (q.v.) passes a given point in the circuit each second. It will thus be apparent that while the ampere is often considered as the amount of current in a circuit, in reality it is the rate of flow of the electricity, the *coulomb* being the definite unit of quantity. Electric current is of course invisible. The only means of determining when there is current in a circuit is by observing its effect and it is always apparent by one or more of a number of effects. For example, if current is flowing in a wire or other conductor and a compass is placed near the conductor in such a position that the axis on which the needle revolves is parallel to the axis of the wire, the needle will be deflected. If the current reverses and flows in the opposite direction in the wire, the needle will be deflected in the opposite direction. The effect of current is also apparent by reason of the heat which it generates in passing through a wire conductor. If the wire is comparatively small and the current correspondingly large, the heat may be sufficient to be noticeable by placing the hand on the conductor. When the current is small, it can be detected by means of delicate instruments. This heating effect is made use of in various types of *ammeters*. The effect of current may also be noted in an incandescent lamp. In this case the current is made to flow through a fine wire inside a globe from which the air has been extracted, and the heat generated by the passing current causes the filament, or fine wire, to glow.

It is a well-known fact that heat causes expansion and this expansion of a fine wire is the principle on which one type of current measuring device operates.

Current is divided broadly into two divisions, *direct* and *alternating*. These two classes may again be separated into several further groups such as *high* and *low frequency alternating*, *continuous* and *pulsating*. Each phase or characteristic of current is taken up more in detail under its particular heading in this encyclopedia. (See *Current, Direction of Flow*, also *Current, Production of*.)

CURRENT, ALTERNATING—A current which does not flow steadily in one direction but changes its direction in the circuit periodically. (See *Alternating Current*.)

CURRENT CARRYING CAPACITY OF WIRE—The amount of current which a wire or other metallic conductor will carry without over-heating. Whenever current flows through a conductor, heat is generated. The amount of heat will be directly proportional to the resistance of the conductor and the square of the current in it. Now the resistance of a conductor depends on its cross-sectional area, length, and also its nature. It is therefore correct to state that the heating will depend on the amount of current flowing and the cross section and length of the wire. Obviously, a large wire will carry more current without over-heating, than will a small wire. Thus, it is necessary when choosing wire for a conductor to carry a certain amount of current, to select a wire of a cross section sufficient to carry the desired amount of current without undue heating.

The following formula for determining the current carrying capacity of various sizes and kinds of wire uses a certain factor T, which is the permissible rise in temperature above surrounding medium—such as air, earth or water. Where d is the diameter of the conductor in inches, T—the permissible temperature rise in degrees centigrade, N the resistance of conductor in ohms per mil-foot at final temperature, and I the current in amperes, then for solid conductors:

$I = \frac{K\sqrt{Td^3}}{r}$ and for stranded conductors: $I = 0.85\,K\frac{\sqrt{Td^3}}{r}$

K is a *constant* (q.v.) depending upon the condition of the surface of the wire and upon the amount of heat convection due to air currents. Values of the constant K for air differ according to different authorities from 800 to 1000, the former referring to still air and the latter to open air.

Table of current carrying capacities follows:

Wires and Cables, Insulated: Carrying Capacities, in Amperes, allowed by The Regulations of The National Board of Fire Underwriters for Interior Copper Conductors.

(For Aluminum 84 Per Cent of These Currents is allowed.)

Single Conductor Cables or Each Conductor of Multiple Conductor Cables.

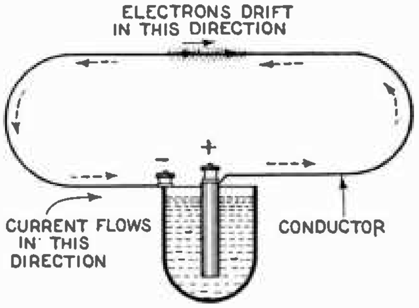
CURRENT, CONVECTION—See *Convection Current*.

CURRENT, CRITICAL—See *Critical Current*.

CURRENT DENSITY—The number of amperes passing through a wire conductor per square inch of area of the conductor. For example, if a conductor is a wire or bar of copper having a cross section of one square inch and ten amperes are passed through it, the current density will be ten amperes per square inch.

CURRENT, DIRECT—Current that flows steadily, and only in one direction. (See *Direct Current*.)

CURRENT, DIRECTION OF FLOW (ASSUMED)—In electrical practice the *assumed direction of flow* of current is often referred to. This refers to the fact that direct current is assumed to flow from the *positive pole* of a battery, or other source of electrical energy, to the *negative pole* and thence back through the battery from negative to positive. This assumed action is shown in the illustration Fig. 1, where the arrows indicate the assumed direction of flow. Now while the current is stated as flowing from positive to negative outside the source, it is the generally accepted theory that the electron stream moves in the opposite direction, or from negative to positive. In other words, the current as we use the term, flows backward along the path of electrons. (See *Electron Flow*.) This reverse action of current and electrons is shown by the illustration Fig. 2 This apparent anomaly



ELECTRONS DRIFT IN THIS DIRECTION
−
+
CURRENT FLOWS IN THIS DIRECTION
CONDUCTOR

Fig. 2. Showing reverse action of current and electrons.

can be likened to a salmon swimming up a rapid. The movement of electrons can be compared to that of the the water in the rapids and while the fish actually swim against the stream, and the electric current flows against the electron flow, the water and the electron stream nevertheless furnish the path of motion in each instance. The reason for the contradiction lies in the unfortunate arbitrary choice of positive and negative poles long before electrons were known. (See *Electron.*)

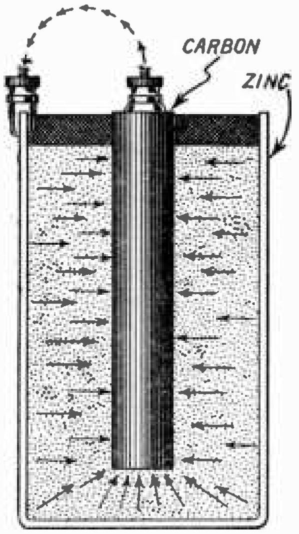


Fig. 1. Illustration showing the assumed direction of current flow in a dry battery.

CURRENT, EDDY—See *Eddy Currents.*

CURRENT, HIGH FREQUENCY—A current that changes direction many times each second. In radio usage, currents having a frequency over ten thousand cycles per second are considered as *high frequency* or *radio frequency currents.* (See *Frequency, Radio Frequency* also *Low Frequency.*)

CURRENT, HIGH TENSION—Alternate term *High Pressure.* When the voltage, tension or pressure, in a circuit is comparatively low, the current is said to be a low pressure or *low tension current.* When the voltage is high, the current is said to be of high tension or pressure. Thus, as applied to radio usage, a dry cell or storage battery giving, respectively, one and a half and six volts for a certain type, are said to produce low tension or low pressure current. A "B" battery (q. v.) giving from 22½ to 45 volts (the usual value) furnishes *high tension* or *high pressure current.* While there is not a very great difference in voltage between a small "B" battery and an "A" type storage battery, the ratio of voltage to current in a "B" battery is far greater than in the ordinary case of the "A" battery and this must be taken into consideration. In general electrical practice the terms are not so arbitrary, and high tension currents might be taken as those above a pressure of several thousand volts.

CURRENT, LOW FREQUENCY—An alternating current that changes its direction of flow a comparatively few times per second. In commercial electrical work any frequency up to about 500 cycles per second is considered as low frequency current. In radio phraseology *audio frequency* (q.v.) currents are termed low frequency. For ordinary radio practice low frequency may be considered as any frequency below about 10,000 cycles. (See *Oscillation* also *Oscillatory current.*)

CURRENT, OSCILLATORY—See *Oscillatory Current.*

CURRENT, PRIMARY—A current which flows directly from its source, such as a cell or generator. The current obtained from any source through a direct conductive circuit is termed a primary current. (See *Secondary Current,* also *Induced Current.*)

CURRENT, NATURE OF ELECTRIC—As explained under the heading *Current,* electric current is manifest or understood by its effects. It may be apparent through the production of heat or light, by producing mechanical action such as required to operate a bell or move an electric motor, or, again, by producing chemical changes (See *Electrolysis*), and still further in its disastrous effects on the human body when the current has sufficient intensity. Without any actual or visible form of manifestation it can best be understood from the *electron* basis. It will be understood that an *electron* (q.v.) small as it is, contains a charge of electricity. When a sufficient number of electrons are in motion in a conductor (Note: current consists of electrons in motion) the current becomes large enough to be measured. As an instance of this fact a current of one ampere intensity (one coulomb per second) requires that about 10^{19} electrons flow past a given point in the circuit each second. When the electrons are not progressing along a conductor, no current flows in the circuit. If no current is being carried by the conductor, the electrons may move about, but they do not progress along the conductor.

CURRENT, PRODUCTION OF ELECTRIC—An electric current is produced in a conductor by applying an *electro-motive force* (voltage) at points of the conductor or by maintaining a difference of *potential* (q.v.) between two points. In the first example we can assume a metal ring or closed coil of wire through which a magnet is pushed or perhaps in the core of which a magnet is being excited, or in the general sense any complete circuit through which the number of magnetic lines of force are being varied. In the second instance the difference of potential may be due to a *primary cell* (q.v.). Thus, the first case can be understood as referring to any mechanical means of producing current, such as *generators.* The other general method is by use of a *voltaic cell,* that is, by chemical action. There are four important methods of producing an *electro-motive force.* The first is by friction, the apparatus used in this connection being termed a static machine; the second is by chemical action, as a primary or secondary cell; third, by mechanical motion, i.e., *dynamos* and *generators,* and fourth, by thermal action—known as a *thermo-junction* which is the wiring of two unlike metals in a conductory circuit so that by heating one of the points of joining an electric current will be set up in the circuit. (See *Static Electricity, Generator, Thermo Couple,* also *Current* and *Electro-Motive Force.*)

CURRENT, PULSATING DIRECT—When an alternating current is rectified by means of any device which permits current to pass only in one direction, the resultant current will move only in one direction, hence it is known as a *direct current.* but unless both negative and positive halves of the *cycle* (q.v.) are rectified or changed to direct current, the resultant current will appear as a series of pulses in one direction. The most common application of this is found in the case of a *crystal rectifier,* or *detector* as used for receiving radio signals or broadcasting.

PHONES

Diagram showing how crystal detector converts alternating high frequency current into pulsating direct current.

When the incoming waves, or high frequency *oscillations* (Q.v.), are impressed on the detector, due to its peculiar properties they can only pass through it in one direction. In other words, granting that the incoming signal, or current, reverses its direction a great many times each second, it will be obvious that at any instant in the *cycle* (q.v.) current is moving in a certain definite direction, as from positive to negative, or vice versa, as stated, due to the peculiar properties of the detector the incoming signal current can only pass through the detector when the current is flowing in the correct direction. This means that only half of the *wave* (q.v.) is passed through and rectified. The result is a series of direct current surges through the balance of the circuit, each surge of current being followed by a space or time interval while the opposite half of the *cycle* or opposite *alternation* (q.v.) is blocked by the uni-directional nature of the crystal. These surges are then audible in the *head phones,* as they will actuate the *diaphragm* (q.v.) whereas a high frequency alternating current such as the original impulse from the broadcasting station would be inaudible. For a more complete explanation of this action see Rectifying action of crystal detector. (See also, *Rectifier, Full Wave Rectification and Rectifying Tube.*)

CURRENT, SECONDARY—A current produced by a *primary current* (q.v.) acting on a *secondary curcuit* which does not receive its energy by direct connection with the primary source. The illustration shows both primary and secondary currents and the manner of production. It will be understood that the primary current in this case must be a varying current. (See *Induced Current,* also *Inductive Coupling.*)

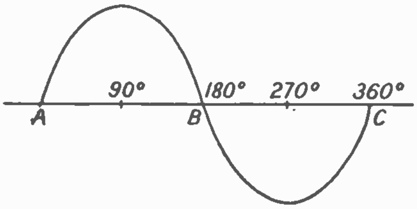
NO ACTUAL CONNECTION BETWEEN PRIMARY AND SECONDARY CIRCUITS

Illustration showing primary and secondary currents and method of production.

CURRENT, THEORY OF ELECTRIC—Under Electromotive force it will be explained that voltage or pressure is the result of a difference of potential (the power possessed by a charge of electricity for doing work) between two points in a conductor. Electric current will flow from the point of higher pressure or *voltage* to the point of lower pressure, the flow continuing as long as the difference is maintained. This action is the same as with water, which will always seek to move from a high point to a lower point. The flow of current is thus an effort to equalize the two *potentials*. (See *Current, Assumed Direction of Flow*, also *Pressure and Voltage*.)

CURVE—A straight or curved line showing the relation between various electrical phenomena or the characteristics (relation of changing values) of an electrical instrument. (See *Characteristic Curve*, also *Sine Wave*.)

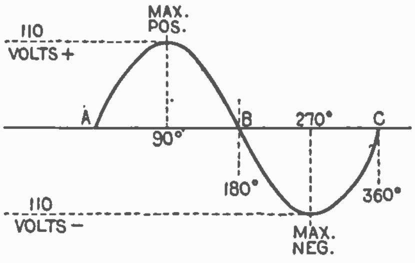
CURVE OF SINES—A curved line representing the vibration of a body that oscillates like a pendulum. The illustration shows a *curve of sines* which may be used to represent an alternating current. (See *Alternating Current*, also *Sine Wave* and *Simple Harmonic Vibration*.)



Sine curve.

CUT OUT—An electrical device to interrupt the flow of current through any particular piece of apparatus or instrument, either automatically or by hand; a switch.

CYCLE—In electricity, a period of time during which certain changes take place in an *alternating current*, (q.v.) the same changes occurring again in each successive cycle. We can imagine an alternating current as travelling along a wire in the form of a wave, one half of the wave being in one direction and the other half being in the opposite direction. That is to say, the current flows from positive to negative for one half of the cycle and then in effect, flows from negative to positive the other half of the cycle. (It will be understood that actually current always flows in the same direction, but the action of alternating current is due to a reversal of polarity at the source.) The difference between direct and alternating current is that, in the case of direct, the polarity always remains the same at the source and hence the direction of flow of the current is always in one direction, whereas with alternating current, the polarity changes twice each cycle due to changes at the source, and thus it flows in one direction for a certain fixed period, then reverses and flows in the opposite direction. In the illustration the current is shown as a *sine wave*. (q.v.) We assume that this represents an alternating current of 110 volts pressure such as in the average house lighting system. Now we consider the wave as a circle. The current flows in a positive direction toward its maximum value and at the 90 degrees it has reached the positive maximum. It then falls back to zero at 180 degrees and reverses, rising to maximum on the negative side, which it reaches at 270 degrees. It then falls back to zero at 360 degrees having completed a cycle or two alternations. The operation is repeated over and over a certain number of times each second. Thus, the rise and fall from A to B or 180 degrees is one *alternation*, the rise and fall from B to C is another alternation, the two alternations, one positive and one negative making a complete cycle. If sixty of these cycles occur each second we say that the frequency (q.v.) is sixty cycles. (See *Alternating Current, Phase, Sine Wave*.)



Curve showing action of 110 volts alternating current during one cycle.

CYMOMETER—The name given a type of *wave-meter* designed by Dr. J. A. Fleming. It is used to measure the wave-length of oscillatory (vibrating) circuits. (See *Wave-Meter*.)

CYMOSCOPE—A term used to designate any instrument which enables one to see the effect of electrical waves or to detect their presence. The original form was merely a loop of wire not completely closed as shown in Fig. 1. When held close to a transmitter of short waves a small spark will pass between the ends of the loop providing the *wave-length* is properly adjusted. This was the form used by Hertz (the discoverer of electro-magnetic waves which form the basis of radio telegraphy and telephony) in his early experiments. The more modern form is shown in Fig. 2 where a small lamp is made to light by holding the loop close to the transmitter. A complicated arrangement used to acually see the waves and study their form is called the *Oscillograph*. (See *Oscillograph*, also *Cathode Ray Tube*.)

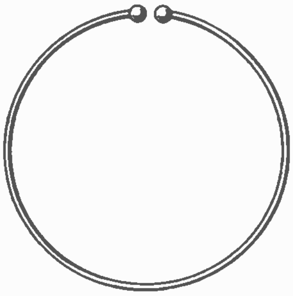


Fig. 1. Early type of cymoscope used to indicate resonance in a circuit.

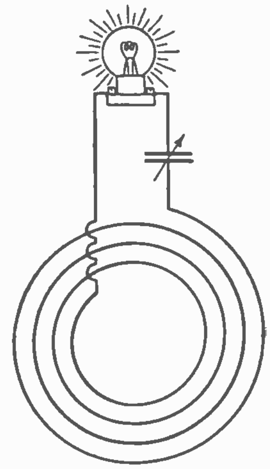

Fig. 2. More modern form of cymoscope.

D

D—The symbol of *electric displacement* (q.v.); also occasionally used as a symbol for diameter in electrical calculations.

DAMPED OSCILLATIONS — Electrical oscillations which die away, each succeeding oscillation in a group having lesser *amplitude* (q.v.) or strength than the preceding one. (See *Damped Waves*.)

DAMPED WAVES—Radio waves in the form of successive trains or groups, in each of which the amplitude or strength decreases with each successive wave. When electrical oscillations are caused by a single impulse, they do not continue indefinitely, but decrease in amplitude or die away. Thus, if oscillations are created in an antenna or other circuit by a discharge from a *condenser* (see spark discharge), each electric spark creates a train of oscillations which die away more or less gradually. Fig. 1 shows a pendulum which is given a momentary impulse. Now as this source of power is only momentary the pendulum will not swing from A to D indefinitely. If the first swing under the impulse carries the pendulum the entire distance A to D, the next swing will cover a lesser arc and so on until the movement has died out altogether.

Now in Fig. 2, the graphic illustration of a train of *damped waves* shows that each crest is a little lower than the one preceding it and after a short period the waves have died out alto-

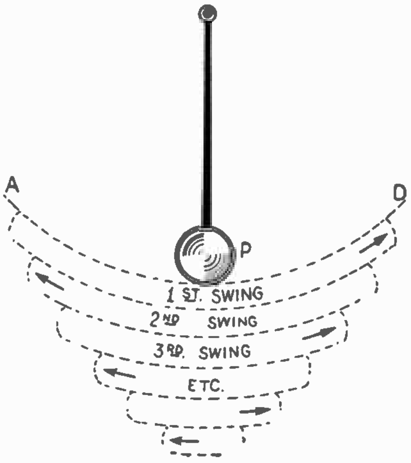

Fig. 1. Pendulum coming to rest after being given a momentary impulse.

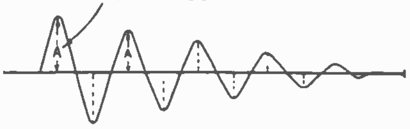

Fig. 2. Train of damped waves.

gether. These curved lines may be considered as an illustration of the path taken by the pendulum in its motion as shown in Fig. 1. The decrease in amplitude of one crest over that preceding is known as the damping, and the naperian logarithm of the ratio of amplitude of any oscillation to the one preceding it is known as the *logarithmic decrement.*

If the impulse of force causing the oscillations is steady—not intermittent—the result will be a sustained series of oscillations that will continue at constant strength or amplitude until the exciting force is withdrawn. Thus, in the case of the pendulum, we can very easily keep exciting it by an evenly exerted force and so insure that the swings will continue without diminishing, as in the case of a momentary impulse. Oscillations or waves that have constant amplitude are known as *Continuous Waves, Undamped Waves* or *Sustained Waves.* (q.v.) (See also *Decrement, Logarithmic;* also *Naperian Base.*)

DAMPING—A progressive decrease in amplitude or strength. (See *Damped Waves, Damping in Instruments.*)

DAMPING COILS—*Short circuited* (q.v.) coils used in electrical apparatus for the purpose of causing damping (i. e., decrease in the intensity of electrical oscillations). The reaction of induced currents in the shorted coil creates the damping effect. (See *Damping.*)

DAMPING DECREMENT—See *Decrement, Logarithmic.*

DAMPING FACTOR—The product of the *logarithmic decrement* (q.v.) and the frequency (rate of alternation) of a damped alternating current. (See *Decrement,* also *Amplitude.*)

DAMPING IN INSTRUMENTS — The term damping is applied in a mechanical sense as in the case of the needle of a measuring instrument such as a *galvanometer.* (q.v.)

In a delicate instrument for measuring current the needle is controlled by the current through the instrument, and when this current is withdrawn the needle is brought back to the neutral position by a fine spring. Now, unless some precaution is taken the needle will have a tendency to swing or vibrate when measurement is being taken. Various devices are used to bring the needle quickly to rest without undue vibration. If the needle comes to rest almost immediately it is said to be a highly damped or *dead beat instrument,* because the oscillations or vibrations die out rapidly the same as in the case of damped waves.

There are two principal methods of damping instruments. When the instrument is of the moving coil type, the coil is generally wound on a light aluminum frame which is mounted between the poles of a permanent magnet. A soft iron core fills the gap between the two poles, allowing space for free movement of the coil. The result is that the metal frame carrying the coil moves through a very strong *magnetic field* and *Eddy currents* (q.v.) are set up in the frame and serve to damp its motion. The other common method is to have a light metallic vane carried by the pointer in its motion and moving in an air chamber to stop vibration. While damping is highly essential in a measuring instrument, too high a degree of damping is not advisable. If there is a very slight tendency on the part of the needle to vibrate, it permits the operator to determine whether it is swinging freely. (See *Voltmeter, Wattmeter.*)

DAMPING MEASUREMENT—See *Decrement, Logarithmic.*

DAMPING WAVES—Term commonly used to denote the gradual decrease in amplitude of a train of oscillations as in radio transmission. If the oscillations persist at constant amplitude or strength, each oscillation being equal in amplitude to the one preceding, there is no damping. When the amplitude of each successive oscillation is less than that of the preceding one there is said to be damping and the oscillations will die out entirely, at a rate dependent on the degree of damping. If the oscillations die out very rapidly they are said to be highly damped; if they die out slowly the damping is said to be feeble.

DANIELL'S CELL—A two fluid *voltaic cell* containing a zinc plate immersed in dilute sulphuric acid, and a copper plate in a saturated solution of copper sulphate; the two solutions being separated by a porous cup. This cell has a constant voltage and shows only slight polarization. Was formerly much used in telegraph work.

D'ARSONVAL GALVANOMETER—A type of galvanometer in which a coil carrying the current to be measured is suspended in a *fixed magnetic field.* (See *Galvanometer.*)

DASH—The long stroke used in *Morse* and *Continental Code.* It is considered as equivalent in length to three dots. (See *Code.*)

D. C. C.—The customary abbreviation for double cotton covered wire.

D. C.—The abbreviation commonly used for *direct current.* (q.v.)

"D" COIL—Occasionally known as Figure Eight coil. A form of inductance, used particularly in tuned radio frequency circuits. The windings are in the shape of a figure eight, either in pancake form (flat wound) or wound on a slotted tube. Owing to the peculiar arrangement of the windings these coils have very little external field and thus can be used in radio frequency amplifiers without the usual oscillating due to conflicting fields. (See *Field, Inductance, Radio Frequency Coils.*)

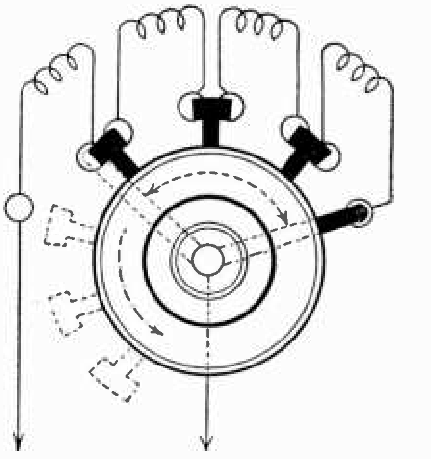
DEAD BEAT INSTRUMENT—A measuring instrument arranged so that the needle comes quickly to rest with little or no vibration is said to be *dead beat* or highly *damped.* (See *Damping in Instruments.*)

DEAD CELL—A *cell* which has been discharged. (See *Cell.*)

DEAD CRYSTAL—A crystal used in a *crystal detector* (q.v.) that has lost its sensitivity. Very often a crystal becomes dirty or oily from contact with the fingers. In some cases they can be brought back to usefulness by cleaning with alcohol, or if the crystal is dead through causes other than dirt on its surface, it may be broken to present a new surface and thus find a new sensitive spot.

DEAD END EFFECT—The effect on a receiving circuit (oscillatory circuit) resulting from unused turns of wire in a coil. In the customary tuning coil or tapped coil a certain portion of the wire is not in use and this idle section, being in metallic connection with the main portion, but not actually in use, acts as a miniature oscillatory circuit. This tends to reduce the efficiency of the tuning unit as a whole. Dead end effect may be eliminated by using the entire coil at all times, doing the tuning solely by the variable condenser, or it may be reduced by the use of a *dead end switch* (q.v.). (See *Tuning Coil.*)

DEAD END SWITCH—A switch used to cut out unwanted turns of wire in a coil in order to eliminate or reduce the *dead end effect* (q.v.). Such a switch is generally arranged so that instead of taps being taken from various points on the coil, the winding is actually in sections and the switch blade connects into the circuit the desired number of sections.



Dead end switch.

DEAD SPACE—In the case of *beat heterodyne* reception if the two frequencies are brought together or the difference is very slight there will be no beat. This space where the two frequencies are identical, or very nearly so, is known as the *dead space.* (See *Beats,* also *Heterodyne.*) The beat resulting from the superposition of two waves differing in frequency is the difference or the sum of the two frequencies. For instance, if two waves are present in the same circuit, of 1,000 and 1,005 kilocycles respectively, the two beat frequencies will be 5 and 2,005 kilocycles. If, however, the two frequencies are made identical, the difference between the two will be zero, and the sum of the two will be twice the original frequency. In the one case, where we take the difference of the frequencies, the beat note is zero, or there is no beat note at all; in the other case, where we add the two frequencies, the resulting frequency is the *harmonic* (q.v.) of the original frequencies, which is the same as an octave in music. In the present instance, this note will not be heard at all as it is above the range of audibility.

DECADENT WAVE—A damped wave. A wave, or oscillation, in a train of *damped waves* (q.v) which is of lesser amplitude or strength than the one preceding it. (See *Damped Waves,* also *Undamped Waves.*)

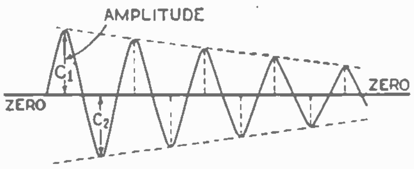
DECAY OF CURRENT—The gradual dying out of current in an *inductive circuit* (q.v.) after the *impressed potential* has been removed. The presence of inductance in a circuit causes the current to lag in time behind the voltage producing it. As a result, when a highly inductive circuit is broken by opening a switch or by other means, the current still tends to flow for a short interval, and the *induced voltage* in the circuit may become very high. This is the reason why a spark often occurs when the switch in a highly inductive circuit is opened. As a result the current decays gradually after the impressed voltage is removed.

It will be noted that the *decrement* (q.v.) or the rate of decay of the oscillations directly affects the number of oscillations in the wave train that will be useful in transmitting signals. For instance, if a certain oscillation in the figure should represent the smallest voltage that will operate a detector, it is evident that all oscillations in the wave train that have smaller amplitudes will be useless. Consequently, the lower the decrement of the wave, the greater will be the number of oscillations before the amplitude becomes too small for useful purposes. This likewise means that a greater amount of the energy in the wave can be utilized.

DECOHERER—In the type of detector, now obsolete, known as the *coherer*, the incoming signals caused the particles of nickel and silver filings in the glass tube of the device to cohere or cling together. (See *Coherer.*) In order to place the coherer in its original state after each impulse, it was necessary to have some means of separating the particles. These were known as *decoherers* and were in many different forms, some as separate attachments, others as a part of the detector or coherer. (See *Detector.*)

DECOMPOSITION, ELECTROLYTIC—The decomposition of chemicals taking place in a cell due to the action of the electrolyte. (See *Cell*, also *Electrolyte.*)

DECREMENT—A term used to indicate the rate of decay or dying out of an electrical oscillation that is subject to *damping.* (q.v.) In the illustration is shown a series of damped waves. It will be noted that the distance from zero to the crest of wave (C-2) is less than the one preceding it (C-1). This distance represents the amplitude and the ratio of any amplitude to the one preceding it is constant, that is the decay or decrease in amplitude is constant. The *Naperian Logarithm* (q.v.) of the ratio—of one wave to the one preceding it—is called the *logarithmic decrement.* The damping of a train of waves is an important consideration as it affects the tuning qualities to a great extent. This is covered by a U. S. Government Statute Concerning Transmitting Stations, decreeing that the logarithmic decrement per complete *oscillation* must not exceed 0.2, which means that for each single spark discharge from the transmitter there must be not less than 24 complete oscillations in the *antenna system.* (See *Oscillations, Damping, Naperian Logarithm, Sharp Wave.*)



Damped waves gradually dying out.

DECREMETER—An instrument used to measure the *decrement* or degree of damping in an oscillatory current. Such meters are made in several different forms. Some types are direct reading in terms of the logarithmic decrement, while others require mathematical reduction from the readings of a dial. All decremeters operate on the basis of comparison of the resonance current in a tuned circuit with that in a circuit out of tune by a known or unknown percentage. (See *Logarithmic Decrement*, also *Damping.*)

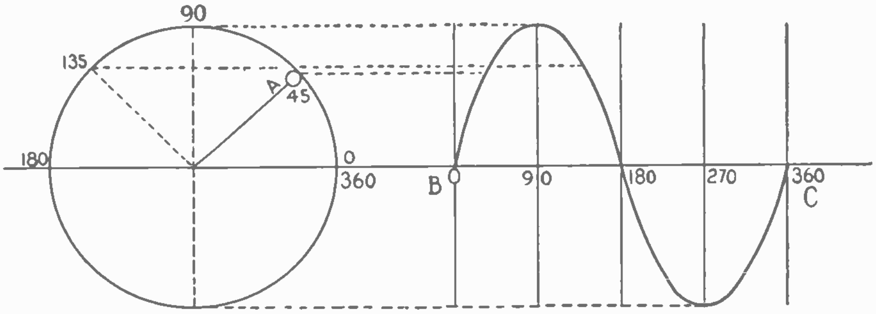
DE FOREST, DR. LEE—Electrical engineer; b. Council Bluffs, Ia., Aug. 26, 1873. Grad. Yale (Sheffield Scientific), Ph. B., 1896; Ph. D., 1899. Inventor De Forest system wireless telegraphy and founder Am. De Forest Wireless Telegraph Co.; system originally adopted largely by U. S. Govt.; demonstrated to the British, Danish, German, Russian and Indian Govts., first used by the U. S. Signal Corps in the war manoeuvres and inst. in Alaska. 1905 invented the Audion or three-electrode vacuum tube. 1906-09 was the pioneer in Radio Telephony. First to broadcast music and opera. 1908 equipped the 24 battleships and destroyers of Admiral Evans for their historic round-the-world cruise. 1913 incorporated De Forest Radio Tel. & Tel. Co., which developed the audion amplifier and oscillator for commercial purposes. These De Forest devices completely revolutionized the radio art and made possible the Bell Tel. Transcontinental System. He was the father of radio broadcasting and all radio broadcasting apparatus is built upon his audion inventions. Since 1919 he has devoted his attention to the phonofilm, photographing sound waves directly on motion picture film. Pres. of the De Forest Phonofilms, Inc.; Dir. of De Forest Phonofilms, Ltd., London. 1921, Awarded Cross of Legion of Honor by the French Govt. in appreciation rendered by audion to the Allies during the war. 1922 awarded Elliott Cresson medal by Franklin Inst. 1922 awarded medal by Inst. of Radio Engineers. Fellow American Inst. of Elec. Engineers. Fellow Inst. of Radio Engineers. Mem of N. Y. Elec. Society; mem. of Nat Geog. Soc.

Dr. Lee De Forest.

DE FOREST COILS—A type of coil named after *Lee De Forest* (q.v.). The wires are wound in a diamond shaped pattern in such manner that the turns of one layer cross the turns of the preceding layer at an angle, thus making the *distributed capacity* (q.v.) very small compared with the capacity of other types of coils. (See *Honeycomb Coils.*)

DEGREES, ELECTRICAL—In an alternating current curve each complete oscillation or cycle is shown as two loops, one above the line representing time, and the other below it, the entire cycle being considered as 360 *electrical degrees.* It is possible in this manner to show relations between current and voltage phases, amplitude at any point, etc. (See *Alternating Current*, also *Sine Wave.*)

The idea of electrical degrees comes originally from the *elementary electric generator*, with two-slip-rings taking off the alternating current, and having only two poles. During one-half revolution of the armature turns, the current increases from zero to a maximum and then back to zero again. During the other half revolution the current increases in an opposite direction from a zero value to maximum and then back to zero again. The curve shown in the figure represents the current variation during the complete revolution, a crosssection of the rotating armature wire being shown at A. The angles indicated on the line BC are laid off to any convenient scale, and the intersection of the ordinates from these points with horizontals drawn from the circle as shown, give the points on the curve.



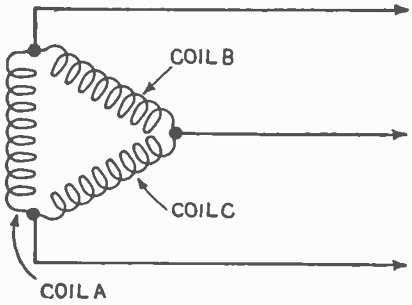
Curve representing current variation during one revolution of the armature of a generator.

The same ideas hold when the generator has more than two poles; in this case a full 360 electrical degrees is taken to represent the armature motion from across two adjacent pairs of poles, so that a complete cycle of voltage or current is generated. In a four pole machine, therefore, a full revolution of the armature could be represented by 2 x 360 or 720 electrical degrees. This corresponds to 2 complete cycles. Or, looking at it the other way, 360 electrical degrees would represent a half revolution of the armature wire.

DEIONIZATION—The action of returning a mass of gas that has become *ionized* (breaking up of the atoms of gas into positive and negative ions being the elements to which and to whose motion, under the action of electric forces, is supposed to be due their electric conductivity) to its original state. In the case of a *spark gap* (q.v.) the ionization creates a conductive path which remains after the actual spark has passed, thus preventing sharply defined oscillations. There are various methods of deionization, including cooling, absorption, air-blast or magnetic field, all tending to deionize or place the spark gap in its previous condition to prevent an arc from following the discharge. This action is also known as *quenching.* (See *Quenched Gap.*)

DELTA—The fourth letter in the Greek alphabet. The capital letter delta (Δ) is used as a symbol for delta connection of *three phase alternating current generators or transformers.* The small or lower case delta (δ) is used as a symbol for *Logarithmic decrement.* (See *Decrement, also Delta Connection.*)

DELTA CONNECTION—Δ In a three phase *alternating current generator,* where three coils are mounted symmetrically around a shaft rotating in a *magnetic field,* the connection or grouping of the windings is called *delta* after the Greek letter which the grouping somewhat resembles. The illustration shows delta grouping in a three phase system. The sum of the instantaneous Electromotive Forces of the three coils is zero, or in other words the sum of the Electromotive Forces of any two coils is equal and opposite to that of the other coil, the *line voltage* thus being equal to the *phase voltage.* (See *Alternator, Polyphase.*)



Delta grouping in a three phase system.

DEMAGNETIZATION—The act of returning a body to an unmagnetized state or of reducing the degree of *magnetization.* In the case of phones used in radio reception the permanent magnets are often weakened or *demagnetized* by connecting them in the *electron-tube circuits* in the wrong way. (See *Magnetization,* also *Telephone Receiver.*)

DENSITY, CURRENT—See *Current Density.*

DENSITY, FLUX—See *Flux Density.*

DENSITY OF ELECTROSTATIC CHARGE—The *electrostatic charge* per unit area. (See *Electrostic Charge,* also *Condenser.*)

DEPOLARIZATION—In an electric cell hydrogen bubbles form on the surface of the positive electrode and unless some arrangement is made to counteract this effect, the usefulness of the cell will soon be impaired due to the insulating action caused by this film of gas, known as *polarization.* Usually some means of oxidizing is employed to act upon the hydrogen as fast as it is produced on the positive electrode, thus preventing or reducing the effect of *polarization.* (See *Cell,* also *Polarization,* and *Depolarizer.*)

DEPOLARIZER—The oxidizing agent or other means used in a cell to counteract the effect of polarization. Bichromate of potash or peroxide of manganese is commonly used for this purpose. (See *Dry Battery,* also *Polarization.*)

DETECTOR—A device for converting oscillating currents of high frequency (radio waves) into a form suitable for operating a telephone receiver or sensitive measuring instrument. It is often referred to as a *rectifier,* because it serves to change the incoming currents from *alternating* to *pulsating direct currents. Detectors* vary in type and efficiency, ranging from the now obsolete *coherer,* to the modern sensitive *regenerative vacuum tube.* The different types of detectors are taken up under their various headings. (See *Crystal Detector, Vacuum Tubes, Electrolytic Detector.*)

DETECTOR CIRCUIT—That part of the circuit in a radio receiver which contains the *detector* (q.v.). The *detector circuit* may be closely coupled to the balance of the receiving circuit by means of a tuning coil or it may be inductively coupled by using a variocoupler or loose coupler. (See *Coupling*).

DETECTOR, DAMPED WAVE—Any special type of detector, such as a crystal, etc., used for reception of *damped waves.* (q.v.). (See *Tikker,* also *Heterodyne,* and *Vacuum Tube.*)

DETECTOR, VACUUM TUBE—The *vacuum tube* used as a *detector* of *radio frequency* (*high frequency*) *oscillations.* A vacuum tube may be used to change or rectify the high frequency alternating currents received at the aerial to *pulsating direct currents* (q.v.) capable of operating a telephone receiver or recording device. Formerly vacuum tubes were made for an individual purpose, such as *radio frequency amplifier, audio frequency amplifier, or detector,* the amplifier tubes being highly exhausted and the detector tube having a low vacuum and requiring critical filament adjustment. Of late tubes have been developed to such an extent that no special tube is necessary for the detector circuit, all being adaptable for almost any purpose. Fig. 1 shows the ordinary circuit for a vacuum tube detector. This method is not much used now since the advent of regeneration, except where stages of radio frequency amplification are used ahead of the detector to amplify the incoming signals. In this case incoming signals are impressed on the grid "G" and the slight variations of potential at this point control comparatively large currents at the plate "P," actuating the telephone "T." (See *Vacuum Tube, Theory of Detector Action.*)

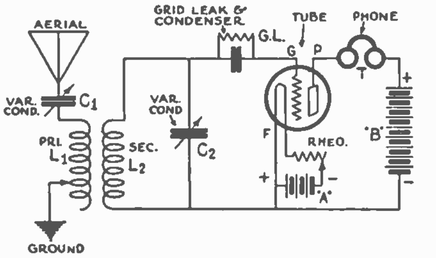


Fig 1. Non-regenerative vacuum tube circuit.

Used in this manner the tube is a considerable improvement over the crystal detector in point of sensitivity. However, by means of regeneration, the sensitivity may be increased many times. Fig. 2 shows a simple *regenerative circuit.* Here the unrectified currents passed through to the *plate* of the vacuum tube are fed back by means of the coil L2 and by being impressed again on the *grid,* further amplification can be attained. (For complete explanation see *Regenerative, Theory of Operation of Vacuum Tube, Detector, Pulsating Direct Current,* also *Crystal Detector.*)

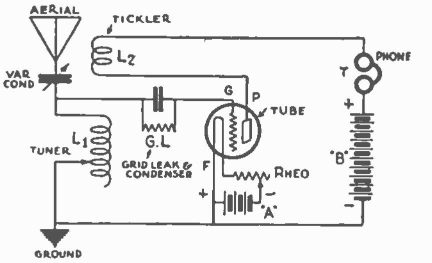

Fig. 2. Simple regenerative circuit.

DETUNING—The opposite of *tuning* (q.v.) The process of varying the effective inductance or capacity or both, to throw the radio receiver out of resonance with the particular signals to which it is tuned. This may be done to decrease the volume of the signals or it may be employed to eliminate or reduce interference from some undesired signals. For example, a station operating with a wavelength of 400 meters might interfere with reception of a station operating on 360 meters, providing it has sufficient power, or the receiver is not particularly selective. If the radio receiver is detuned slightly below 360 meters, the desired signals will still come in, though at lesser volume, but the interfering signals will be lost entirely. Tuning is the act of *producing* resonance and detuning is the act of *destroying* resonance. In the case of a *heterodyne receiver* (q.v.) the heterodyne circuit is slightly detuned from the incoming oscillations, thus producing a difference in frequency or *beat frequency* (q.v.). (See *Resonance,* also *Dead-space.*)

DIAGRAM—A system of lines drawn to represent the circuit or connections for radio receivers or transmitters or associated apparatus, etc. Diagrams may be in any of several forms, the two common methods being known as schematic and perspective. In the schematic form, symbols are generally used to represent the various pieces of apparatus, whereas in the perspective form, drawings of the apparatus are used. Fig. 1 illustrates a typical schematic diagram of a simple crystal receiver. Here the tuning coils, de-

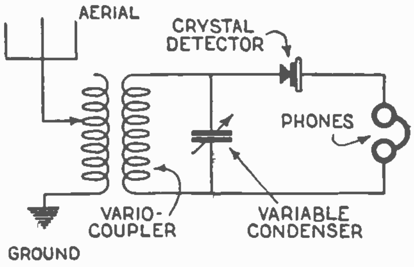

Fig. 1. Schematic diagram of a simple crystal receiver.

tector, phones and so on, are shown in the form of symbols. Fig. 2 shows the same circuit in perspective form, with the tuning coil and other parts actually pictured. Diagrams may be used to show connections for any electrical or radio circuits or for individual parts of instruments. (See *Hookup*.)

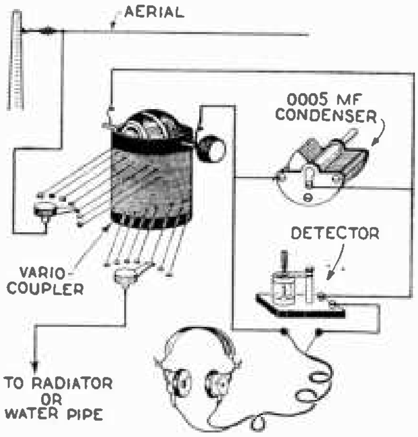

Fig. 2. Showing in perspective form the circuit given in Fig. 1.

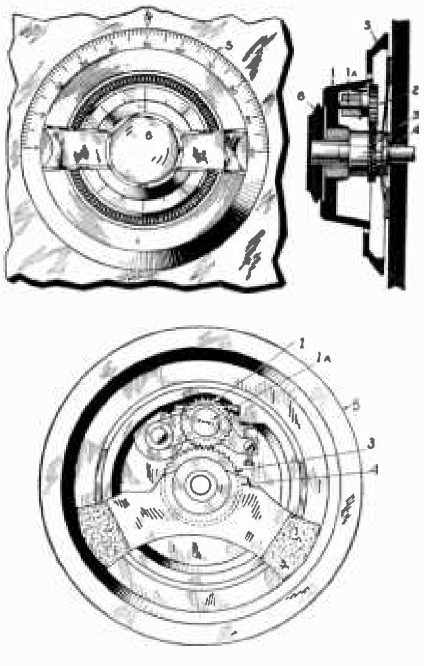
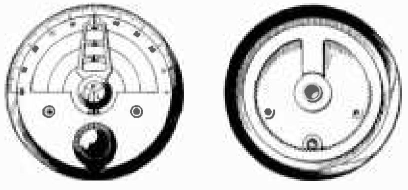
DIAL—Devices used to control the movement of condensers or other moving parts of radio apparatus. Most dials are made of a composition such as Bakelite or hard rubber; some are made of metal. The periphery is generally spaced off in numbers from 0 to 100 or 180, for purposes of keeping a record of the positions at which the various stations are received. Dials may be arranged to have the readings refer to definite values by means of *calibration* (q.v.). (See *Dial Vernier*. See *Log*.)

DIAL, VERNIER—A term incorrectly applied to a dial arranged with slow-motion linkage in order to permit very fine adjustment. The illustrations show two types of vernier dials. Vernier dials are generally used on *variable condensers* and occasionally on other instruments, where close adjustment is necessary. They are particularly useful in the case of a *Super-Heterodyne receiver*, the oscillator control being critical, and the wavelength control as well, in certain cases. (See *Dial*, also *Critical*.)



This dial utilizes the slip tooth principle. 5 is the main dial. 6 turns the slip gears (3) and (4), which cause 2 to turn. 2 is mounted on the shaft (1A) fastened in the main dial (1). 5 is the scale, fastened to the condenser shaft.



A simple vernier dial using a pinion and internal rack.

DIAMAGNETIC MATERIAL—Substances not readily susceptible to *magnetism*. If a substance does not pass magnetic lines of force, but rather is repelled by a magnetic pole, it is said to be *diamagnetic;* its permeability, or ability to permit magnetism to pass through it, is considered negative or less than unity (air). Diamagnetic substances are apparently repelled from the poles of a magnet. If placed in a magnetic field they have a tendency to diminish the *magnetic induction* (q.v.). (See *Paramagnetic*, also *Permeability*.)

DIAPHRAGM—A thin disk, generally of soft iron used in *telephone receivers* and *microphones* (q.v.) to either produce or detect electrical pulsations by means of vibrations caused by an *electromagnet*. Variations in the current through the electromagnet cause corresponding vibrations in the diaphragm. While the common type of diaphragm is made of soft iron, there are numerous other materials used. Certain alloys have higher permeability, and therefore are more responsive to the attraction of the magnet. In one type of telephone receiver that is particularly sensitive, there are two diaphragms—one that is actuated directly by the electromagnet under the influence of a varying current and another of thin mica, coupled to it by a fine wire. Another type employs a small iron armature suspended on a pivot, and attached to a mica diaphragm by means of a delicate lever, at right angles to the armature. The vibrations of the armature in the magnetic field of the magnets are communicated to the diaphragm by means of this lever. (See *Baldwin Receiver*.) Another type is of metal with fine corrugations and still another is a mica or parchment disk with a piece of soft iron in the center. (See *Microphone*, *Telephone Receivers*.)

DIAPHRAGM, CARBON—A phone diaphragm in the form of a thin carbon disc. (See *Diaphragm*.)

DIELECTRIC—This term is rather broadly used in electrical work to indicate a non-conductor or *insulator*. A dielectric may be a solid, liquid or gas and is generally employed to separate two conducting surfaces. The most common instance of the application of a *dielectric* is in the case of a condenser. Here the plates are separated by a dielectric material, the nature of this material depending on the particular type and purpose of condenser. A *variable condenser* for receiving purposes generally employs air as the dielectric. That is, the two sets of plates are kept from actual contact while one is being rotated, by an air space. In *fixed condensers* the dielectric is usually waxed paper, mica, glass, oil or compressed air, depending on the purpose for which the condenser is to be used and the dielectric strength necessary. While we refer to a dielectric as a non-conductor or insulator, there is actually no dividing line between conductors and insulators, practically any dielectric permitting passage of a certain amount of current under the proper conditions. If a substance is a very good insulator it is said to have good dielectric properties, while one that is a poor insulator and permits leakage of current is a correspondingly poor dielectric. (See *Insulator*, *Conductor*, *Resistance*, also *Dielectric Coefficient and Constant*.)

DIELECTRIC ABSORPTION—The tendency of the dielectric in a condenser to apparently absorb a certain amount of the power applied to it. When a condenser is charged by a direct current source such as a battery, the instantaneous charge is often followed by a small charge or flow of current that steadily decreases as it flows into the condenser. This additional charge is in effect absorbed by the dielectric of the condenser. The reverse effect is obtained when the condenser is discharged, the instantaneous discharge being followed by a steadily decreasing additional discharge. It will be apparent, then, that if the condenser is charged from an *alternating current* source, such as by *radio frequency currents*, the dielectric will show a tendency to withhold a certain part of the charge, and as the charging and discharging goes on rapidly due to the rapid reversals of the current (see *High Frequency Alternating Current*), the dielectric will continue to hold back this portion of the power as long as the charging and discharging process persists.

This loss, due to the absorption in the dielectric, must not be confused with the losses due to faulty dielectric materials, wherein a certain portion of the current is allowed to leak away by conductance through or on the surface of the insulator. *Dielectric absorption* is often referred to as *dielectric viscosity* or *hysteresis* because of its similarity to viscosity in liquids. Viscosity is the property possessed by liquids to resist deformation. The usual method of measuring viscosities is by measuring the time taken by a known volume of the liquid, at a known temperature, in flowing through an aperture of known form and dimensions under a known pressure. Thus tested, water will flow rapidly, while cylinder oil is very sluggish, and hence is said to possess great viscosity. (See *Condenser*, also *Dielectric*.)

DIELECTRIC COEFFICIENT and CONSTANT—The specific *inductive capacity* of a dielectric. Generally speaking, its properties to act as a *dielectric*. In the *Centimeter Gram Second system* (q.v.) the *inductive capacity* and the *dielectric constant* are numerically equal, the constant being the dielectric value of the material as compared with air at ordinary pressure taken as the standard (1). The table of constants for the more important dielectric materials follows.

It will be seen that glass, oils and mica have the highest values, for which reason they are widely used. (See *Specific Inductive Capacity, Dielectric*, also *C. G. S.*)

TABLE OF DIELECTRIC CONSTANTS

Dielectric	*Constant*
Air at ordinary Pressure (Taken as the Standard)	1.000
Manila Paper	1.50
Celluloid	1.555
Parrafine (clear)	1.68 to 2.32
Beeswax	1.86
Parrafine Wax	1.9936 to 2.32
Parrafined Paper	3.65
Hard Rubber (Enonite)	2.05 to 3.15
India Rubber (pure)	2.22 to 2.50
Gutta Percha	2.46 to 4.20
Shellac	2.74 to 3.60
Olive Oil	3.00 to 3.16
Glass (Low Frequency value)	3.25 to 4.00
Glass (High Frequency value)	4.21
Mica (Pure Sheet)	4.00 to 8.00
Porcelain	4.38
Castor Oil	4.80
Flint Glass, very light	6.57
Flint Glass, light	6.85
Flint Glass, very dense	7.40
Flint Glass, double extra dense	10.10

DIELECTRIC CONSTANTS—See *Table of Constants* under *"Dielectric Coefficient* and *Constants."*

DIELECTRIC HYSTERESIS—When the *electric field* in a dielectric material is varied rapidly, as when the condenser is charged by *high frequency currents*, heat may be generated. This is due to *dielectric hysteresis which is* synonymous with *dielectric absorption* (q.v.)

DIELECTRIC STRENGTH—When an electric field is established in a dielectric, that is to say, a charge is applied to a condenser, and the field attains a certain intensity, the dielectric ceases to be an insulator and becomes, in effect, a conductor. This condition generally is accompanied by a puncturing of the dielectric material. When the charge applied to a condenser is too high the spark will burn through the dielectric and the condenser is then said to have broken down. In some cases the condenser may be permanently ruined by this action, and in others, the dielectric may be conductive at a certain voltage, while remaining effective as long as the voltage is held below the safety point. The particular voltage (critical voltage) or field intensity at which the breakdown of the dielectric occurs is called the dielectric strength of the material. (See *Dielectric*, also *Table of Dielectric Strength.*)

DIFFERENCE FREQUENCY—The frequency of oscillations produced by superposing oscillations of one frequency on oscillations of a different frequency. In Super-heterodyne receivers the action is based on the production of a difference or beat frequency. If the incoming oscillations from the antenna are combined with oscillations of a different frequency produced locally in the receiver, a new series of oscillations will be produced, these oscillations having a frequency numerically equal to the difference in frequency between the other two sets of oscillations. (See *Beat Frequency*, also *Super-Heterodyne.*)

DIODE—A thermionic vacuum tube having only two *electrodes*, namely *filament* and *plate*. The original vacuum tubes were known as *Fleming Valves* and contained a hot filament and cold plate but no grid as found in the three element vacuum tube now in general use. Several types of *diode* are still in use as detectors, their chief value lying in the fact that they require no careful adjustments as in the case of a *crystal detector.* (See *Triode, Vacuum Tube*, also *Fleming Valve.*)

DIPLEX RECEPTION OR TRANSMISSION — The simultaneous reception or transmission of two series of signals by or from a single operating station. The systems are so arranged that two messages may be sent or received at the same time without interfering with each other. (See *Duplex Signalling.*)

DIRECT CONDUCTIVE CIRCUIT—Any circuit having a direct conductive path and not depending on capacity or electromagnetic coupling. A metallic, conducting circuit.

DIRECT COUPLING—The coupling or relation between two or more coils or circuits, wherein the connection is *metallic*. In the illustration Fig. 1 is shown a two slide tuning coil. In this case A-B is the primary or aerial circuit and C-D the secondary or detector circuit. The two circuits are joined together by metallic connection.

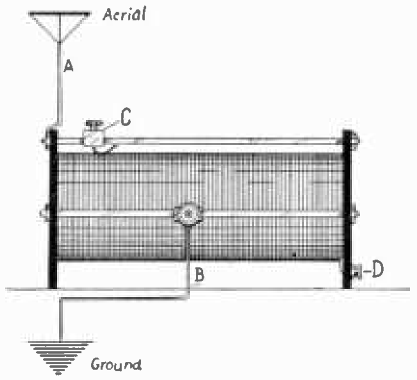


Fig. 1. Double slide tuner which affords direct coupling between the primary and secondary circuits.

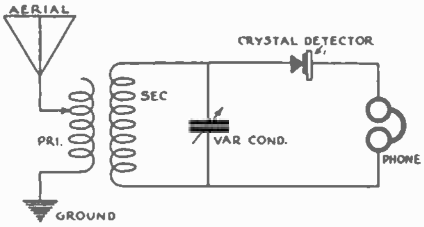

Fig. 2. Circuit in which primary and secondary are inductively coupled.

The illustration Fig. 2 shows essentially the same circuit, except that the primary and secondary are two separate coils. Here the two coils or circuits are joined by *inductive* coupling.

DIRECT COUPLED—Circuit in which primary and secondary circuits are metallically connected. Generally permits little selectivity. For this reason, *inductive coupling* is more generally used to permit close tuning or selectivity (q.v.). (See *Coupling, Inductive Coupling.*)

DIRECT CURRENT—See *Current, Direct.*

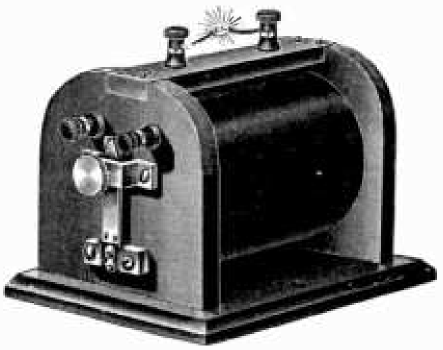
DIRECT READING—A term applied to various measuring or recording instruments which are so arranged as to show values directly without requiring mathematical reduction. *Voltmeters, Ammeters* and such instruments, used widely for showing the *voltage, current*, etc., of *batteries* or *cells*, are direct reading, showing the values directly in *volts* or *amperes*. A *decremeter* or *wavemeter* very often shows a reading that requires application of a formula to produce the desired quantity. (See *Calibration.*)

DIRECTION FINDER—See *Radio Compass.*

DIRECTIONAL—The effect of an aerial wherein waves are transmitted better, or entirely, in a certain direction, or received from a certain direction, depending upon the type and direction of aerial. (See *Transmitting Aerial*, also *Receiving Aerial.*)

DIRECTIONAL EFFECT OF ANTENNA—An effect of an antenna (aerial) for reception or transmission wherein signals from a certain direction are more readily received than from another direction, or in the case of transmission, the range being greater in a certain direction.

DISCHARGE—Generally speaking, a comparatively sudden passage of electricity. The term however, as applied to a *storage battery* will mean merely the effect of releasing the *electrical charge* stored up in it, in this case the discharge not being necessarily rapid. A *condenser* has the ability to hold charges of electrical energy and to release them suddenly when the proper contact is made. The term "discharge" as applied to a *transmitter* indicates the passage, usually in the form of a spark or succession of sparks, of the electrical energy across a gap between *electrodes*. The illustration shows spark discharge from spark coil. (See *Spark Discharge, Storage Battery*, also *Discharger.*)



Discharge from a spark coil.

DISCHARGER—Any device allowing a path for an electrical discharge. The term may be considered roughly a synonym for *spark gap*. Usually two or more *electrodes*, either stationary or rotary, spaced a short distance apart to permit the released electrical energy to bridge the space and thus complete an *oscillatory circuit*. (See *Disc Discharger Rotary Gap.*)

DISC DISCHARGER—A form of *discharger* employing one or two rotating discs carrying the sparking surfaces. With the advent of modern undamped transmission methods, these dischargers are gradually passing out. (See *Synchronous Discharger.*)

DISPLACEMENT CURRENT—A current which flows for a short interval in an insulating material or *dielectric* when an *electromotive force* is impressed across it, or when the intensity of the electromotive force impressed across it is increased or decreased. This *displacement current* will flow only when the impressed electromotive force is altered in intensity. After the initial current due to the sudden change in the electromotive force being impressed across the material, the dielectric material or insulating material will remain in a state of strain as long as the *charging force* persists without further change in intensity, and no further displacement current will flow. (See *Current*, also *Dielectric.*)

DISPLACEMENT, PHASE—See *Phase Displacement*, also *Phase Angle.*

DISRUPTIVE VOLTAGE—The voltage sufficient to disrupt or break down a sample of *dielectric* material under given conditions. Known also as *breakdown potential.* For example, if a *condenser* will stand an impressed potential or voltage of 500 volts without injury, but will be punctured by a potential of 1000 volts minimum, the disruptive voltage is said to be 1000. (See *Break Down Potential.*)

DISSOCIATION THEORY—A theory advanced by Arrhenius in 1887, explaining *electrolytic conduction* by the assumption that a substance in solution is dissociated or separated into *positive and negative ions*, these ions carrying their respective charges in opposite directions. (See *Electrolytic Action.*)

DISSONANCE—"Discord; disagreement"—Webster. The antonym of *resonance.* A term broadly applied in radio to indicate lack of resonance, or coordination of signals or impulses. When an alternating current is superimposed on another alternating current of different frequency, the resulting lack of resonance—*dissonance*—is known as a *beat.* (See *Distortion.*)

DISTORTION—Lack of purity or faithfulness in the reproduction of a vibration or series of vibrations. The most common application of the term in broadcast reception is in the case of reproduction by a loud-speaker. It will very often be found that music or speech is not perfectly reproduced, due to any of a variety of causes. Vacuum tubes may themselves cause distortion; too high potential applied to the plate of a tube may result in distortion; many transformers used in audio frequency amplifier circuits may distort notes of certain frequencies, or it may be due to *self-oscillation* or *regeneration* in the receiving set. This effect is also caused by inefficient transmitting (broadcasting) apparatus, or by lack of careful adjustment. The transformation of speech or music into electrical impulses and its subsequent transmission and reception are attended by many difficulties.

The control of wave form in broadcasting is known as *modulation.* (q.v.). If the transformation of speech or music into electrical impulses and its propagation into space is accomplished without materially changing or distorting the wave form from the original voice or music vibrations, the problem of accurate reproduction is entirely dependent on the receiving apparatus. Distortion may often be traced to the diaphragm of the loud-speaker, certain types being more efficient in this respect than others. (See *Loud-speakers.*) If the ordinary type of disc diaphragm is used, it may become bent and thus cause inequalities in the vibrations, producing distortion of the music or speech being reproduced. (See *Wave Form, Modulation,* also *Amplifier.*)

DISTRESS SIGNAL—At the International Radio Telegraph convention held at Berlin, Germany, in July, 1908, the call letters C Q D, established by the Marconi Co. in February, 1904, as the official distress call, were superseded by the letters S O S as the Marine distress signal.

S O S is the International distress call for ships and airships requiring assistance. The letters have no particular significance, being chosen mainly for their distinctive sound. In the International Morse code, S O S is composed of three dots, three dashes and three dots, thus: . . . — — — . . . an unusual combination which permits easy recognition among other messages and calls. When distress signals are heard, the nearest government transmitting station generally sends out immediate notification to all broadcasting stations in the vicinity to suspend operations until the ship has been located and assistance rendered.

DISTRIBUTED CAPACITY—The condenser effect in a coil of wire. Any coil of wire possesses *inherent capacity* to a certain extent, depending on its particular shape, size, etc. In the case of a coil of wire wound on a cylindrical form as indicated in the illustration Fig. 1, the passage of current through the coil sets up a *local magnetic field*, but also an *electrostatic field*, the latter being in the form of lines of force perpendicular to the conductor. Thus in effect, each two adjacent turns of wire act as a miniature condenser (Fig. 2).

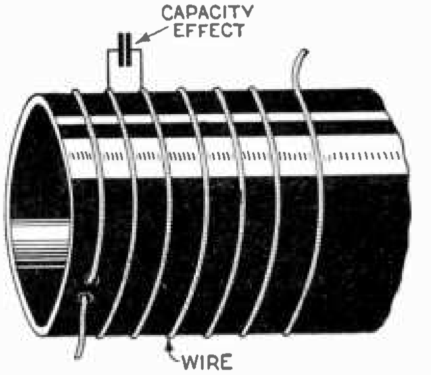


Fig. 1. Coil showing effect of distributed capacity between winding.

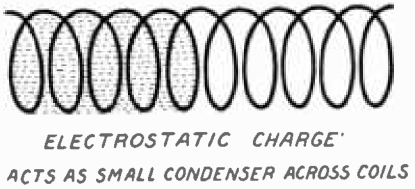

Fig. 2.

There are numerous methods and forms for winding coils in order to do away as much as possible with this effect. (See *Low-Loss Coils.*)

DISTRIBUTED INDUCTANCE—In a long cable or any great length of wire used for electrical purposes, additional inductance (wire) distributed throughout the entire length to compensate for the inherent capacity of the line. (See *Distributed Capacity.*)

DOT—The short signal in the International Morse Code. (See *Code.*)

DOUBLE AMPLIFICATION CIRCUIT—Also known as *dual amplification circuit.* The arrangement whereby a vacuum tube or several tubes may be made to do double duty, acting as both *radio frequency* and *audio frequency amplifiers.* (See *Reflex.*)

DOUBLE COTTON COVERED WIRE—Abbreviation D. C. C.—Cotton covered copper wire widely used in radio work for coils and all forms of inductances. The insulating covering is composed of two distinct layers of cotton, wound on in opposite directions to prevent loosening. Such wire is obtainable in a variety of sizes according to the standard gauges. (See *Wire Gauge.*)

DOUBLE FREQUENCY OSCILLATIONS—Sometimes referred to as a *double humped wave.* An irregular wave resulting from two frequencies, generally due to too close coupling of the *oscillation transformer.* When the coupling between the open and *closed oscillatory circuits* is too tight, the *open circuit* very often oscillates at two frequencies, resulting in the radiation of an irregular or *impure wave.* The illustration Fig. 1 shows in graphic form, such an irregular wave. The two peaks of resonance explain the term double humped wave. Fig. 2 shows another curve illustrating two frequencies.

In this case however, the amplitude of the second wave is considerably less than that of the first or main wave. According to U. S. Government regulations, if the amplitude of the lesser wave is not more than 0.1 of the amplitude of the main wave, it is said to be pure. In other words, where there are two frequencies, but the strength of one less than one tenth that of the other, it is considered negligible as it cannot be expected to cause any appreciable interference. (See *Resonance, Amplitude, Decrement,* etc.)

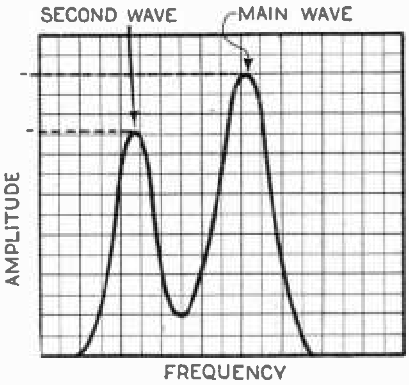

Fig. 1. Resonance curve showing second wave of interfering nature.

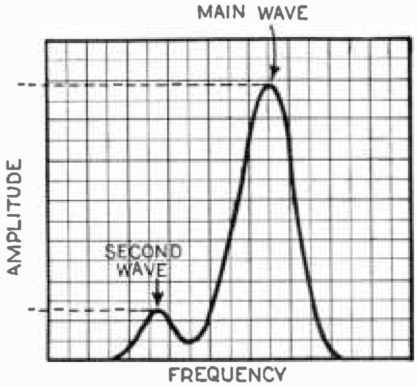

Fig. 2. Resonance curve showing second wave of negligible proportion.

DOUBLE GRID TUBE—A vacuum tube having two distinct *grid* members in addition to the usual *filament* and *plate* elements. Such a tube is used in circuits where the customary "B" battery is not employed, the extra grid acting as a booster for the electron flow, the "A" battery furnishing a small positive potential to the plate. (See *Solodyne,* also *Theory of Vacuum Tubes.*)

DOUBLE MODULATION—Successive modulation of a *radio frequency alternating current* at two lower frequencies. The *intermediate frequency* is usually above *audio frequency* and the lowest frequency is customarily within audio limits or a combination of audio frequencies, as in the case of *radio* *telephony* (broadcast). (See *Modulation.*)

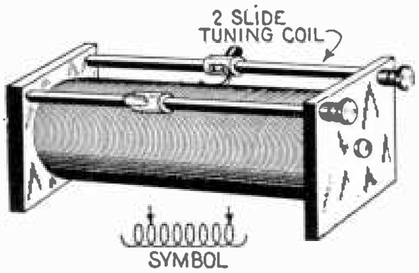
DOUBLE POLE SWITCH—A switch used in electrical practice and in radio installations having two poles or connections, thus permitting both sides of a circuit to be opened or closed simultaneously.

DOUBLE RANGE METERS—Meters used for electrical measurements, arranged to read to two scales. As an example, the voltmeter shown has two scale readings, one in fine degrees for a maximum of 7.5 volts, the other a coarser scale to a maximum of 150 volts. Three binding post connectors are furnished, one being a common positive for both scales. A meter for almost any measurement might be made to have double range, although such instruments are generally confined to measurement of current in amperes and pressure in volts—i. e., ammeters and voltmeters. (See *Meter.*)

Photo by Courtesy of Weston Electrical Instrument Co.

Double range meter, one range to 7½ volts, higher range to 140 volts maximum.

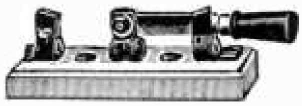
DOUBLE SLIDE TUNER—A tuning coil provided with two sliding contacts, generally used in crystal receivers.



Two-slide tuner.

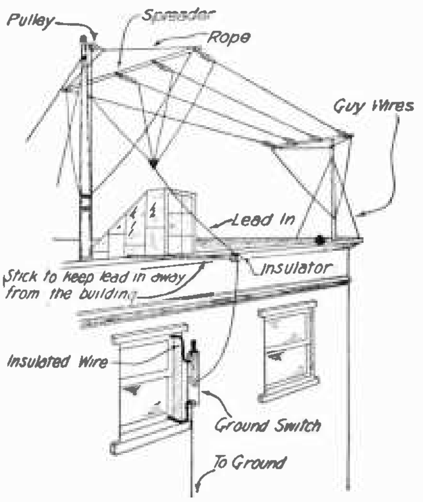
The illustration shows a common type of two slide tuner. (See *Coupling Crystal Receiver*, also *Tuning.*)

DOUBLE THROW SWITCH—A switch so arranged that a circuit or a certain instrument is connected in either of two different positions by throwing the switch lever. The illustration shows a single pole double throw switch. (See *Switch.*)



Double throw single pole switch.

DOWN LEAD—More commonly known as *lead-in.* The wire running from the aerial to the receiving or transmitting apparatus, whereby the signal energy is either collected from, or fed to, the aerial. The illustration shows a typical down lead or lead-in for a receiving set. Obviously the chief difference between such a lead for receiving purposes and for connecting a transmitter to the antenna is the matter of insulation. The comparatively feeble impulses received or collected by the aerial when receiving require only ordinary care, whereas the high voltages used in transmitting require careful insulation and much heavier apparatus all around. (*For more complete details regarding insulation, etc., see Aerial.*)



A typical 4-wire aerial showing lead in and method of installing lightning switch.

DRIFT, AVERAGE ELECTRON—The assumed rate of flow or drift of *electrons* under average or specific conditions. (See *Electronic Flow.* Also *Current, Assumed Direction of Flow.*)

DRIVER—A term broadly used to denote any system used to produce *oscillations* (vibrations) of a local nature. More specifically any means of producing oscillatory currents as used to test or make measurements in radio circuits. A buzzer connected inductively to a circuit to produce oscillations in that circuit for the purpose of making measurements of *capacity, wavelength,* etc. Another means might be a circuit involving a vacuum tube and the necessary apparatus to make it oscillate at a given or variable frequency. The term may be used to signify the tube circuit used to produce local oscillations in the case of a *super-heterodyne* (q.v.). Here the driver produces a series of oscillations of a frequency different from the incoming oscillations, the difference between the two being known as the beat frequency. (See *Heterodyne, Local Oscillations, Buzzer, Excitor.*)

DRIVER CIRCUIT—The circuit of the apparatus used to produce oscillations for purposes of test or measurement, or, in the case of a super-heterodyne, to produce a beat effect. (See *Driver.*)

DRUM ARMATURE—A form of armature winding in the approximate shape of a drum. (See *Armature.*)

DRY BATTERY—A battery or group of cells not employing a liquid electrolyte, the cell being filled with a mixture of carbon, manganese dioxide and sawdust (or other absorbent) saturated with a solution of sal ammoniac, these forming a paste, as distinguished from Wet Battery. (See *Battery,* also *Cell* and *B Battery.*)

DRY CELL—See *Dry Battery.*

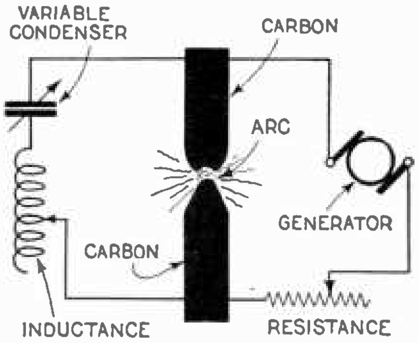
D. S. C.—The abbreviation for "Double Silk Covered" as applied to copper wire having two distinct layers of silk, wound generally in opposite directions. This wire is furnished in standard sizes according to the various wire gauges. (See *Brown & Sharpe Gauge.*)

DUAL AMPLIFICATION—The process of obtaining both *radio frequency* and *audio frequency amplification* from the same tube instead of using two separate tubes. (See *Double Amplification Circuit,* also *Reflex.*)

DUBILIER, WILLIAM—President and technical director; born, New York, July 25, 1888. Educated New York Schools, Technical Inst. and Cooper Union; Chief Engineer of Continental Wireless Tel. & Tel. Co.; 1910 President of Com. Wireless Tel. Co.; at present Technical Director of Dubilier Condenser and Radio Corp. of New York, The Dubilier Condenser Company Ltd. of London, The Deutsche Dubilier Kondensator Gesellschaft in Berlin, La Protection Electrique Capart-Dubilier in Paris. Has obtained over three hundred patents and applications of electrical devices, which have been purchased or licensed by many companies. Member American Institute Electrical Engineers, Inst. of Radio Engineers, Honorary Member of Societe Academique D'Historie Internationale. Member of Royal Society of Arts.

DUCON—Trade name of a device which can be fitted to any electric light socket and made to serve in place of the usual outdoor aerial. This attachment consists essentially of two condensers, so arranged as to prevent the passage of any direct current or low frequency alternating current from the lighting main to the receiving set, but at the same time to permit passage of the incoming radio signals, the electric light line acting, therefore, as an aerial. (See *Adapter, Aerial.*)

DUDDELL SINGING ARC—Also called *Musical arc.* An *arc* actuated by a source of direct current through a *resistance* and shunted by a *condenser* and *inductance* in series. An *oscillating current* is thus produced in the condenser circuit, the result being a singing note corresponding in pitch to the frequency of the oscillations in the condenser circuit. The schematic arrangement is shown by the illustration. (See *Arc Generator.*)



Schematic arrangement for operation of Duddell singing arc.

DULL EMITTER—The English term for vacuum tubes having *thoriated filaments* and operating with low current consumption. While the term is generally used to denote the tubes requiring only one or two dry cells to operate, it may apply as well to storage battery tubes where the current requirements are low. (See *Filament, Thoriated.*)

DUOLATERAL COILS—An alternate term for *honey-comb* coils; inductances wound in diamond-shaped layers to reduce the distributed capacity effect. (See *Honey-Comb Coils.*)

DUPLEX SIGNALLING or DUPLEX TELEGRAPHY OR TELEPHONY—The simultaneous transmission of signals or telephony in both directions between two stations. (See *Diplex Reception or Transmission*, also *Telephony.*)

DUST CORE—A form of core for certain types of transformers, employing iron filings or dust in place of the customary iron wire or laminations. Iron dust is used occasionally where simplicity of construction is desired, the assembly of such a core being obviously much easier than with wire or laminated types. (See *Core.*)

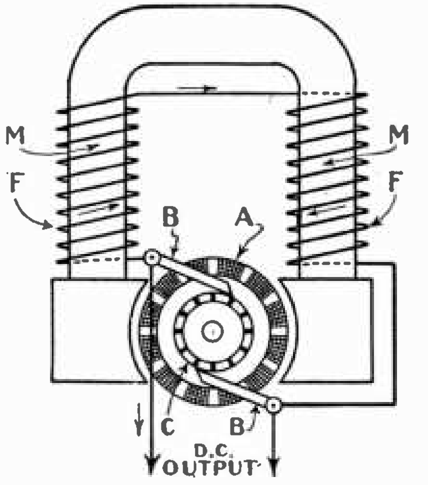
DX—The popular term for long distance; referring to the transmission to or reception from distant points of radio signals or broadcasting.

DYNAMIC CHARACTERISTIC—The curves obtained by impressing an alternating E. M. F. (electromotive force) on the grid of a vacuum tube, as distinguished from the curves obtained by application of a steady direct potential. When alternating potentials such as incoming signals are impressed on the grid of a tube, the curve resulting is apt to take an entirely different form from that of the curve showing *static characteristics* (q.v.). (See *Vacuum Tube characteristics.*)

DYNAMIC CONDENSER—A term occasionally applied to a *synchronous motor* used to improve power factor (in alternating current circuits, the ratio of the electric power in *watts* to the apparent power in *volt amperes* is known as the power factor). Used in this manner the motor has the effect of advancing the current phase in a manner similar to that of a condenser. (See *Angle of Lead or Lag.*)

DYNAMIC ELECTRICITY—A term sometimes used for electric currents to distinguish them from *static electricity* (q.v.).

DYNAMO—A machine for converting mechanical energy into electrical energy. Is also known as *generator*, but usually confined to machines for generating *direct* current. The action of a dynamo is based on the production of an *electromotive force* in a conductor moving in a magnetic field. Fundamentally a dynamo is a machine that generates alternating current, but instead of collecting this current by means of rings, which would cause alternating current to flow in the external circuit, a device known as an *armature* is employed in such a manner that the current collected by brushes and delivered to the external circuit is direct—that is, it flows more or less steadily in one direction. Thus the kind of current delivered for use depends on the method used to collect the currents generated. (For more complete explanation of the production of alternating current see *Alternating Current, Theory of Production.*) In the case of a dynamo, the essential parts are the *field magnets*, the *armature* and the *commutator*. Now in the case of an *alternator*, each end of the loop or armature is connected by a brush bearing against a collector ring and the end of each loop is always connected to the same brush. This *results in an external current that changes its direction with each reversal of direction of the induced electromotive force.* If the external current is to be direct it is necessary to have some means of collecting the current through one brush at the positive instant and the other at the negative instant. This is done by means of an armature, which is in effect a switching arrangement, so designed that it will reverse the connections of the external circuit at the instant of each reversal of current in the armature. The illustration shows a *shunt* wound dynamo. MM are the field magnets, FF the field windings, BB the brushes, A the armature and C the commutator. (See *Alternator, Armature, Generator.*)

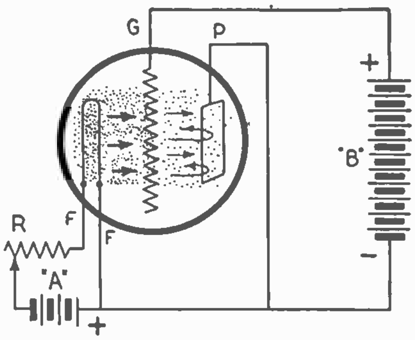


Shunt wound dynamo.

DYNAMOMETER—A delicate and accurate instrument for the measurement of currents and voltages or both. Such instruments depend upon the action of a circuit carrying current upon another carrying the same current. Essentially it comprises two coils, one fixed and the other movable. This system of measurement is used in a *wattmeter*, where it is necessary to measure the instantaneous current and voltage, i.e., power. (See *Wattmeter*, also *Electro Dynamometer.*)

DYNAMOTOR—A direct current machine which acts either as a *motor* or *dynamo*. It has an armature with two separate windings and two separate commutators, one at each end of the armature. Either winding may be used as a motor and the other as the generator winding. Such a machine is used to convert high voltage direct current into low voltage direct current or vice versa, thus performing the same function with direct current as a power transformer performs for alternating current. (See *Converter.*)

DYNATRON—A form of vacuum tube generally used for producing oscillations as in radio telephony, wherein the phenomena of "*secondary electron emission*" is used. In this form of tube the electrons traveling at high speed from the hot filament or cathode are made to collide with a metallic surface. The collision of these electrons on the surface of the interposed element has the effect, under proper conditions, of jarring other electrons out of the metal. The secondary emission thus obtained depends upon the speed of the original electrons which collide with the metal surface. Normally, these secondary electrons will immediately re-enter the surface from which they were emitted, but if another electrode of higher potential is in the vicinity they will travel toward it in the same manner as the electrons are attracted to the plate of an ordinary three element tube. A standard tube can be connected as shown in the illustration to act as a dynatron. Here the filament F emits electrons, some of which pass through the grid G and collide with the plate P. This collision with the plate P may jar loose from the surface additional electrons, which normally would immediately re-enter P. However, as the grid G is held at a higher potential (higher positive voltage) than P, the electrons will be drawn toward it. A tube arranged in this manner may be used for practically any of the purposes of the standard tube, such as regenerative detector, detector of continuous waves or as a generator of high frequency oscillations, but it has not been shown to have any advantages in this respect, being used mainly as an *oscillator* (q.v.). (See *Electron Emission, Vacuum Tube*, etc.)



Showing how a standard vacuum tube can be connected to act as a dynatron.

DYNE—The unit of force in the absolute or CGS system of units. It is defined as the force which, acting on a mass of one gram for one second, will impart to the mass a velocity of one centimeter per second. (See *CGS System*, also *Force.*)

E

E—Common symbol for *Electromotive force* (q.v.).

EAR CUSHION—Pads or cushions of soft rubber used in conjunction with head-phones to prevent unpleasant pressure against the ears and also to exclude outside sounds when listening in.

EARTH—An alternate term for *ground*, where the earth or any metallic connection thereto is used as a return in transmission or reception of *electromagnetic waves*. (See *Ground.*)

EARTH CURRENTS—See *Ground Currents.*

EARTH, DEAD—See *Ground.*

EARTH DETECTOR—See *Ground Detector.*

EBONITE—See *Insulating Materials.*

EBURIN—An insulating compound used for *strain insulators* (q.v.). (See *Insulating Materials.*)

EDDY CURRENT LOSS—The portion

of the total loss in electrical apparatus due to *Eddy Currents* (q.v.).

EDDY CURRENTS—Currents induced in the mass of a solid *conductor* due to the action of a varying *magnetic field.* The most common example of eddy currents will be found in the case of a *dynamo* or *generator*. Here the useful current generated in the *armature* is produced by the motion of the armature in the magnetic field. At the same time currents are generated in the iron core due to its motion in the magnetic field. As all currents generated in an electrical machine are produced at the expense of a certain amount of energy, and since the Eddy currents cannot be gathered or put to useful account in this case, they represent a loss. This loss usually is apparent in the form of heat. If the core is made up of solid metal it will be obvious that a good closed path is offered for eddy currents produced. Now if the core is composed of a number of sheets or *laminations*, insulated by thin layers of paper or by an insulating scale (see *Transformer Steel*) the path for the eddy currents is partially broken and the effect is reduced. Eddy currents are produced in the core of a transformer due to the same action—the variation of the magnetic field in which the core is located. In order to reduce the effect, laminated cores are employed as in the case of many generating machines. Eddy current loss is often given as the loss in watts per pound of core material at 10,000 *gausses* (q.v.) and 60 cycles for a sheet 0.0141 inch or 0.0358 centimeter thick. While eddy currents are usually productive of losses they are put to useful account in certain types of instruments. For example, the eddy currents produced in the metal frame of a moving coil meter may be employed to *damp* or retard the free *oscillations* of the needle. (See *Damping of Instruments.*) Eddy currents are also used in a form of speed indicator where the reaction of eddy currents created in a moving disk are made to deflect a pivoted, spring controlled, magnetic needle. (See *Core Loss, Hysteresis,* also *Foucault Currents.*)

EDDY CURRENT COEFFICIENT—The coefficient or numerical multiplier, generally termed K_1, used in calculations of eddy current loss. Its numerical value depends upon the *specific resistance* (q.v.) of the iron used in the core of the machine in question, the character or *wave shape* of the induced voltage, the distribution of *magnetic flux* (q.v.) in the core material, the degree of insulation between sheets, where *laminations* are used, and upon the *flux distribution* (q.v.) due to the shape of the magnetic circuit. Its value will also vary according to the units used in the computation.

EDDY CURRENT LOSS, FORMULA FOR CALCULATING—A common formula for calculation of eddy current loss is the following: $P_\epsilon = \epsilon V(xfB)^2$. Here the loss is expressed in watts as P_ϵ, V is the volume of core metal in cubic centimeters, x the thickness of the sheets in centimeters, f the *frequency* in cycles per second, B the *flux density* (q.v.) in *gausses* and ϵ the eddy current coefficient.

EDGE EFFECT—The effect on the capacity of a condenser due to the curving of the lines of stress at the edge of the plates. This effect is not very pronounced where there is considerable *dielectric* surface (insulating material) extending beyond the edge of the plates. (See *Distributed Capacity.*)

EDISON BATTERY—A number of Edison cells grouped together in one case to supply various currents and voltages as in radio. The illustration shows an Edison "B" battery, used to supply potential to the plates of vacuum tubes. (See *"A" Battery, "B" Battery, Plate, Filament,* also *Storage Battery.*)

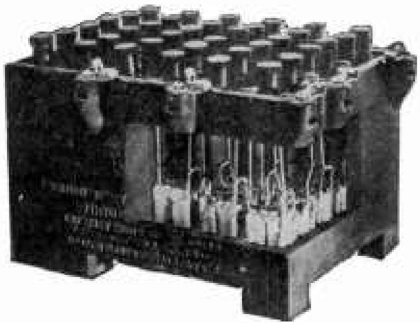


Photo by Courtesy of Edison Storage Battery Co.

Edison "B" battery with portion of case removed to show interior construction.

EDISON CELL—A storage cell employing electrodes of nickeled steel and a solution of potassium hydrate for the electrolyte as distinguished from the usual type of storage cell using lead plates and dilute sulphuric acid as the electrolyte. The chief point of superiority of this type of cell is its comparative ruggedness, due partially to steel construction and also its freedom from the usual ills of cells employing acids and lead plates. The positive electrode in the Edison cell is made by tamping nickel hydrate and alternate layers of pure flake nickel into perforated steel tubes under pressure. The negative electrode is made by pressing iron oxide into flat perforated steel pockets. A number of these pockets are forced into a steel grid to form the complete negative plate. (Note: The *negative* electrode connection on the outside of the cell is referred to as the *positive* pole because it is positive in its relation to the external circuit. Similarly the *positive* electrode connection will be known as the *negative* pole.) The potassium hydrate or hydroxide which takes the place of the acid solution used in the lead plate type of cell acts as a preservative of the steel elements. This naturally means greater life; in fact, it is not subject to the chemical deterioration of other cells. The illustration shows a cell with part of the sides cut away to show the interior construction. (See *Edison Battery.*)

Edison cell with part of case cut away to show how constructed.

EDISON, THOMAS ALVA—Born 1847. An inventor famous for his experiments in applied electricity. He began life with newspaper work which he soon abandoned for telegraphy, making many original inventions in duplex systems of operation. After a varied experience in that line he came to New York in 1871, where his talents were recognized and he had opportunity to profitably develop his ideas. The duplex telegraph was made a success the following year, and two years later the quadruplex; and thereupon he began manufacturing on a large scale for the Western Union Telegraph Co. In 1876 he gave up his factory, and established his experimental station at Menlo Park, N. J., where for several years he worked upon the problem of the incandescent electric light, exhibiting a successful bamboo filament lamp in Paris in 1881. He invented the phonograph in 1878. He superintended the construction of the first incandescent lighting station in New York in 1882. Moving his laboratory to Orange, N. J., he established there a large plant for electrical experiment and invention and as a result of his labors there he has taken out 400 patents. Among his inventions may be further named: a type of dynamo, a microphone, the chemical electrical meter, an electric pen, the mimeograph, the magnetic ore separator, dead beat galvanometer, the electric torpedo, a telephone transmitter, and a storage battery. His chief fame rests with his development of the telegraph, his invention of the incandescent lamp and the phonograph.

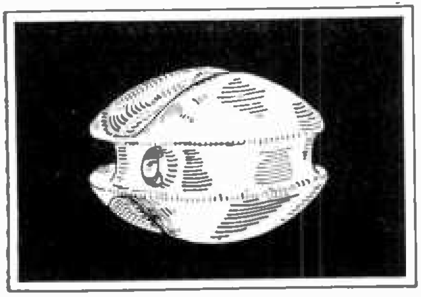
Thomas A. Edison

EDISON EFFECT—The blackening of the inner surface of an electric light bulb during use. Edison noticed that after the lamp had been burned for some time a coating of black formed on the inner surface and increased in density, becoming finally almost opaque. Edison's experiments, followed by those of *Professor Fleming* (q.v.) resulted in the development of the *Fleming valve* (q.v.)., it having been determined that the black coating was due to the discharge of *electrons* from the hot *filament*. (See *Vacuum Tube, Electron Emission*, etc.)

EFFICIENCY—A very flexible term in electrical practice. Generally speaking, the ratio of useful output of any piece of apparatus to total input. Efficiency is customarily expressed in terms of percentage. Thus, broadly, a piece of apparatus may produce as useful output 80 per cent of the total input. (See *Power Factor*.)

EFFECTIVE ELECTROMOTIVE FORCE—The square root of the mean square of the full alternating current wave. Usually abbreviated R. M. S. (root—mean—square). The effective value of the E. M. F. (electromotive force) is thus taken as the square root of the mean of the squares of the *instantaneous values* over a complete period. (See *Instantaneous Values*.)

EGG INSULATOR—A name applied to a certain type of *strain insulator* due to its egg-like form. The illustration shows such an insulator. The two connections to the insulators are so arranged that the wires will still be looped together in the event that the insulator breaks. (See *Insulator*, also *Insulation of Aerial*.)



An egg insulator.

ELASTICITY—A property of matter which permits it to resist any change in shape or bulk and permits it after such a change to return to its original state. This property of materials by virtue of which they are enabled to return to their original state after the force causing the distortion has been removed is a very important one in all branches of engineering. Its chief application in radio is in the matter of aerials and aerial guy wires. While the average aerial installation does not represent any serious problems in stress, the large aerial systems of commercial stations must be carefully designed in this respect. For example, a guy wire of one material may have more elasticity than one of similar size in another material. The amount which the wire will stretch under a certain load may be determined by use of a table giving the elasticity of various metals. (See *Electric Elasticity*.)

ELECTRIC ABSORPTION—An effect in *condensers*. That quality of a condenser by means of which it absorbs or "soaks up" a charge of electricity, and conversely, retains part of the charge when the condenser is momentarily discharged. This effect is more apparent in cases where a solid *dielectric* material is used. In fact, *air condensers* (q.v.) are said to have little electric absorption. The reason for this is that mica or other solid dielectrics are strained to a greater extent than air dielectric after the condenser has received a charge. (See *Soaking In*, also *Dielectric Absorption*.)

ELECTRIC DISPLACEMENT—A term proposed by Maxwell to denote a quantity expressing the state or condition of a dielectric in an electric field in accordance with the supposition that such a field is created by the transfer of positive electricity to one end of the field of force and negative electricity to the other end of the so-called *tubes of force* (q.v.). (See *Displacement Current*, also *Electrostatic Induction*, and *Flux Density, Electrostatic*.)

ELECTRIC ELASTICITY—In a dielectric material, the property which permits it to arrest passage of a *displacement current* (q.v.) due to electric stress. It is equivalent to the electric stress divided by the electric strain. (See *Dielectric*, also *Displacement Current*.)

ELECTRIC FIELD—The area surrounding an electrified body in which the electrical influence of that body can be measured or noticed. Also any area or region in which there is an electric force either steady or varying in intensity. For example, the *dielectric* or insulating surface of a *condenser* (material separating the plates) contains an electric field. Similarly, an electric field always surrounds a wire or other conductor carrying electric current. (See *Field, Magnetic; Field, Electromagnetic; Field, Electrostatic;* also *Flux*.)

ELECTRIC INDUCTION—The transfer of an electric state from a charged or electrified body to a non-electrified body without electrical contact. (See *Induction*.)

ELECTRICITY—The term given to an invisible form of energy. Electricity is not tangible to the human senses, but its effects can readily be detected. The phenomenon of electricity is regarded as due to the separation and independent movement of constituent parts of atoms—known as *electrons*. While electricity is really an intangible thing so far as the human perceptions are concerned, it is known to science not only through its effects or manifestations of energy, but has actually been reduced to quantities. The mass of electricity has been determined, as has also the *rate of flow*, etc. We have units which are used for the basis of all calculations in electricity. Thus, *voltage* is regarded as the propelling force; the quantity of electricity is given in *coulombs*, the *current* or rate of flow of electricity is given in *amperes*, etc. Each term for the various phases of electricity is based on a certain unit which represents definite values under given conditions. The universally accepted theory in chemistry is that all matter is made up of molecules, which in turn are composed of one or more atoms. These atoms now are regarded as comprising minute solar systems made up of positive and negative electrical particles. (For more complete explanation of the *electron theory* see *Electron Theory*; see also *Magnetism, Current, Voltage*.)

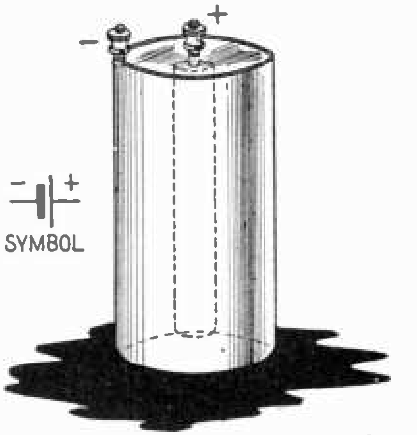
ELECTRO-CHEMICAL CONDENSER—See *Electrolytic Condenser*.

ELECTRO-CHEMICAL EQUIVALENT—The amount of a substance liberated by *electrolytic action* (electrolysis) by the passage of one *coulomb* (q.v.) of electric current. It represents the weight in grams of each element of an *electrolyte* (q.v.) which is deposited by one coulomb of electricity. It has been determined that one coulomb will liberate .00001035 grams of hydrogen, which is therefore used as the electro-chemical equivalent of hydrogen. Electro-chemical equivalents are much used in applying the law of electrolysis. This law states that the amount (weight) of an *ion* liberated at an *electrode* each second during *electrolysis* is equal to the strength of the *current* (amperes) multiplied by the electro-chemical equivalent. The corresponding equivalents of other elements compared to hydrogen may be determined by multiplying the figure .00001035 by the atomic weight of the other element in grams and dividing the result by the *valency* (q.v.) of the element in question. (See *Electrolysis*, also *Electrolyte*.)

ELECTRO-CHEMICAL SERIES—A table of metals arranged in accordance with the *potential* they produce in a particular *electrolytic* solution.

ELECTRO-CHEMISTRY — The science dealing with chemical changes due to electricity or effected by means of electricity. (See *Electrolysis*, also *Cell*, and *Storage Batteries*.)

ELECTRODE — The conductor through which electric current enters or leaves an electrical device. That is to say the pole or terminal of the current carrying conductors separated by a medium through which electric current can flow from one to the other. The most common usage of the term is in referring to the *positive* and *negative* poles (q.v.) of a *primary* or *storage cell*. In the case of a *dry cell*, the two electrodes are the carbon rod or block in the center and the zinc container in most cases. In radio it is used to designate the *filament* and *plate* elements of a vacuum tube. The filament is termed the *cathode*, or *negative electrode* and the plate is the *positive electrode* or *anode*. The illustration shows an ordinary *dry cell* or *primary cell* with the two electrodes designated as positive and negative. (See *Anode, Cathode, Battery, Electrolysis, Positive Electrode* and *Negative Electrode*.)

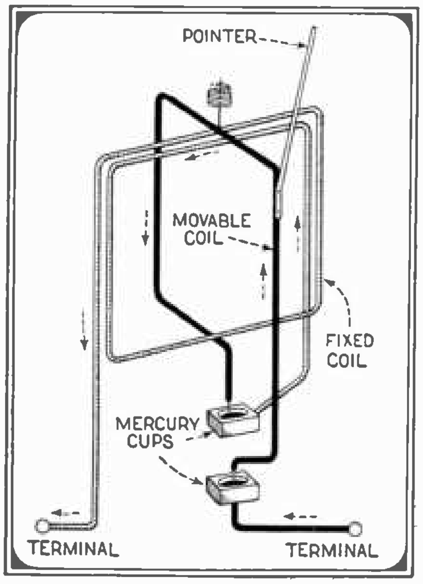


Dry cell showing positive and negative electrodes.

ELECTRODYNAMIC—Term used to denote electric currents or the forces exerted by one current upon another.

ELECTRO-DYNAMICS — A branch of the science of electricity dealing with electricity in motion; the study of the force exerted by electric currents upon each other. This branch of electricity was first accorded serious attention when the French scientist, *A. M. Ampere* (q.v.) announced the result of his investigations in collaboration with D. F. J. Arago. Ampere stated in 1820 that *parallel conductors* through which electric currents were flowing in the same direction had a tendency to be attracted to each other and to be repelled when the currents were flowing in opposite directions. The subject is discussed under its various separate headings. (See *Ampere, Electricity, Magnetism.*)

ELECTRO-DYNAMOMETER—A device for measuring the *current* and *voltage* in a circuit; that is, the actual power in a circuit. It is a form of *wattmeter* (q.v.) designed to indicate the power in *watts*. It is of particular importance in measuring the power in *alternating current* circuits. In the case of *direct current*, the watts in the circuit are the product of the volts multiplied by the amperes, the result being the actual power. In the case of alternating current, however, the product of the volts and amperes is not necessarily, in fact, seldom, the true power or watts. Here we have the problem of true watts and apparent watts, or volt-amperes. If a voltmeter and an ammeter are connected in a circuit and read separately, the readings indicate the maximum voltage and the maximum current or amperage. The product of these two values is the power in watts in a direct current circuit. If the current is an alternating one, the true watts or actual power will be the product of the *instantaneous values* (q.v.) of voltage and current. Under certain conditions in a circuit carrying alternating currents, the current may lag behind or precede the voltage. In other words, the maximum value of current is not reached at the same moment as the maximum value of the voltage. In this case the true watts can only be determined by obtaining the values of volts and amperes at the same instant, i.e., instantaneous values. The electro-dynamometer shown in the illustration gives the instantaneous values, or rather their product, and thus indicates the power or true watts. Here the heavy lines represent the current or moving coil and the light lines the stationary or voltage coil. (See *Dynamometer*, also *Wattmeter.*)



Electro-dynamometer with the current or moving coil shown by heavy lines and the stationary or voltage coil by light lines.

ELECTROLINES—A term advanced by *Professor J. A. Fleming* (q.v.) to designate the lines of electric force radiating from an electron. These lines are pictured as analogous to long straight wires extending in all directions from the center of a small sphere. (See *Electron*, also *Electromagnetic Waves.*)

ELECTROLYSIS—The decomposition of a comopund substance, generally a liquid, into its component parts by the action of an electric current passing through it. While electrolysis is an undesired effect in certain phases of electrical power work, causing composition of grounded structures, its application to radio is mainly in the case of cells for producing an *electromotive force* or to furnish current for lighting tubes. The constituent elements of a chemical compound such as used in a wet cell or any device using an electrolyte for the production of electric current, are known as *ions* (q.v.). These ions, which are separated during electrolysis, are of two kinds. The electro-positive ions are known as *cations*, and the electro-negative ions are known as *anions*. The electro-positive ions appear at the cathode or negative electrode during electrolysis and therefore are of positive origin. The electro-negative ions appear at the positive electrode and are therefore of negative origin. This is easily understood when the ions are considered as moving from the positive electrode or to the negative. Thus the ions appearing at the negative electrode must have come from the positive electrode and are therefore considered electro-positive in nature. The illustration shows the action of the ions in a typical *primary cell* (q.v.). The ions are considered as carrying the current through the electrolyte—each ion carrying a fixed charge of electricity of positive or negative nature. An ion is capable of carrying only a certain fixed charge of electricity and therefore any increase in the current will necessarily be accomplished by an increase in the number of ions. (See *Primary Cell, Electrolyte, Electrolytic Detector, Interrupter* and *Condenser.*)

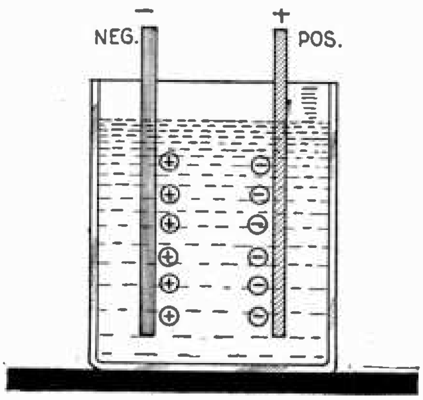


Illustration showing the action of ions in a primary cell.

ELECTROLYTE—The liquid decomposed during electrolysis, as the exciting fluid or solution in a wet cell or primary cell. The liquid used in any primary, secondary or electrolytic cell. (See *Cell*, also *Storage Battery.*)

ELECTROLYTIC ACTION—The decomposition of a chemical compound (electrolyte) into its constituent elements—ions, by the passage of an electric current through it. (See *Electrolysis, Ions*, also *Cell.*)

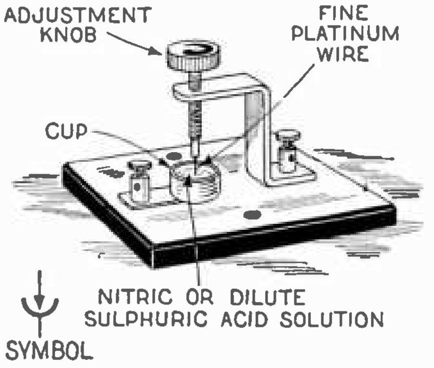
ELECTROLYTIC BATTERY CHARGER—A device for converting alternating current such as supplied for house lighting purposes, to direct current for the purpose of charging storage batteries. Essentially one or more cells containing an electrolyte and two metal electrodes, generally lead and aluminum, so arranged that current can only pass in one direction, thus making it uni-directional and suitable for charging batteries. Such chargers are arranged to rectify either one-half of the alternating current cycle, or both halves of the wave. (See *Charger, Storage Battery, Electrolytic Rectifier*, also *Electrolytic Cell.*).

ELECTROLYTIC CELL—An arrangement of two *electrodes* in an electrolyte through which electric current can be passed to produce electrolysis. The electrolyte is decomposed or separated into ions by the action of the current, and at each of the electrodes one of the substances of which the electrolyte is composed accumulates. Such a cell is often used to measure electric current, as the amount of a substance deposited on the electrode depends directly on the amount of current passed through the electrolyte. (See *Electrolysis.*)

ELECTROLYTIC CONDENSER—A form of condenser making use of two electrodes placed in an electrolyte and used for alternating current circuits of high voltage and low frequency, low voltage and high frequency or high voltage and high frequency. The action of such an arrangement as a condenser depends on the fact that upon the passage of certain forms of alternating currents through it, a gas is formed around the electrodes, causing *polarization* (q.v.) and opposing the current. This polarization creates a very good insulating medium and a condenser of such nature can be made to have very high capacity. An electrolytic condenser may be used to prevent any sudden surge of pressure due to lightning or other causes. The polarization is instantaneous when any surge of voltage takes place and thus forms an automatic safety device which operates instantly and returns to its normal characteristics as a condenser as soon as the surge has passed. (See *Capacity*, also *Condenser.*)

ELECTROLYTIC CONDUCTION—The action in an electrolyte wherein the ions that have been separated carry positive and negative electric charges in opposite directions to the electrodes. (See *Electrolysis.*)

ELECTROLYTIC DETECTOR A device which converts high frequency currents into direct current pulsations capable of operating a telephone receiver. It is an extremely sensitive detector of electromagnetic waves (radio signals). The illustration shows a simple form as originally used in place of the customary crystal detector. A fine platinum wire dips into a

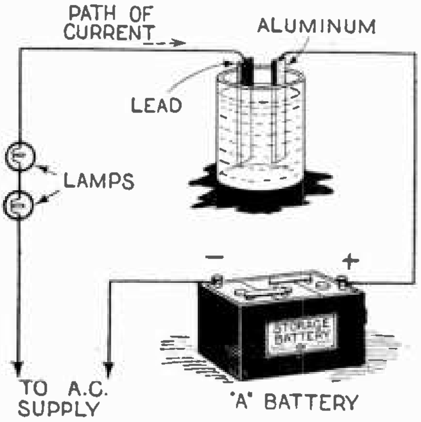


Electrolytic detector originally used in place of a crystal detector for radio reception.

cup of acid solution, generally either nitric or dilute sulphuric. The fine wire is lowered until it just touches the acid solution and must be very carefully adjusted as it has a tendency to curl up, its diameter being usually but one five thousandth of an inch or less. The high frequency currents can pass in only one direction through the detector which gives the rectifying action and makes the signals audible in the head phones. There are several theories regarding the action of an electrolytic detector, the most probable one being that the contact of the wire on the surface of the acid solution gives the effect of a very small *electrolytic condenser.* (q.v.) When the high frequency currents are passed through the detector there is a polarization action which causes high resistance to current in one direction but not in the other. (See *Detector,* also *Polarization.*)

ELECTROLYTIC INTERRUPTER—A device using electrodes immersed in an electrolyte for the purpose of interrupting or breaking up the flow of current. It is used mainly for induction coils for producing high voltages. The common form comprises a lead plate as a cathode or negative element and a platinum wire extending beyond a glass or porcelain tube in which it is tightly imbedded, both immersed in an electrolyte of dilute sulphuric acid. When current passes through, bubbles form on the platinum electrode causing temporary stoppage of the current. The bubbles are automatically dissipated and the current flows again, this operation occurring at rapid intervals and giving as many as 1000 interruptions per second. (See *Interrupter,* also *Induction Coil.*)

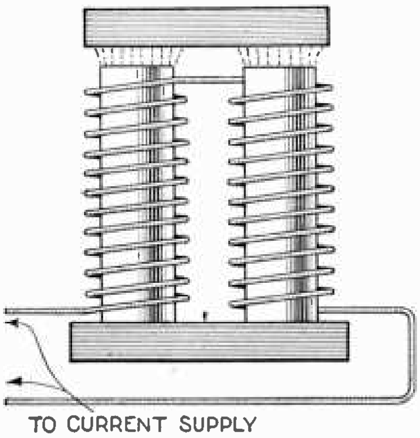
ELECTROLYTIC RECTIFIER—A device for changing alternating current into direct current by use of electrodes placed in an electrolytic solution. The action of such electrolytic cells or rectifiers is to permit current to pass only in one direction, thus suppressing one half of each cycle and producing a direct current. The illustration shows one of the customary arrangements for electrolytic rectification, being an electrolytic cell with two electrodes, one being aluminum and the other a lead electrode. One or more lamps are placed in series or shunt in the circuit to permit the proper current flow. The positive pole of a storage battery is connected to the aluminum plate as shown and the lead electrode connects to the other side of the alternating current line and back to the negative side of the battery. At one instant current flows in the normal direction through the battery, but when the current reverses and flows in the opposite direction through the electrolytic cell, oxygen is given off at the aluminum electrode and forms a thin film of aluminum oxide which acts as an insulator and prevents the passage of the current in that direction. Thus with one cell one half of each alternating current cycle is stopped or cut off when the aluminum electrode is made positive and the result is an intermittent direct current suitable for charging batteries. Such rectifiers are also used for supplying current to the filaments of vacuum tubes, or voltage to the plate members of the tubes, particularly for transmitting. (See *Electrolytic Rectifier Full Wave,* also *Balkite Battery Charger.*)



Customary method of electrolytic rectification.

ELECTROLYTIC RECTIFIER FULL WAVE—This system is much used for charging storage batteries from an alternating current house lighting supply. Four cells are used in this instance. The electrolyte may be a solution of hydrolchloric or sulphuric acid, or a saturated solution of sodium phosphate or bicarbonate of soda. Each cell has two electrodes, one iron or aluminum and the other lead. The positive pole of the storage battery is connected to the lead electrodes of two cells and the negative pole is connected to the aluminum electrodes of two cells. By this means both halves of the alternating current cycle are rectified to direct, pulsating current. This is known as *full wave rectification* (q.v.) (See *Charger, Storage Battery, Balkite Battery Charger,* also *Rectifier.*)

ELECTRO-MAGNET—A magnet using a curved or straight piece of soft iron or other magnetic material so arranged as to become magnetized by the passage of electric current through a coil of wire surrounding it. The illustration shows one of the commonest forms of electro-magnet. This type is used in a bell or buzzer to draw down the vibrator bar and break the circuit. (For explanation of action see *Buzzer.*) When the current is withdrawn from an electro-magnet, the magnetic force or attraction ceases. Electro-magnets are used for a variety of purposes in radio, such as for test buzzers, head phones, relays, etc. (See *Magnet,* also *Magnetic Lines of Force.*)



One of the common forms of electro-magnets.

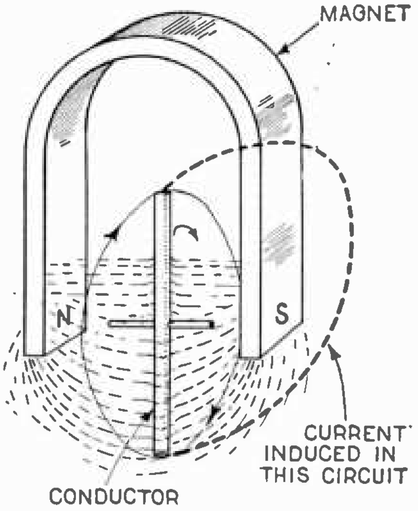
ELECTROMAGNETIC CONTROL—The control of various switches and other apparatus by means of *electromagnets,* usually through an auxiliary contact at a distant point. (See *Remote Control,* also *Electromagnet.*)

ELECTROMAGNETIC FIELD—The space understood to be filled with *electromagnetic lines of force.* (See *Flux,* also *Lines of Force.*)

ELECTROMAGNETIC FLUX—The distribution of the lines of force through an electromagnetic field. (See *Flux,* also *Lines of Force.*)

ELECTROMAGNETIC IMPULSE—An impulse or electromagnetic disturbance conveyed to the ether from a conductor carrying high frequency currents. Another term for the electromagnetic waves involved in radio. (See *Electromagnetic Waves.*)

ELECTROMAGNETIC INDUCTION — The production of electric currents through a change in a *magnetic field* (q.v.). Its production is due to a change in the number of lines of force which are linked with a conducting circuit. The simplest example of this means of producing current is shown in the illustration. Here a conductor is arranged to be moved in the immediate vicinity of a magnet, causing a change in the number of lines of force that link the conductor and creating an induced current. This current will persist only so long as the conductor continues to be moved in the magnetic field. That is to say when there is no longer any change in the magnetic lines of force linking the conductor, there will be no current induced. The discovery of electromagnetic induction and formulation of its laws was primarily due to the scientist *Faraday* (q.v.). Faraday's law governing electromagnetic induction follows: "The induced electromotive force around any circuit is the rate of the decrease of the total flux of magnetic induction through the circuit." (See *Induction, Flux,* and *Lines of Force.*)



Simple method of producing electric currents by causing changes in the magnetic field.

ELECTROMAGNETIC INSTRUMENTS —Electrical measuring instruments such as voltmeters, ammeters, etc., which depend for their action on the exertion of electromotive forces upon iron armatures. (See *Ammeter, Thermal;* also *Voltmeter.*)

ELECTROMAGNETIC MICROPHONE —A type of microphone in which the sound waves due to speech or music cause vibrations of a suspended coil in a magnetic field, inducing in the coil minute waves of electromotive force corresponding in form to the original sound waves. A form of microphone used in radiophone (broadcasting) transmission when purity of sound is an important consideration. Such a microphone requires that the induced currents be heavily amplified. (See *Microphone*, also *Speech Amplifier.*)

ELECTROMAGNETIC RADIATION—The propagation or radiation of electromagnetic waves through the ether. (See *Electromagnetic Waves*, also *Ether.*)

ELECTROMAGNETIC ATTRACTION—The attraction existing between unlike poles of electromagnets. This attraction is identical with that of two unlike poles of ordinary magnets. (See *Magnetic Attraction and Repulsion.*)

ELECTROMAGNETIC REPULSION—The tendency of two like poles of electromagnets to act against or repel each other. (See *Magnetic Attraction and Repulsion.*)

ELECTROMAGNETIC SWITCH—A switch for breaking electrical circuits by the action of an electromagnet. (See *Electromagnet*, also *Remote Control.*)

ELECTROMAGNETIC THEORY OF LIGHT—The theory and consequent scientific proof that radio waves and light waves are practically identical in nature. Light waves travel at a tremendous speed through the ether, approximately 186,000 miles per second, which is also understood to be the velocity of electromagnetic or radio waves. (See *Electromagnetic Waves.*)

ELECTROMAGNETIC UNITS—The fundamental or absolute units employed in electricity as a basis for calculations and on which the practical units are based. The effects of electricity, and hence electricity itself, can be measured in two ways. The first is the measurement of the quantity of electricity by the force it exerts upon another stationary quantity of electricity. This is known as the *electrostatic system.* The second is by measuring the force which a given quantity of electricity exerts upon a *magnetic pole* when flowing through a nearby conductor. This is referred to as the electromagnetic system. Fundamental or absolute units are derived from the fundamental units of *length, mass* and *time.* These units are the *centimeter of length, the gramme of mass* and the *second of time.* The term centimeter-gramme-second, referring to this system, is abbreviated C.G.S. system. The practical units of electricity are known as *volts, amperes*, etc., and are based on the absolute units. (See *Electrostatic, Units, C.G.S. System*, also *Ampere, Erg, Dyne* and *Coulomb.*)

ELECTROMAGNETIC WAVES—The term applied to the energy radiated from an *antenna* in radio transmission. So called because it is understood to travel in the form of waves. One-half the energy of such a wave is electrical and the other half electromagnetic. *Electromagnetic waves* travel with the speed of light waves or approximately 186,000 miles per second. These waves are of extremely high frequency—that is, their direction changes many thousand times each second. This will be better understood by means of the illustration showing the arrangement of the electric and *magnetic fields* around a radiating antenna. Here the lines represent the electric field and the shaded portion the magnetic field. The lower loops or "feet" of these waves are assumed to pass over the surface of the earth which is a conductor. Thus when electromagnetic waves are being radiated from an antenna, circular distributions of electric charges are in the earth's surface around the antenna, these charges being alternately negative and positive, the bands of charge spreading out or radiating from the antenna in the manner shown in the illustration. These waves are subject to various influences which have a tendency to refract or reflect the waves much in the manner of light waves.

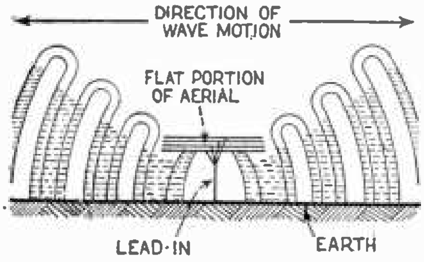


Illustration showing the arrangement of the electric and magnetic field around a radiating antenna.

As these waves move out from the antenna they gradually increase in height, although the distance between the "feet," i.e., from one wave to another, remains the same. This distance is known as the wave-length. (See *Reception of Electromagnetic Waves*, also *Wave-length, Radiation Transmission.*)

ELECTROMETER—An instrument used for measuring potential differences (voltages) and, under certain conditions, power in *watts.* The operation of the instrument depends upon the attraction or repulsion of electrostatic charges and it may be used for either direct or alternating current measurements. (See *Voltmeter, Electrostatic.*)

ELECTROMETRY—The practice or science of electrical measurement. (See *Meter, Voltmeter.*)

ELECTROMOTIVE FORCE—Symbol E or e—abbreviation E.M.F. The force or electrical pressure which starts and maintains a current of electricity through a conductor. Electromotive force is commonly referred to in terms of volts and is abbreviated E.M.F. The electromotive force in electricity is analogous to the difference of level which produces pressure in pipes carrying water and forces the water to flow. Electromotive force is produced by a difference of potential, and this in turn sets up the flow of current. The illustration *Fig. 1A* shows a simple primary cell or electrolytic cell, and *Fig. 1B* is the analogous action of two tanks holding water, connected by a pipe and so arranged that the water level in one tank is higher than in the other, thus having a difference of level and creating pressure which makes the water flow. The water in tank A being at a higher level than in the other, the pressure causes the water to seek its common level and it flowed into tank B through the pipe. This flow continues as long as there is difference of level. In the case of the cell *Fig. 1A* there are two electrodes, one of which is at a higher potential than the other. That is to say, one is in a state of higher electrification than the other, causing a difference of potential and producing an electromotive force. This force is in the direction from the point of greater potential to point of lesser potential as in the case of the water, and causes a flow of current in that direction. Here the flow is from B to A in the electrolytic solution and from A to B externally through the conductor C. Thus as long as there exists a difference of potential, current will flow in an attempt to equalize the potentials. (This statement holds true only under ideal conditions. See *Polarization.*) This flow of current in the illustration *Fig. 1A* is according to *Ohm's law* (q.v.), i.e., a difference of potential of one volt will cause one ampere to flow through the external circuit when the resistance of the circuit is one ohm. (See *Ampere, Ohm, Volt, Resistance.*)

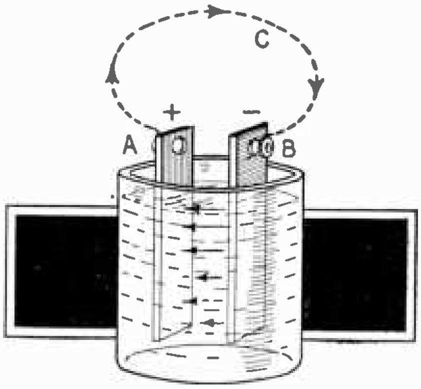

Fig. 1-A. A simple primary or electrolytic cell.

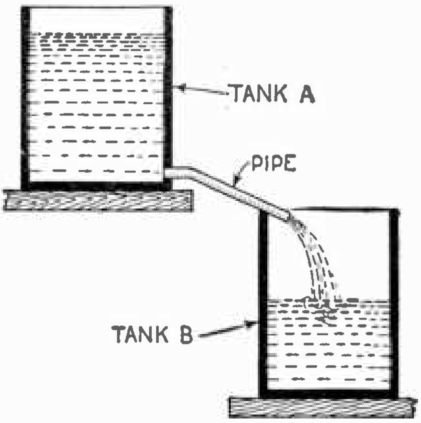

Fig. 1-B. Water in tank "A" seeks its level by discharging into tank "B" in a manner analogous to the flow of electric current where a potential difference exists.

ELECTRON—The smallest negative charge of electricity known. An English investigator, Dr. Johnstone Stoney, is credited with having named the electron, although it was so named by him in anticipation of its being isolated and measured. The actual proof of the earler assumptions was due to Sir J. J. Thomson and others, who actually measured, and in all effect weighed, the minute particles of negative electricity. (See *Electron Theory.*)

ELECTRON FLOW—The theory of movement of free electrons along a conductor through which an electric current is flowing. (See *Electron*, also *Current, Assumed Direction of Flow.*)

ELECTRON EMISSION—The emission or discharge of electrons or minute particles of negative electricity from a heated body, particularly in a vacuum. The emission of electrons in a vacuum tube is the basis of operation of all vacuum tubes as used in radio. (See *Electron Theory*, also *Vacuum Tube, Theory of Operation.*)

ELECTRON THEORY—The assumption that the atoms of all substances contain one or more particles of negative electricity, which is of course paramount to saying that all matter is electricity. These particles are known as electrons, and while the assumption is referred to as a theory, it has been rather definitely proven by numerous experiments, and electrons have actually been measured. Under the electron theory it is assumed that the charge carried by a single electron is the smallest possible charge which can exist in nature and that no charge of electricity exists or can be produced which is not an integral multiple of this charge. (Note: This is merely a mathematical way of stating that any charge of electricity is equivalent to the combined charges of a certain number of electrons.) Probably the most accurate conclusion regarding the charge carried by an electron is due to experiments carried on by Prof. A. E. Millikan of the University of California. His measurements state this charge of a single electron as being 4.77×10^{-10} electrostatic unit, which is 1.59×10^{-19} of a *coulomb* (q.v.). While the mass or weight of an electron is said to vary with its velocity, assuming a velocity of less than one-tenth that of light, the mass will be 8.9×10^{-28} grams. This is approximately one seventeen hundredth of the weight or mass of an atom of hydrogen. For purposes of calculation the electron is assumed to be in the shape of a sphere. The radius has been estimated at approximately 10^{-13} centimeter. When it is considered that a centimeter is somewhat less than half an inch it is readily seen that an electron is an infinitesimal affair.

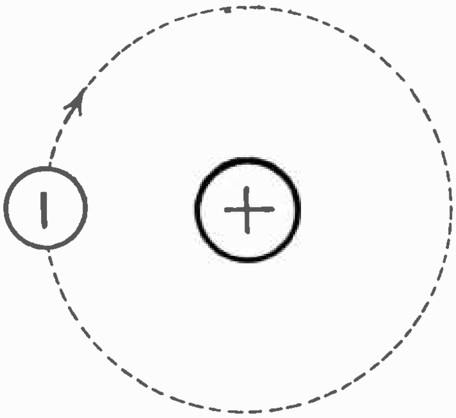

Illustration showing the electron, or negative particle, revolving around the proton or positive nucleus.

The figures as to velocity of electrons vary somewhat with different authorities, but it is probably about 100 kilometers (approximately 62½ miles) per second at a temperature of zero degrees centigrade, the speed increasing as the temperature rises. Electrons may be understood as comprising minute solar systems of their own. In the illustration the *electron* or negative particle is shown revolving around the *proton* (q.v.) or positive nucleus in the manner of a planet revolving around the sun. This represents a normal atom of hydrogen, the simplest of all atoms, which, as shown, is composed of a single positive nucleus and a single electron revolving around it. In the case of an atom of helium there is a doubly charged positive nucleus, or proton, and two negative electrons revolving around it. Other atoms have as many as 92 electrons.

All vacuum tubes used in radio operate on the basis of the emission of electrons from a heated filament within the tube. These electrons are being emitted from the hot filament at all times during operation of the tube. When the incoming signals are such as to charge the grid negatively they are repelled and held back to the filament, thus offering no path for the signals. When the incoming signals have reversed their polarity, as they do thousands of times each second, the grid will be positively charged and the electrons will be aided in their travel to the plate, thus forming a conductive path for the currents. This, of course, results in the elimination of one-half of each cycle of the incoming currents or oscillations. That is to say, they are rectified to direct pulsating currents. (See *Amplifier, Vacuum Tube, Theory of Operation* and *Space Charge.*)

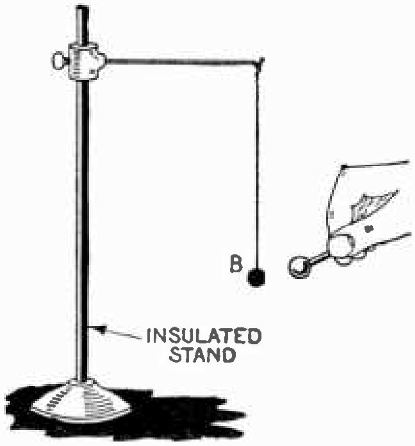
ELECTRON RELAY—A term occasionally applied to a three element tube (vacuum tube). This alternate term is obviously derived from the fact that the vacuum tube makes use of the path of electrons and in effect acts as a relay. (See *Electron.*)

ELECTRON TUBE—Any tube using a high vacuum and depending for operation on the emission of electrons from a heated *cathode.* (See *Electron,* also *Vacuum Tube.*)

ELECTRONEGATIVE—Having the property of being attracted to the positive pole of an electrolytic cell. The electronegative component. (See *Anion,* also *Cathion.*)

ELECTROPOSITIVE—Having the property of being attracted to the negative pole of an electrolytic cell during electrolysis. The electropositive component. (See *Anion,* also *Cathion.*)

ELECTROSCOPE—A device for detecting minute differences of potential (voltages). Such a machine will not measure the voltage but merely indicate its presence. The simplest form of electroscope is shown in the illustration. Here a ball B, composed of the pith of some wood, preferably elder due to its extreme lightness, is suspended by a thin silk thread from an insulated stand. The object under investigation is moved near the pith ball, which will be repelled or attracted by the object if the object is in a state of electrification; but will remain motionless if no difference of potential exists. (See *Voltmeter, Potential, Difference of.*)



Simplest form of electroscope.

ELECTROSE—An insulating composition much used in electrical power work and for radio purposes. It has very high compressive strength, is hard and tough without being brittle, and is moisture, water and oil proof. Electrose is used extensively for antenna insulation. (See *Insulator*).

ELECTROSTATIC—The term used to designate EMF's (electromotive forces) or potentials, charges, etc., and the resultant forces. That is to say, electricity at rest or stationary in a body in order to distinguish it from the forces due to *electro-dynamics* (q.v.).

ELECTROSTATIC CAPACITY—The amount of electricity which a condenser or similar body is capable of storing. If a condenser is capable of receiving and storing one *coulomb* of electricity under a potential of one *volt* it is said to have an electrostatic capacity of one *farad,* which is the unit of electrostatic capacity. The electrostatic capacity of a condenser depends on several factors, mainly the size of the plates and the nature and thickness of the dielectric material (insulating sheets). (See *Capacity,* also *Condenser.*)

ELECTROSTATIC CHARGE—The presence of electricity in the form of electrostatic lines of force in a body such as a charged conductor. (See *Charge.*)

ELECTROSTATIC COUPLING—The association or coupling of circuits one to another by means of electrostatic action, i.e., condensers. Any capacitive association of one circuit with another. (See *Coupling.*)

ELECTROSTATIC FIELD—A region wherein forces are present and exerted due to the presence of electric charges. It is the area immediately surrounding a charged body. (See *Field, Electromagnetic,* also *Field, Electrostatic*).

ELECTROSTATIC FLUX—Lines of force making up an electrostatic field. (See *Field, Flux,* also *Flux, Electrostatic*).

ELECTROSTATIC FLUX DENSITY—The density or number of electrostatic lines of force in a unit area of an electrostatic field. (See *Electrostatic Field,* also *Flux Density.*)

ELECTROSTATIC FORCE—The force due to interaction of electric charges. (See *Electrostatic Field,* also *Electrostatic Flux Density.*)

ELECTROSTATIC INDUCTION—The production of a charge in a body due to the presence of an opposite charge in a nearby conductor, or synonymous with displacement in the case of a condenser. Electrostatic influence or induction is the basis on which condensers operate. In the illustration *Fig.* 1 is a simple circuit containing a source of potential, which in this case is a battery. As the circuit is closed through the key a momentary flow of current takes place. This flow of current is accompanied by a condition of electric strain in the insulating material of the condenser. The electrically strained dielectric or insulating material exerts a back pressure against the pressure or force of the battery, and when this back pressure is equal to the original battery pressure the flow ceases. The strain in this dielectric is known as *electric displacement* and this displacement can be transmitted or passed on to neighboring parts of the medium and thence into space. Under the proper conditions this displacement and the magnetic field which accompanies it may be detached from the circuit and move independently in space. This is the fundamental process in the radiation of *electromagnetic waves* (q.v.). Now, in *Fig.* 2, A and B represent two conductors, both insulated. If conduc-

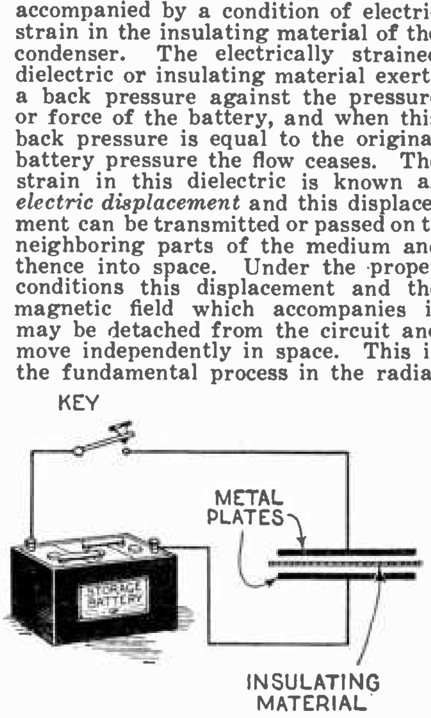


Fig. 1. A simple circuit for illustrating electrostatic induction.

tor A has a positive charge and is brought close to conductor B, although not in actual contact with it, the result is a displacement of electric charge which results in the near side of conductor B becoming negative, while the opposite side assumes the same sign (positive) as conductor A. Actually B has received no charge, but has been placed in a state of strain due to electrostatic induction between it and the conductor A. Due to the negative charge induced on B, the positive potential difference of A has been decreased and in order to maintain the constant potential it must be given a further supply of electricity. In this manner it is actually possible to store the electricity by electrostatic induction between two conductors or plates, by reason of the strain in the insulating medium—air in the case of the two conductors—which in turn passes the displacement on to conductor B. (See *Conductor, Capacity, Electrostatic,* also *Induction.*)

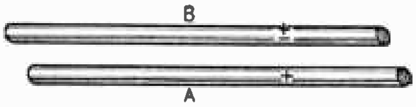

Fig. 2. Illustration of displacement of electric charge due to proximity of charged conductors.

ELECTROSTATIC LEAKAGE—The gradual loss through leakage, of the electrostatic charge in a body, due to the fact that perfect insulation is impossible to obtain. (See *Electrostatic Induction.*)

ELECTROSTATIC LINES OF FORCE—The lines of force traversing an electrostatic field. That is to say the *electrostatic flux* (q.v.).

ELECTROSTATIC STRAIN—The strain or state of stress in which a body is placed when in an electrostatic field. In a condenser, the strain experienced by the *dielectric* (q.v.) when the condenser is in a state of charge. (See *Condenser,* also *Capacity, Electrostatic*).

ELECTROSTATIC SYSTEM—The electrostatic system of C.G.S. units. One of the absolute unit systems in electrical practice. (See *C.G.S.*, also *Electrostatic Units* and *Electromagnetic Units.*)

ELECTROSTATIC UNITS—A system of measurement used in electrical engineering based on the unit of electric quantity under the *C.G.S. system* (q.v.). This unit quantity of electricity is the quantity of electricity which, placed on a small sphere will repel an equal quantity of electricity of the same sign (both negative or both positive) on a similar sphere with a force of one *dyne.* (q.v.) when the centers of the respective spheres are one centimeter apart. With this definition it is assumed that the spheres are in a vacuum, otherwise the distance between centers would vary according to the dielectric or insulating medium. (See *C.G.S., Electromagnetic Units,* also *Conversion Factors.*)

ELECTROSTATIC VOLTMETER — A meter for measuring voltage, depending for its action on the electrostatic action between a fixed and a moving plate connected respectively to the two poles or terminals between which the source of potential is connected. (See *Electrostatic Force,* also *Voltmeter.*)

ELECTROSTATIC WATTMETER — A type of wattmeter depending on the electrostatic action between two sets of fixed and moving plates. (See *Electrostatic Force,* also *Wattmeter.*)

ELECTRO-THERMAL METER — The term sometimes applied to a *hot-wire ammeter* (q.v.) or voltmeter operating on the principle that the heat generated by the passage of an electric current through a constant resistance will be equal to the square of the current. (See *Thermal Ammeter.*)

ELEMENT—A term primarily applied in chemistry to the substances which are not subject to decomposition by electric analysis (see *Electrolysis*). These elements are hydrogen, helium, etc. The term is also used quite generally to denote components such as the electrodes in a primary cell or the plate, grid and filament members of a vacuum tube. (See *Cell,* also *Vacuum Tube.*)

EMANATE—"To flow forth or proceed, as from a source."—Webster. Thus, emanating, issuing from, as the emanation of electrons from a hot filament in a vacuum tube. The throwing off of electrons. (See *Electron Emission.*)

E.M.F. — The abbreviation for electromotive force. The practical unit of E.M.F. is the volt. (See *Electromotive Force,* also *Volt.*)

EMISSION—The act of sending forth. Used chiefly to designate the emission of electrons from the filament of a vacuum tube as used in radio. The flow of these electrons between filament and plate is controlled by the grid. (See *Electron Emission,* also *Vacuum Tube, Theory of Operation.*)

EMISSION CURRENT—In a vacuum tube for transmitting it is the product of the tube current multiplied by the plate voltage and is generally given in watts. Generally speaking, the power for which the tube is designed. (See *Transmitting Tube, Power Rating,* also *Vacuum Tubes.*)

EMISSIVITY OF FILAMENT — The ability of a filament to emit electrons when heated by an electric current. (See *Electron,* also *Vacuum Tube.*)

EMPIRE CLOTH OR PAPER—A closely woven cambric coated with two or more films of an oxidized oil, or a tough paper treated with some oxidized oil. Empire products serve as insulating materials for transformers, condensers and various other devices requiring thin insulating sheets. In a transformer for relatively high voltages, insulated paper is used between the layers of windings and in certain types of fixed condensers it is used as a dielectric material. The cloth has a higher breakdown strength; that is, it will stand higher voltages than paper. (See *Breakdown Potential,* also *Dielectric.*)

ENAMELED WIRE — Wire, generally copper, covered with a coating of enamel as an insulating covering and to protect it from moisture and corrosion. (See *Magnet Wire.*)

ENDODYNE—A term occasionally used to describe reception of radio signals by means of locally generated oscillations such as in the case of the *heterodyne* (q.v.), but wherein these oscillations are created by a circuit or system that is part of the receiving circuit and not a separate arrangement. (See *Self Heterodyne.*)

ENERGY—The capacity for doing work in an electrical sense. Energy is something furnished to a body by means of work done on it. Thus, if a ball is thrown, the operation of throwing is the work, and the ball itself in traveling performs work, the means of doing this work being the energy.

There are two kinds of energy, *potential,* as in the case of electricity, and *kinetic,* the energy of a body due to motion. Kinetic energy belongs properly in the realms of mechanics and so will be passed over here with only this brief mention.

When we speak of a difference of potential in a primary cell, it means in effect that the body or cell has potential energy. That is to say, the energy is present although not active. If, now, a wire is connected across the two terminals of the cell, the difference of potential will cause electric current to flow from one pole to the other. Actually, in a cell of this type, we have chemical energy stored up. When a circuit is completed, the stored chemical energy is converted into electrical energy or creates the difference of potential, which in turn causes current to flow and electrical *work* is thus done. (See *Potential,* also *Voltage* and *Generator.*)

EPSTEIN HYSTERESIS TESTER — A device for measuring *hysteresis* and *Eddy current loss* in a sample of sheet iron by using an alternating current wattmeter. The device is used for determining the properties of samples of iron, particularly those to be used for transformers. (See *Eddy Currents,* also *Transformer, Hysteresis* and *Wattmeter.*)

EQUIVALENT RESISTANCE — The value which a resistance would be required to have in order to permit the same quantity of current to flow with the same applied electromotive force (voltage) as in the case of a piece of apparatus wherein there are other factors besides pure resistance to determine the amount of current. (See *Impedance,* also *Reactance.*)

ERG—The fundamental unit of mechanical work under the *C.G.S. system* (q.v.). This is defined as the work done by a force of one *dyne* (q.v.) when the body producing the force and the body on which the force acts are one centimeter apart. (See *Joule,* also *Practical Units.*)

E.S.U. — Abbreviation sometimes used for *electrostatic units* (q.v.). (See *Electromagnetic Units.*)

ETHER—or **AETHER**—The term used to denote the supposed or hypothetical medium by means of which electromagnetic and light waves are propagated. (See *Ether Waves.*)

ETHER WAVES—Term sometimes applied to electromagnetic or radio waves on account of the assumption that they travel through the supposed medium ether. The assumption of an all-pervading medium such as ether has been the basis of the major part of the extensive research work carried on with light and electromagnetic waves for many years. Various experiments have shown beyond reasonable doubt that there is some such medium, capable of conducting or rather permitting passage of light waves and radio waves. So accurate has this work been that it has been proven beyond question that light waves travel through the ether with the tremendous velocity of 186,000 miles per second (approximately). It has also been determined that radio waves travel at this same speed through the ether. It has further been proven that radio waves all travel at the same identical velocity, regardless of their length, form and other factors. (See *Electromagnetic Waves,* also *Theory of Propagation of Electromagnetic Waves.*)

EXCITER—A small direct current dynamo used for the purpose of exciting the field magnets of an alternating current generator. Such a device is generally a part of the main machine and mounted on the main shaft, but it may also be a separate unit. The purpose is to furnish current to the field magnets (electromagnets) to create a magnetic flux. (See *Alternator*, also *Generator.*)

EXPLORING COIL—A coil of insulated wire wound on a rotating form as an integral part of a direction finder or *goniometer*. (See *Direction Finder*, also *Goniometer.*)

F

F—The abbreviation for *dielectric field intensity* (see *Field*, also *Dielectric*), also used as the symbol for the unit of *magneto-motive force*, the *gilbert* (q.v.). The small or lower case f is sometimes used to denote the *farad*, the practical unit of *electrostatic capacity* (q.v.) and also as a symbol for *frequency* (q.v.).

FADING—The tendency of radio signals to decrease in volume or amplitude, or to fade. The strength of a signal is seldom the same at different hours of the day or night, generally being stronger during the dark hours of the night. This has been attributed to a variety of causes, the most plausible being that the air is more free of disturbances during the night and thus permits more ready passage of the waves through the ether. The difference between the strength of signals in the daytime and at night is sometimes very pronounced, but the phenomenon of fading is usually noticed only when distant signals are being received. It has been fairly definitely established that fading of signals is due to the reflection of the transmitted waves. (See *Wave Distortion*, also *Reflection and Refraction.*)

FALL OF POTENTIAL—See *Potential Drop.*

FAN AERIAL—An aerial, usually for transmission, constructed in the shape of a fan. (See *Aerial.*)

FAN CONNECTOR—A small triangular or fan-shaped piece of metal arranged with several holes along one edge, with set screws for fastening in each the several wires of the lead-in of a multiwire aerial. The lower apex is fitted with some sort of connecting device to permit a single wire to be led in to the receiver. (See *Lead-In.*)

Illustration by Courtesy of Radio Specialty Co., Inc.

Fan Connector—The leads from each wire of a multi-wire aerial go to the wide portion and are held by the set screws: the lead to the set goes to the small end.

FARAD — The unit of *electrostatic capacity*. It is the practical unit of capacity and is defined as the capacity of a condenser that is capable of being charged to a potential difference of one volt by a charge of one ampere for one second; i.e., one *coulomb* (q.v.). "Farad" is a contraction of the name of the distinguished English scientist *Michael Faraday* (q.v.). Inasmuch as the farad is too large a unit for practical purposes, the *micro-farad*, or one millionth of a farad, is commonly used. (See *Electrostatic Capacity*, also *Condenser.*)

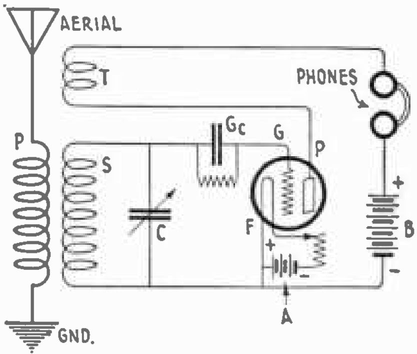
FARADAY, MICHAEL. Born 1791, died 1867. An English scientist famous for his discoveries in chemistry, electricity and magnetism. He first produced the rotation of the magnetic needle around the electric current in 1821, based upon Oersted's discovery of electromagnetism in 1820; he discovered electromagnetic induction (1831), a principle upon which is founded the development of dynamo machinery; specific inductive capacity (1838); magnetic polarization of light (1845); diamagnetism (1846). He was a brilliant experimenter, and contributed greatly to the knowledge upon which is based present-day practice of electricity.

Michael Faraday.

FEEBLY DAMPED—In spark transmission, signals that are only slightly damped. Where each succeeding oscillation in a train of oscillations is of slightly lesser *amplitude* (q.v.) than the one preceding it, the signals are said to be slightly damped to distinguish them from signals that are highly damped and thus die out quickly. (See *Damping*, also *Damped Waves.*)

FEED—In electrical parlance, to furnish with a current of electricity. (See *Feed-Back.*)

FEED-BACK—A term applied in radio to the coupling of one circuit to another, whereby a portion of the current present in one circuit is fed back or returned to the other circuit. The common use of the term is in reference to regeneration, where a certain portion of the radio frequency current present in the plate circuit of a detector is returned to the grid circuit of the tube by some form of coupling between the two circuits. It may also apply to the tendency of high-frequency currents to become transferred from one circuit to another due to undesired coupling between two or more circuits. The illustration shows a simple feed-back or regenerative circuit. The incoming signal energy is transferred from the primary of the coupler to the secondary by means of inductive coupling and tuned by the condenser C. A grid condenser and leak GC are placed in the grid circuit in the customary manner. A feed-back or reaction coil T is placed in the plate circuit and inductively coupled to the main coil. A portion of the radio frequency current in the plate circuit or output circuit is transferred back to the grid circuit by the coupling effect between the coil T and the secondary of the coupler. This serves in effect to reduce the resistance of the grid circuit and produces more current in the output or plate circuit, thus acting as a form of amplifier. (See *Regeneration, Tickler.*)



Regenerative circuit in which the coil "T" returns, or "feeds back" to the grid circuit a portion of the radio frequency current in the plate circuit, resulting in increased amplification.

FEED-BACK COIL—An inductance coil placed in the plate circuit of a regenerative receiver and arranged in inductive relation to the grid coil (secondary of tuner) for the purpose of effecting feed-back or regeneration. (See *Feed-Back*, also *Regeneration.*)

FEED-BACK COUPLING—Any process by which the plate circuit of a detector is coupled to the grid circuit to allow a portion of the output current to be transferred back to the grid circuit to produce regeneration. (See *Feed-Back*, also *Regeneration.*)

FEED-BACK EFFECT — The effect of feeding back of currents from one circuit to another as in the case of a *regenerative circuit* (q.v.). Generally the expression "feed-back effect" refers to an undesired feed-back. This may be the action of radio frequency components of the currents present in one part of a circuit being fed back to another part of the circuit due to the coupling effect of various coils or other devices used in the circuit. (See *Feed-Back*, also *Regeneration.*)

FEED-VOLTAGE MODULATION — A process of modulating or varying the amplitude of a radio frequency alternating current to correspond to any wave form of speech vibrations as in radio broadcasting. The system involves the introduction of additional power into the circuit of the radio frequency generator until the desired wave form variations are obtained. This is done particularly in the case of a vacuum tube transmitter, in which case the voltage supplied to the plate of the tube is altered (increased or decreased) to accomplish the purpose. (See *Modulation.*)

FERRO-MAGNETIC MODULATOR—A device for modulating or varying the amplitude of radio frequency current to correspond in wave form to the speech or music vibrations in broadcasting. The system makes use of what is known as the *hysteretic energy absorption* of iron, or in some cases utilizes the variation of inductance of iron-core coils. (See *Modulation*, also *Ferro-magnetic Substances.*)

FERRO-MAGNETIC SUBSTANCES — Elements or compounds such as iron, nickel, cobalt and others which are strongly attracted by magnetic fields of force. Such substances vary widely in their magnetic properties when subjected to temperature changes. Soft iron loses its magnetization almost immediately on removal of the magnetizing source, and for this reason it is used as a pole piece in an electromagnet. (See *Electromagnet*, also *Magnetism* and *Magnetic Properties.*)

FESSENDEN, REGINALD AUBREY. —Canadian-American Radio expert. Born at Milton, Canada, October 6, 1866, and educated at New York and Port Hope, Ontario. Fessenden became inspecting engineer for the Edison Company, New York, and afterwards professor of physics and electrical engineering at Western University, 1892. Professor Fessenden is the author of a well-known system of wireless, and below are briefly described some of the patents bearing his name.

In 1906 and 1907 Fessenden invented a number of microphone transmitters which carried heavy currents for long periods, and also a heavy current telephone relay which allowed the controlling of heavy currents by means of small currents originating in an ordinary microphone circuit or coming from a telephone line. One of these transmitters was called by Fessenden a trough transmitter. It consisted of a soapstone annulus to which were clamped two plates having platinum-iridium electrodes. Through a hole in the center of one plate passed a rod attached at one end to a diaphragm, and at the other to a platinum-iridium spade. The two outside electrodes were water-jacketed. This form of transmitter required no adjusting, all that was necessary being to place about a teaspoonful of carbon granules in the center space. It was able to carry as much as 15 amperes continuously without articulation falling off, and had the advantage that it never packed. By a combination of the trough transmitter and a differential magnetic relay, Fessenden produced a transmitting relay for magnifying very feeble currents. An amplification of fifteen times is possible without any loss of distinctness. Fessenden is also responsible for a duplex system of Radio telephony, and the *heterodyne* method of reception is due to him. Fessenden has written largely on radio subjects, and is one of the leading authorities on both transmission and reception.

Reginald Aubrey Fessenden.

FIBER—or **FIBRE**—A term used for a variety of substances, composed of fine slender thread-like materials, particularly a composition of vulcanized or compressed paper. It is much used in radio as an insulating material for panels and connection blocks. It is not as efficient as insulating medium as bakelite or some forms of rubber composition, but is durable, cheap and comparatively easy to drill. (See *Bakelite.*)

FIELD—The space occupied by electric or magnetic lines of force. (See *Electric Field.*)

FIELD DENSITY—The strength of an electric or magnetic field. It is measured by the number of electric or magnetic lines of force contained in a given cross-sectional area. (See *Density. Flux*, also *Electric Field* and *Field, Magnetic.*)

FIELD, ELECTRIC — The space traversed or occupied by electric lines of force. (See *Electric Field.*)

FIELD, ELECTROMAGNETIC — The total area traversed by electromagnetic lines of force. The region in which electromagnetic lines of force are exerted. (See *Field*, also *Electrostatic Force.*)

FIELD, ELECTROSTATIC—The region in which electrostatic forces are present or exerted. The total area traversed by electrostatic lines of force. (See *Field*, also *Electrostatic Flux.*)

FIELD MAGNET — An *electromagnet*, usually a core of soft iron surrounded by a winding of insulated wire, employed in generating machines to produce a strong magnetic field. As the *armature* of a *generator* revolves the conducting surfaces pass through the *magnetic field* created by the *field magnets.* This field may be merely the ordinary magnetic force due to permanent magnets, but is usually due to the powerful magnetic lines of force resulting from passage of electric current through electromagnets. (See *Alternator*, also *Alternating Current, Theory of Production* and *Electromagnet.*)

FIELD, MAGNETIC—The region through which magnetic flux passes. Usually refers to the space (air) through which the magnetic flux lines pass as distinguished from the activity in the iron path tself. (See *Field*, also *Magnetic Flux.*)

FIELD REGULATOR or **RHEOSTAT**—Any device for varying the magnetic strength of the field magnets in a dynamo or electric motor, by which variations certain changes may be accomplished in the operation or performance of the machine. A field rheostat is often used in an electric motor to vary the strength of the field and thus either increase or decrease the speed of the machine without the necessity of changing the applied voltage. If the strength of the field (magnetic) is reduced by insertion of resistance, the armature or rotating part speeds up in an attempt to generate the same *counter-electromotive force* (q.v.), which means greater speed. On the other hand, if the resistance is removed—that is, the strength of the field increased—the fact that the armature is running through a stronger field reduces the speed of rotation, the same counter-electromotive force being present. The use of a field regulator or rheostat in connection with a generator is for the purpose of varying the output voltage without the necessity of altering the speed of the machine. The illustration shows the connection of a field rheostat or regulator in the circuit of the *shunt wound generator* (q.v.). (See *Generator, Rheostat, Resistance.*)

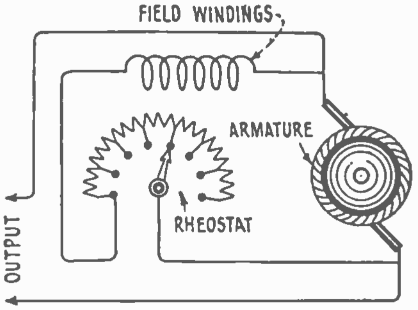


Illustration showing method of connecting a field rheostat or regulator in the circuit of a shunt wound generator.

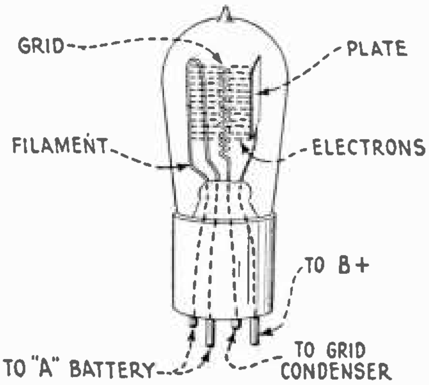
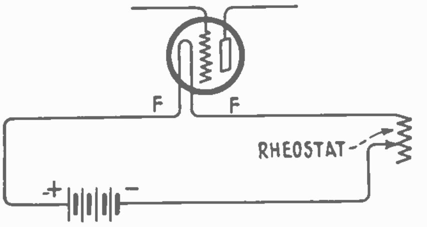
FILAMENT — A fine wire, one of the elements of a vacuum tube, which is heated to throw off electrons. The term is also used to refer to the fine wire used in an incandescent lamp. The filament of a vacuum tube is generally made of tungsten and is supported by glass pillars within the tube in such manner as to be insulated from the other elements. Filaments are made to be heated with various voltages from 1.1 to 6 volts in most receiving tubes, but much higher in the case of high power transmitting tubes. The filament may consume considerable current as in the old styles of six-volt tubes which consumed one ampere. The modern tubes have thoriated filaments, tungsten treated with thorium, which permits maximum efficiency with a minimum of current consumption. When the filament is heated in the vacuum tube, by having the proper amount of voltage applied, electrons are thrown off and fill the space between filament and grid and grid and plate as shown in the illustration. (See *Electron Theory*, also *Vacuum Tube, Theory of Operation.*)



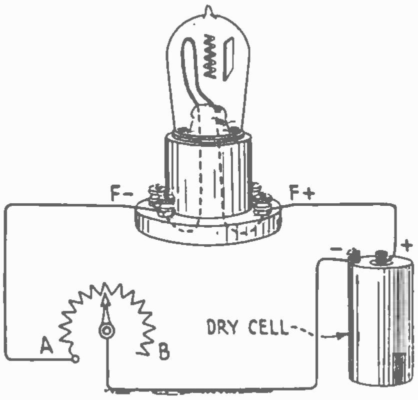
When an "A" battery is connected to the filament terminals, heating the filament, electrons are thrown off and fill the space between filament, grid and plate.

FILAMENT BATTERY—The battery or cell used in lighting the filament of a vacuum tube. These range from a *dry battery* (q.v.) having a voltage of one and a half volts, to storage batteries of six volts. Filament batteries are connected across the filament of a vacuum tube in the manner shown in the illustration. The rheostat is inserted to permit the supply of current to the filament to be varied and thus change the operation of the tube. (See *Filament*, also *Vacuum Tube, Theory of Operation.*)



Method of connecting "A" battery in series with rheostat to regulate filament of vacuum tube.

FILAMENT CONSUMPTION — The amount of current consumed by the filament of a vacuum tube. The current requirements of vacuum tubes are always stated by the manufacturer, either in amperes or fractional amperes, or in the case of extremely low consumption, in thousandths of an ampere (milliamperes). Some typical examples are the UV201A and C201A types, which require one-quarter ampere at five volts; the WD11 and 12 and C11 and 12 types, which require one-quarter ampere at approximately 1.1 volts, and the UV200 and C200 tubes, which require one ampere at six volts. Of the so-called standard types, the UV199 and C199 tubes consume the least current, requiring but sixty milliamperes or .06 ampere, with from three to four and a half volts. The statement that a certain tube consumes one-quarter ampere indicates that in operation one-quarter ampere is consumed each hour, this current being supplied by dry cells or storage batteries known as the *"A" battery* (q.v.).



The current produced by the dry cell battery, flowing through the rheostat and filament, is consumed by the filament, at a rate depending upon the type of tube.

It will be apparent from the above that the more current consumed by the filament the greater will be the drain on the dry cells or storage battery. For this reason, and also to lengthen the life of the filaments, it is well to operate the tubes at the lowest efficient brilliancy. The brilliancy of the filament may be controlled by adjustment of the filament rheostat. In the illustration the usual "A" battery, which in this case is a dry cell, is shown connected to the filament of a vacuum tube with a rheostat in series between one filament connection and the negative terminal of the dry cell. Now as the arm of the rheostat is moved from A toward B resistance is introduced into the circuit between the filament and dry cell. As this resistance increases the current in the circuit of the filament will decrease according to *Ohm's Law* (q.v.); i.e., Current = Voltage ÷ Resistance, the current in amperes or fractional amperes and the resistance in ohms. (See *Ampere, Current, Filament Resistance or Rheostat* and *Vacuum Tube.*)

FILAMENT CURRENT — The current used to light the filament of a vacuum tube. Different tubes require different amounts of current; that is, one tube may consume a small fraction of an ampere and another may require a full ampere. Of the tubes most commonly used, the UV199 type uses the least current, this tube requiring only .06 of an ampere each hour. The WD11 and 12 types require one-quarter ampere per hour and also the UV201A, while the now obsolete UV200 and UV201 required a full ampere. The 199 type operates with filament voltage of 3 volts, although it is often used with three dry cells in series which deliver 4½ volts; the WD11 and 12 require 1.1 volts each, which is usually furnished by a dry cell, while the UV201A type is operated with a six-volt storage battery. (See *Vacuum Tubes, Types of*, also *Vacuum Tube, Theory of Operation.*)

FILAMENT, FORMULA FOR ELECTRON FLOW—The extent of electron emission—that is, the number of electrons—emitted from a hot filament in a vacuum tube is subject to certain definite laws. In ordinary practice the actual number of electrons are not referred to, the ability of the filament to emit electrons being measured in fractional amperes of output current. Thus a tungsten filament having a diameter of .0125 centimeters operating with a power dissipation of 3.1 watts per centimeter of length has been found to emit a current of .03 amperes. This result was obtained with a filament having a clean surface and with no absorbed gas on its surface. The formula for electron flow most commonly used is as follows:

$$I_B = AT^{1/2}\,\epsilon - \frac{b}{\tau}$$

I_B is the electron current in milliamperes per square centimeter of filament surface, T is the absolute temperature and A and b depend on the metal used for the filament.

FILAMENT RESISTANCE or RHEOSTAT—A device placed in the filament circuit of a vacuum tube, connected between the filament battery and either filament lead on the tube socket for the purpose of reducing or controlling the filament voltage. The illustration Fig. 1 shows one type of filament rheostat which is used to permit variation of the filament current. Fig. 2 shows the manner of connecting such resistance in the filament circuit of a vacuum tube. Fig. 3 illustrates a type of filament control known as an automatic rheostat. In this form of filament resistance a fine wire is placed in a glass tube filled with an inert gas. The wire has the property of increasing its resistance rapidly with any increase in the current passing through it. It is thus possible to arrange such a device to pass only a fixed amount of current for any type of vacuum tube. The device is thus not only an automatic rheostat, but also a safety valve which prevents excessive current reaching the filament and injuring it. These controls are coming into widespread use due to these features and the fact that they reduce the number of controls necessary to operate a receiver. Fig. 4 shows a resistance which is used in series with a rheostat having small resistance in order to enable its use with tubes requiring less current to operate. (See *Filament*, also *Vacuum Tube.*)

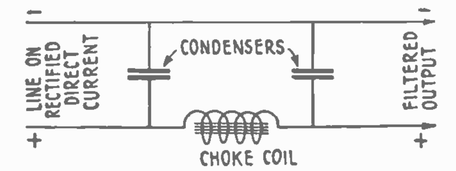
Fig. 4. Resistance used in series with a rheostat having a small resistance in order to enable its use with tubes requiring less current.

FILAMENT, THORIATED—A filament or heating element of a vacuum tube in which a certain amount of *thorium* (q.v.) has been incorporated. The introduction of this rare metal into the filament in small quantities gives it the property of emitting electrons at a relatively low temperature. From a practical standpoint this permits a vacuum tube to be operated with a low *filament consumption* (q.v.). A common example of the use of thorium in filaments is that of the UV201A or C201A vacuum tubes, which operate with a filament voltage of 5 volts and consume but one-quarter ampere of current, giving essentially the same results as the former type UV201 and C201 tubes which consumed one ampere. The value of thorium used in this manner is readily appreciated, the current consumption being materially lessened and the life of the tube conceivably lengthened. (See *Thorium Treatment of Filaments*, also *Vacuum Tubes, Type UV201A and C201A.*)

FILTER—In radio, a device arranged to permit passage through an electrical circuit of currents of certain frequency or *frequencies* (q.v.) while excluding others of different frequencies, or any device for producing smooth direct current from a generating source such as a *direct curent dynamo*, or for smoothing out *rectified direct current.* Filters of one sort or another are much used where rectified direct curent or direct current from a generator is to be used for operation of tubes in radio transmission or reception. In the case of rectified direct current, that is the current derived from any device for changing alternating to direct current, there is always present a tendency on the part of the current to surge or ripple. In other words, it is not smooth and of constant voltage, or there may be present a generator hum which will seriously interfere with proper operation of a tube. The illustration shows the conventional method of filtering rectified direct current for use as plate supply with vacuum tubes in receiving sets. This system may also be used in connection with the output of a direct current generator or dynamo. A filter circuit may be arranged to pass a band of frequencies (see *Band Pass Filter*) or it may be made to pass either high or low frequency current. (*See Filter, High Pass;* also *Filter, Low Pass.*)



Conventional method of filtering rectified direct current for use as plate supply of a vacuum tube.

FILTER, BAND PASS—See *Band Pass Filter.*

FILTER CONDENSER—The condenser, either fixed or variable, forming a part of a circuit for filtering. (See *Filter*, also *Acceptor, Wave Trap* and *Rejector.*)

FILTER, HIGH PASS—A filter circuit arranged to permit current above a certain frequency to pass freely while blocking out or attenuating all frequencies below it. (See *Filter*, also *Filter, Low Pass.*)

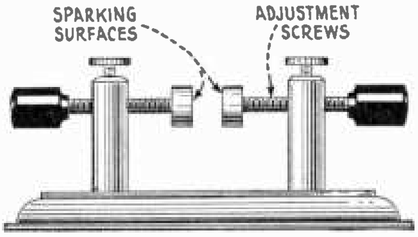
FILTER, LOW PASS—A filter circuit arranged to permit currents below a certain frequency to pass freely while blocking currents of higher frequency. (See *Band of Frequencies*, also *Filter, High Pass.*)

FIXED COILS—Inductance coils as used in radio circuits, having no mechanical means of variation, such as in a *Vario-coupler or movable coil.* (q.v.) The majority of tuned radio frequency receivers employ fixed coils, shunted by variable condensers. These are known as *tuned radio frequency transformers.* (q.v.) (See *Coupler, Loose*, also *Coupler, Vario.*)

FIXED CONDENSER — A condenser having a certain definite or fixed value of capacity. Any condenser that is not variable. (See *Condenser*, also *Condenser, Variable.*)

FIXED RESISTANCE—Any resistance device having a fixed or non-variable value. (See *Rheostat*, also *Potentiometer.*)

FIXED DISCHARGER—A fixed *spark gap.* (q.v.) A spark gap used in transmission of radiotelegraphic signals in which the electrodes or sparking surfaces are not moved during operation. (See *Disc Discharger.*)



A type of fixed spark gap.

FLAME MICROPHONE—A type of microphone for radio telephone transmission, wherein the height of a coal gas flame is varied by and according to the speech fluctuations and the resulting pulsations made audible by means of a selenium cell and phones. (See *Microphone*, also *Selenium Cell.*)

FLASH SIGNALLING— See *Code*, also *Morse Light.*

FLAT-TOP AERIAL or ANTENNA—An aerial, generally composed of a number of wires placed adjacent to each other equally spaced on a spreader, or hoop, and suspended parallel with the earth. A flat-top aerial may be of the kind known as the *T type aerial* (q.v.) or in the form of an inverted L. (See *Aerial.*)

FLAT TUNING—A term sometimes applied where the *resonance curve* (q.v.) has a flat top, that is where the peak of resonance is not sharply defined. The effect is known as *broad tuning.* (q.v.) (See *Resonance*, also *Tuning.*)

FLEMING, JOHN AMBROSE. British radio expert. Born in Lancaster, November 29, 1849, he was educated at University College, London, the Royal School of Mines, and St. John's College, Cambridge.

From 1873-74 Fleming was demonstrator at the Royal College of Chemistry, and in 1877 he began work under Clerk-Maxwell at the Cavendish Laboratory, Cambridge. There he carried out a series of experimental researches on the British Association Standards of Electrical Resistance. In 1881 Dr. Fleming was appointed the first professor of mathematics and physics at University College, Nottingham, but the following year he joined the Edison Electric Light Company, and on the amalgamation of the Edison and Swan Companies, he was appointed advising electrician, a post he held for twenty years. In 1885 Fleming was appointed to the newly founded professorship of electrical engineering at University College, London, and he was entirely responsible for the design and equipment of the new electrical and engineering laboratories which were opened in 1893. In 1892 he was elected Fellow of the Royal Society.

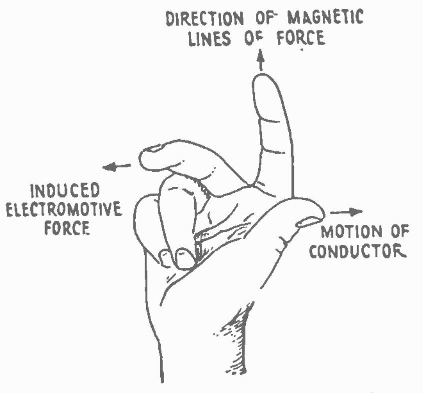
Dr. Fleming has been very closely associated for many years with radio telegraphy and telephony, and has since 1899 acted as the scientific advisor to Marconi's Wireless Telegraph Company. He is well known as the inventor of the thermionic two electrode vacuum tube, or glow-lamp detector, which was one of the greatest steps forward in radio telephony.

Dr. Fleming has written a very large number of papers and books on wireless telegraphy and telephony, and his "Principles of Electric Wave Telegraphy" is the standard treatise on the subject. He has also published an "Elementary Manual of Radio Telegraphy and Radiotelephony"; "The Wonders of Wireless Telegraphy"; "The Thermionic Valve and Its Development"; "A Pocket Book for Wireless Telegraphists," and other books. As a lecturer at the Royal Society of Arts he has obtained a world-wide reputation for his lectures on electric oscillations and electric waves, Hertzian wave telegraphy, high-frequency measurements, etc. He has given many lectures on wireless at the Royal Institution.

John Ambrose Fleming.

Fleming was awarded the Hughes gold medal of the Royal Society in 1910 as an acknowledgement of the value of his work in electrical science and engineering, and he has twice been awarded the Institution Premium of the Institution of Electrical Engineers, the highest award for communicated papers, and he is an Albert Gold Medalist of the Royal Society of Arts awarded to him for the pioneer invention of the thermionic valve.

FLEMING'S RULE—A rule for determining the direction of the *induced current* (q.v.) in a circuit. Hold the right



DIRECTION OF MAGNETIC LINES OF FORCE
INDUCED ELECTROMOTIVE FORCE
MOTION OF CONDUCTOR

Method of using the right hand in determining the direction of the induced current.

hand as shown in the illustration with the thumb, forefinger and middle finger as nearly as possible at right angles to each other. If the thumb is then pointing in the direction of motion of the conductor and the forefinger points along the direction of the magnetic lines of force, the middle finger will then point in the direction of the induced electromotive force. (See *Induced Current*, also *Electromotive Force*.)

FLEMING VALVE—The forerunner of the modern vacuum tube. It was invented in 1904 by Professor J. A. Fleming and was for a short time used as a detector in place of the customary crystal or coherer types. The value of the discovery of the Fleming valve lies chiefly in its influence on the course of radio development, as in itself it was not nearly as efficient as a good crystal detector. As a result of the discovery of the Fleming valve, however, many leading scientists bent their efforts toward the discovery of better methods of detecting radio waves, culminating in the three element vacuum tube designed by Dr. Lee De Forest.

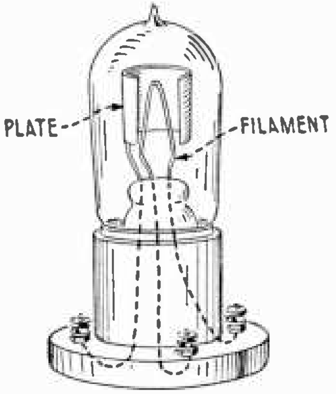


Fig. 1. The Fleming valve, which contained but two elements; i. e., filament and plate. It was the forerunner of the modern vacuum tube.

The Fleming valve consists essentially of an incandescent lamp using a filament of carbon, tungsten or tantalum which can be rendered incandescent by an electric current. The filament is sealed in a glass tube which is highly evacuated, that is from which practically all air has been excluded. Surrounding the filament, but separated from it is a metal cylinder, both ends of the filament and the plate being attached to outside connections by means of leads sealed in the tube. The illustration, Fig. 1, shows the general arrangement of such a tube. The operation of the tube is due to the emission of electrons from the heated filament. It was demonstrated by several investigators that a filament made of certain metals has the property of throwing off minute particles of negative electricity or electrons when heated to a relatively high temperature. It was also found (see *Electron*) that these electrons are thrown off in greater profusion when the filament is placed in high vacuum. It was also found that the escape of negative electrons from the filament would in time leave it positively charged, this charge having an attraction for the negative electrons and preventing their escape from the filament. Hence it was necessary to apply a charge of negative electricity to the filament. The electrons were now found to escape in great number, but had the effect of forming a *space charge* (q.v.) of negative electricity around the filament, which in time served to repel the escape of any more electrons. To counteract this tendency a strong positive charge was applied to the metal plate surrounding the filament. This made the plate positive in respect to the electrons and served to attract them away from the filament. The stream of electrons thus affords a path for current to flow from filament to plate, and the action of the tube as a detector of high frequency waves depends on this principle. If the tube is connected as indicated in the illustration, Fig. 2, it will serve to rectify the incoming signals, that is change them from high frequency alternating currents, to pulsating direct current. The action is as follows: The aerial is connected to the secondary circuit by means of a standard coupler. The coils, marked L2, are the primary and secondary of this coupler; C1 and C2 are variable condensers, F the filament of the Fleming valve, B the battery for lighting the filament of the valve and also to supply voltage to the plate, T a pair of headphones, P a 400 ohm potentiometer and R a standard filament rheostat. The incoming signals in the form of high frequency currents, change direction many times each second. Thus, at one instant the plate will have a positive charge while the next instant it will have a negative charge as a result of the changes in direction of the currents impressed across the tube from the antenna circuit. While the plate is positive, electrons will be attracted away from the filament, which at that instant will be negative with respect to the plate. The current thus flows for an instant, stopping when the impressed current changes its direction and makes the plate negative. In this manner we have a flow of current from filament to plate in one direction in the form of surges appearing at every other alternation or change of current. The diaphragms of the phones will respond to these uni-directional surges and will give out sounds almost identical with the original signals transmitted. The tube thus serves as a rectifier of the incoming signals and is known as a detector of high frequency waves, or oscillations. The Fleming valve principle is used in rectifying tubes for changing alternating current to direct current for charging batteries, its use as a detector for radio reception having died out almost entirely. (See *Charger*, *Storage Battery*, *Detector*, *Tungar*, *Rectigon*, also *Vacuum Tube*.)

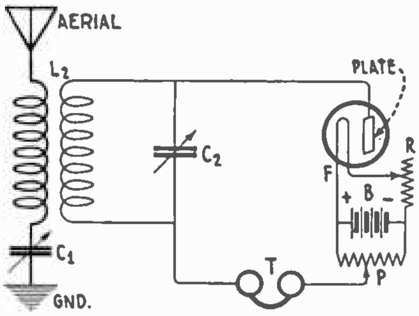

Fig. 2. Method of connecting a Fleming valve in a radio receiving circuit.

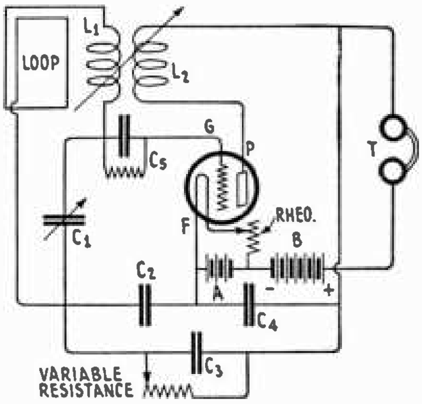
FLEWELLING CIRCUIT—A modification of the Armstrong Super-regenerative circuit, designed by the American experimenter, Flewelling. In this system, the tendency toward *self-oscillation* (q.v.) is retarded by the use of fixed condensers which are arranged to have a *damping* (q.v.) effect on the grid of the detector tube, automatically controlling the oscillations of the tube. The circuit controls the self-oscillation of the tube without the necessity for the separate control tube used in the Armstrong circuit. The illustration shows the original Flewelling circuit. It is essentially a standard regenerative circuit with certain necessary modifications.

The coils L1 and L2 give magnetic coupling between the plate circuit and the grid circuit. C1 is a variable condenser for tuning and condensers C2, C3 and C4 are of the fixed type and afford a path of relatively low *impedance* (q.v) for the high frequency currents. C5 is the customary grid blocking condenser across which a grid leak is shunted. The usual telephone receivers T, the plate battery B and the filament battery A are included in the circuit in the customary manner. The coils L1 and L2 may be two honey-comb coils having respectively 50 and 75 turns. The tuning condenser C1 should be .0005 mfd. for the broadcast band of wave-lengths and the loop may be almost any form.



The Flewelling circuit.

In operation three forms of current pass through the plate circuit including the coil L2, namely, the direct current from the plate battery B, the unidirectional surges of rectified current due to the action of the tube as a rectifier and the high frequency currents transferred through the medium of the magnetic coupling of the two coils L1 and L2. The battery current is present only in the plate circuit, the condensers C2, C3 and C4 blocking the direct current from the grid circuit. These condensers also block the rectified currents but afford two paths for the high frequency currents or oscillations. The condensers C2, C3 and C4 have definite values, respectively .005, .005 and .006 micro-farads, to allow a by-pass through the grid to the filament, thus causing accumulation of electrons on the grid and stopping oscillation of the tube. The charge then leaks off by means of the grid leak connected across C5, the tube then building up oscillations again and continuing the process during operation. The high resistance connected across C3 is variable and permits control of the by-pass of high frequency current of the grid. Careful adjustment is necessary to obtain maximum signal strength without distortion. (See *Armstrong Circuits*, *Regenerative Circuit*, also *Super-Regenerative Circuit*.)

FLEX—Term used in Great Britain and occasionally in this country to refer to a number of small wires twisted or stranded together to form a single flexible conductor. (See *Flexible Wire*.)

FLEXIBLE LEAD—Any conductor, particularly the connections from rotary parts of couplers or condensers, in which the conductor is made up of a number of fine wires in such a way that the necessary bending in operation of the unit will not snap the wire as would be the case with a solid conductor. (*See Pig-tail*, also *Flexible Wire.*)

FLEXIBLE WIRE—Any conductor composed of a number of fine wires to permit constant handling and bending without breaking. (See *Flexible Lead.*)

FLOAT, BATTERY — Term sometimes applied to the bulb or float in a hydrometer for testing the condition of storage batteries. (See *Hydrometer.*)

FLOW OF CURRENT—An expression used to denote the passage of electric current along a conductor. (See *Current, Direction of Flow* (*Assumed*), also *Current.*)

FLOW OF MAGNETIC FLUX—The passage of lines of magnetic force through any magnetic circuit. (See *Flux*, also *Field, Magnetic.*)

FLUCTUATING CURRENT—An electric current that does not have steady value, rising and falling in strength or pressure. A current that is not constant. (See *Constant Current*, also *Voltage, Constant.*)

FLUORESCENT SCREEN—A screen or surface coated with fluorescent matter, used to exhibit shadows cast by rays from various types of tubes. Its application in radio is chiefly in the *Cathode Ray Tube.* (q.v.)

FLUX—A very broad term in physics. The three more common examples of flux are: (a) to denote *electrostatic or magnetic flux* (q.v.); (b) a substance used in soldering for the purpose of making the solder flow readily and making it adhere to the parts being united, and (c) in metal smelting, a mineral—customarily chalk or limestone—added to the charge in the furnace to absorb mineral impurities and dispose of them in the form of slag. *Flux* is also used to refer to the amount of heat or light flowing or passing through a given distance or area in a given time. (See *Electrostatic Flux, Flux Density*, also *Flux, Magnetic.*)

FLUX DENSITY—The number of lines of force per square centimeter of sectional area of a magnetic path. The unit of magnetic flux in the C.G.S. (Centimeter Gram Second) or electromagnetic system of units is the Maxwell. It is generally referred to as a "line." As a magnetic flux is merely the effect of magneto-motive force, we can take the rule that the magnetomotive force is 1.257 x ampere turns as the rule for determining the intensity or density of magnetic flux. (See *Flux; Field, Magnetic*, also *Ampere Turns* and *Maxwells.*)

FLUX DISTRIBUTION—The distribution of lines of force in a magnetic or electrostatic field of force. (See *Field*, also *Flux.*)

FLUX, ELECTROSTATIC — Another term for electric displacement as in the case of a condenser. The density of electrostatic flux refers to the intensity of an *electrostatic field.* (q.v.) (See *Flux Density, Field, Electrostatic*, also *Electric Displacement.*)

FLUX LEAKAGE—Any loss or dissipation of magnetic or electrostatic flux. (See *Flux, Electrostatic*, also *Flux, Magnetic.*)

FLUX LINES—The lines of force in a field of force in which electrostatic or electromagnetic force is exerted. An alternate term for *lines of force.* (q.v.)

FLUX, MAGNETIC—The term broadly used to denote the grouping of magnetic lines of force in a *magnetic field.* (q.v.). The most common example of magnetic flux is in the case of an ordinary bar magnet as shown in the illustration Fig. 1. Here the lines of force or magnetic flux create a magnetic field indicated by the dotted lines. The number of lines of force in a field of unit area is used as a basis for determining the density of the flux. (See *Flux Density.*) This effect or magnetic flux field is also present when a current of electricity is allowed to circulate around a coil of wire, the larger the current and the greater the number of turns, the more powerful the flux created. The illustration Fig. 2 shows a coil of wire through which current is assumed to be passing, the dotted lines indicating the flux field. (See *Choke Coil, Transformer, Magnet*, also *Flux, Electrostatic* and *Magneto-motive Force.*)

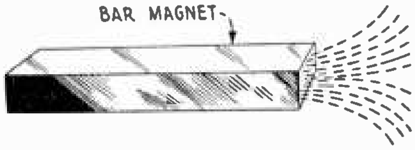


Fig. 1. Bar magnet, showing how the lines of force, or magnetic flux, create a magnetic field as indicated by dotted lines.

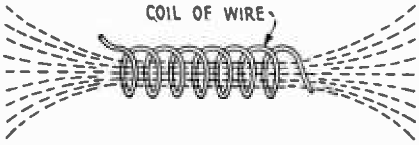

Fig. 2. Coil of wire through which current is assumed to be passing, the dotted lines indicating the flux field.

FLUX MAGNETISM — The magnetic flux, or total number of lines of force passing through a magnetic circuit. It is equal to the product of the magnetic density (see *Flux Density*) and the cross sectional area of the magnetic path. It is also referred to as magnetic flow. (See *Magnetic Flow.*)

FLUXMETER—A device for measuring flux density. The Grassot fluxmeter uses an *exploring coil* (q.v.) in conjunction with a special form of moving coil galvanometer. The coil is suspended on a silk fiber and its movements actuate a pointer across a scale. (See *Flux, Magnetic.*)

FLUX, SOLDERING—See *Soldering Flux, Flux.*

FOCUS or FOCI—The point or points at which converging lines meet. The magnetic foci are the points on the earth's surface in the vicinity of the magnetic poles, where the magnetic force of the earth is the greatest. Essentially a mathematical term.

FORCE—An influence exerted upon a body so as to produce a change or a tendency to change its state of rest or motion. This is mechanical force. In electricity we have its electrical analogy—*electromotive force.* This is the force which causes motion of electricity and sustains the electric currents against the resistance of a circuit. (See *Electromotive Force.*)

FORCE, MAGNETO-MOTIVE—The force which produces magnetic flux as in the case of a magnet moving through a magnetic circuit. The abbreviation is M. M. F. and its unit is the *gilbert.* (q.v.) (See *Magneto-motive Force.*)

FORCED OSCILLATIONS — Electrical vibrations or high frequency oscillations which are imposed upon an *oscillatory circuit* without being in tune or resonance with the natural period of vibration of the circuit. The opposite of a free oscillation in which case the circuit oscillates freely on its own account at the same frequency as the imposed or incoming oscillations or one of the *harmonics* (q.v.) of this frequency. Free and forced oscillations may be present in the same oscillatory circuit, the forced oscillations being set up during the first stages of induction of free oscillations. (See *Free Oscillations*, also *Oscillatory Circuit.*)

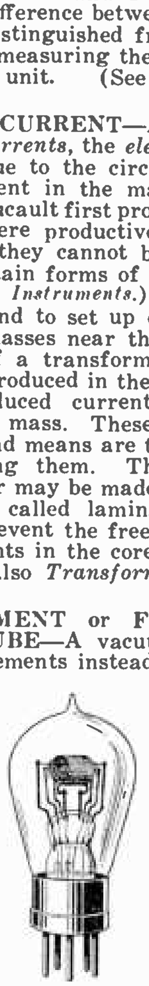
FORM FACTOR—The ratio of the *root-mean-square value* (q.v.) to the algebraic mean ordinate taken over one alternation (half cycle), starting with zero value of current. It is the ratio of the r.m.s. value of an alternating electromotive force, current, etc., to its true mean value. (See *Wave Analysis.*)

FORMULA—A principle or rule expressed in mathematical terms or chemical symbols. Formulae are much used in radio to state a problem as, for example, a formula for calculation of wave-length, which is written: Wave-length=$1884\sqrt{LC}$. This states the problem or rule for the determination of wave-length. Here we have certain values represented by symbols. The capacity is represented by C, the inductance by L, the wave-length in meters being the product of the square root of the product of these two multiplied by the factor 1884. (See *Measurement of Wave-length.*)

FOSTER BRIDGE—A form of *Wheatstone Bridge* (q.v) of the slide wire variety designed to permit comparison of two low value resistances that are nearly equal. It was devised by Professor Carey Foster and is used to determine the difference between two resistances as distinguished from the usual bridge for measuring the resistance of a single unit. (See *Wheatstone Bridge.*)

FOUCAULT CURRENT—Another name for *eddy currents*, the *electro-magnetic currents* due to the circulation of induced current in the mass of a conductor. Foucault first proved that these currents were productive of losses of energy as they cannot be utilized except in certain forms of meters. (See *Damping of Instruments.*) Alternating currents tend to set up eddy currents in metal masses near them. Thus in the case of a transformer, eddy currents are produced in the iron core due to the induced currents circulating through its mass. These currents are wasteful and means are therefore used for reducing them. The core of a transformer may be made of numerous flat pieces called laminations, which serve to prevent the free movement of eddy currents in the core. (See *Eddy Currents*, also *Transformer* and *Core Losses.*)

FOUR ELEMENT or FOUR ELECTRODE TUBE—A vacuum tube having four elements instead of the usual three. The standard tube has three elements, namely, grid, filament and



A four element vacuum tube.

plate. The four element tube has an additional grid element. The illustration shows one form of tube having a double grid arrangement. Such a tube can be used for high and low frequency amplification and as a detector simultaneously or it may be used in conjunction with the Solodyne system, which does not use the customary B battery to supply potential to the plate element. (For more complete explanation of the action of a four element tube in the latter manner see *Solodyne*). (See also *Vacuum Tube.*)

FOURTH CIRCUIT—A method of controlling oscillation of a regenerative detector used in the *Cockaday Circuit.* (q.v.)

FRAME AERIAL—An alternate name for *loop aerial,* a type of aerial consisting of a number of turns of wire wound on an insulated frame and used in place of the regular outdoor aerial with sensitive receiving sets. (See *Loop Aerial.*)

FREE ALTERNATING CURRENT—Term applied to alternating current assumed to be produced by the application of a single impulse of electricity to an *oscillatory circuit.* (q.v.) See *Free Oscillations.*)

FREE ELECTRONS—Name given to the outer electrons of an atom, which become detached under various chemical transformations and are assumed to participate in electrical effects or phenomena. Free electrons are so named to distinguish them from the bound electrons of the proton or positive nucleus of an atom. (See *Electron,* also *Proton.*)

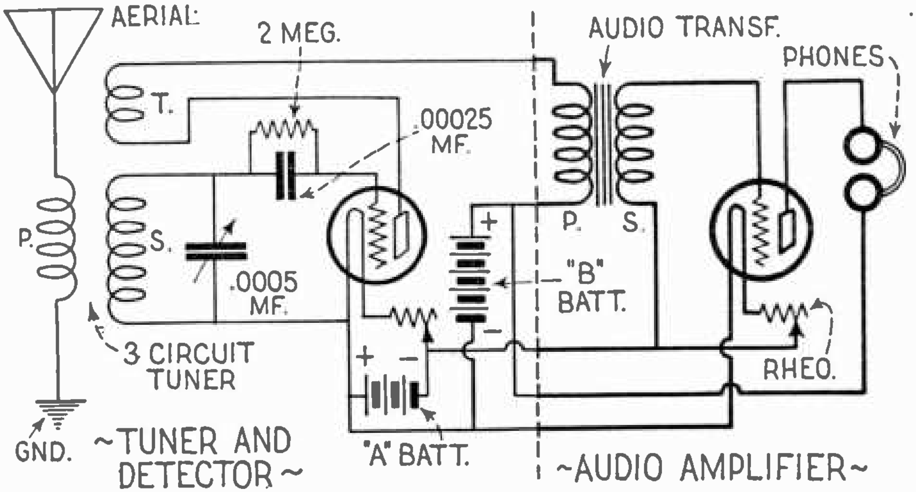
FREE MAGNETISM—The portion of magnetism which does not follow the magnetic path through the metal of a magnetized body, but leaves the surface of the magnet. Sometimes referred to as *surface magnetism.* (See *Magnetism.*)

FREE OSCILLATIONS—Oscillations having the natural frequency of the circuit in which they occur. (See *Forced Oscillations.*)

FREQUENCIES—The plural of the term denoting the number of complete cycles per second in an alternating current. In referring to vibrations, particularly audible or so-called *voice frequencies,* the term is used to imply all frequencies that are normally considered audible. (See *Frequency.*)

FREQUENCY—A term adapted from academic English to use in electrical practice. Thus, the number of times a certain action is repeated per unit of time. In the case of an *alternating current* (q.v.) the current reverses its direction of flow at certain definite intervals. If the reversing process takes place 120 times per second—that is 60 reversals from negative to positive and vice versa—the frequency of the current is said to be 60 cycles. In ordinary commercial practice the majority of alternating current generators produce an alternating current or E.M.F. having a frequency from 25 cycles per second to 60 cycles per second. In radio transmission the alternating current or E.M.F. (Electro Motive Force) has an infinitely higher frequency—the reversals taking place many thousands of times each second. (See *Alternating Current, Theory of Production,* also *Alternation, Cycle* and *Periodicity.*)

FREQUENCY, AUDIO—In radio, a frequency within the limits at which audible sounds are produced. It is generally considered as a frequency less than 10,000 cycles per second, although some authorities refer to frequencies up to 16,000 or 20,000 cycles as being within the limits of audibility. For ordinary practice, the human ear is capable of hearing sounds only up to about 2,500 cycles per second. In receiving sets the audio frequency currents appear only in the circuits carrying the rectified currents, although some types of super-heterodyne receiver use an intermediate frequency as low as 30,000 cycles per second, these signals then being rectified and made audible in the telephone receivers. (See *Frequency Circuit, Audio,* also *Frequency, High.*)



In the diagram above, the heavy lines to the right of the dotted line indicate the audio-frequency circuit of a radio receiver.

FREQUENCY, ALTERNATOR OF—The frequency of an alternating current dynamo or alternator is expressed in cycles per second. With each complete revolution of the *armature* a complete *cycle* or double *alternation* of current is generated. (See *Alternator.*) It is therefore a simple matter to determine the frequency of alternating current generated when the number of revolutions per second and the number of field poles or magnets is known. The frequency will be $f=\frac{N \times S}{2}$, N being the number of field poles and S the number of revolutions per second. The divisor 2 is used to convert the result in *alternations* per second to cycles per second, one cycle representing two alternations. (See *Alternating Current, Theory of Production of,* also *Frequency.*)

FREQUENCY BAND—A term used to denote all the frequencies lying within a certain minimum and maximum limit. Thus, in broadcasting, the frequency band will be the frequencies corresponding to the wave-lengths within the broadcast band. This will be generally between 550,000 and 1,500,000 cycles, or a wave-length band of approximately 200 to 550 meters. (See *Band of Frequencies.*)

FREQUENCY CARRIER—In radio broadcast transmission, the radio frequency (high frequency) wave with which the audio frequency speech variations are superposed. (See *Broadcasting, General Treatise on Methods,* also *Carrier Wave.*)

FREQUENCY CHANGER—A device for converting currents at a certain frequency into currents of a higher or lower frequency, without change of phase or voltage. A frequency converter. Generally an *alternator* driven by a *synchronous motor.* The term is also applied erroneously to certain forms of super-heterodynes. (See *Ultradyne.*)

FREQUENCY CIRCUIT, AUDIO—Any circuit in a radio receiver or transmitter which carries currents within the arbitrary limits of audibility. In the diagram shown herewith, the heavy lines are the connections of the audio frequency circuit. In this part of the circuit only currents of audio frequencies are present. (See *High Frequency Component of Plate.*)

FREQUENCY CIRCUIT, RADIO—The circuits in a receiver in which only high or radio frequency currents are supposed to be present. (See *Feed-Back, Audio Frequency,* also illustration in connection with *Frequency Circuit, Audio.*)

FREQUENCY, FUNDAMENTAL—The frequency of the fundamental wave. (See *Fundamental Frequency.*)

FREQUENCY, GROUP—The frequency of the separate trains of waves in radio communication. (See *Group Frequency,* also *Wave Train.*)

FREQUENCY, HIGH—Frequencies over certain definite limits, generally from 10,000 to 20,000 cycles per second in radio usage. Commonly used as synonymous with radio frequency. It is the opposite of low or audio frequency. (See *Frequency,* also *Audio Frequency, Limits of Audibility.*)

FREQUENCY, LOW—Frequencies below certain limits, generally 10,000 or 20,000 cycles per second. (See *Frequency; Limits of Audibility.*)

FREQUENCY METER—A device for indicating the frequency of an alternating current in cycles per second. The most simple form uses a system of tuned, vibrating reeds. The illustration shows a frequency meter of the

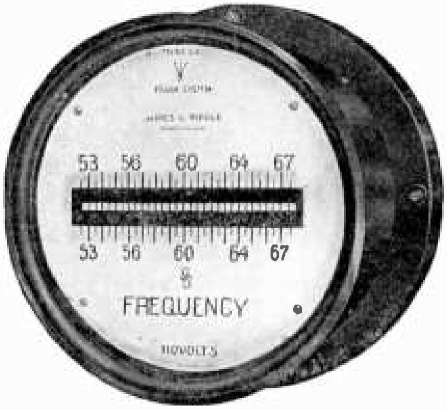


Illustration by Courtesy of Jas. G. Biddle.
A vibrating reed type of frequency meter.

reed type. These reeds may be arranged to respond to various frequencies in a similar manner to the reeds in various musical instruments. These reeds are acted upon by an alternating current magnet. When the magnet is acted upon by an alternating current sent through the windings, the reed nearest to that frequency will vibrate in sympathy with the vibration due to the alternating magnetic effect on the magnet. Such meters and also those of the *induction type* are used for comparatively low frequencies such as occur in commercial lighting systems. For measurement of the high frequencies used in radio communication somewhat different systems are used.

FREQUENCY, RADIO—An alternating current or electromotive force above certain definite limits, generally above 10,000 or 20,000 cycles per second. The line of demarcation between *audio frequency* and *radio frequency* is not very sharply defined, as, in radio usage frequencies that are actually inaudible to the human ear may yet be referred to as audio frequencies. The term is used to differentiate between the rectified or audio currents and the high frequency oscillations such as are impressed on the antenna in receiving or transmitting. (See *Audio Frequency,* also *Frequency, Low.*)

FREQUENCY, UNIT OF—Frequency of alternating currents is expressed in cycles per second and is generally written f. (See *Frequency,* also *Cycle.*)

FREQUENCY, VARIATION OF POWER FACTOR WITH—When a condenser is charged and *dielectric absorption* (q.v.) takes place, it is always accompanied by a loss of power which is apparent in the form of heat produced in the condenser. This loss of power varies with the frequency of the current impressed on the condenser and it is therefore said that the *power factor* (q.v.) varies with the frequency. (See *Condenser, also Dielectric Absorption.*)

FULL LOAD CURRENT—The current delivered from any electrical source, such as a dynamo or generator operating at its maximum load. The maximum current obtainable from an electric source.

FULL WAVE RECTIFICATION — In rectifying alternating current, the process of rectifying both the positive and negative alternations or half cycles. The majority of rectifiers for charging storage batteries rectify only a half wave, or half cycle, and thus do not utilize the full alternating current cycle. (See *Rectifier, Full Wave,* also *Charger, Storage Battery.*)

FULLER CELL—A type of primary cell formerly much used in telephone, telegraph or any intermittent work. (See *Cell, Open Circuit.*) A zinc electrode cast in the shape of a cone is at the end of a soft copper wire and rests at the bottom of a porous cup immersed in a dilute solution of sulphuric acid. The carbon electrode is in an outer jar in a bichromate solution. (See *Cell.*)

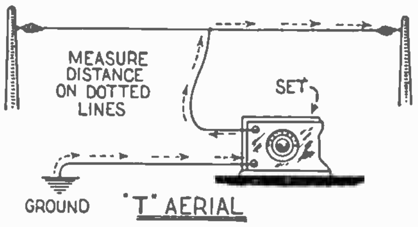
FUNDAMENTAL FREQUENCY — The frequency or number of cycles per second of the fundamental wave. (See *Frequency,* also *Fundamental Wave.*)

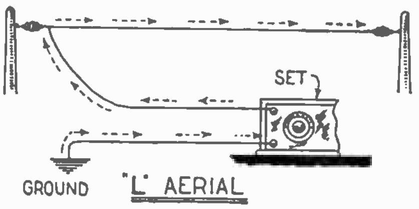
FUNDAMENTAL UNITS—Units based on the fundamental quantities of length, mass and time. Under the *C. G. S. system* the unit of length is the centimeter; of mass, the gram; and time, the second. The absolute system of units. (See *Centimeter-Gram-Second.*)

FUNDAMENTAL WAVE—In an alternating current, the component of the wave form that is a pure sine wave of the principal frequency. Upon this principal frequency the various higher frequencies (harmonics) may be superposed. A fundamental wave when combined with other frequencies which are a whole multiple of it produce the harmonious note. These terms are derived from acoustics in which the fundamental is the pure sound wave or pure note. (See *Sine Wave of Alternating Current or EMF.*)

FUNDAMENTAL WAVELENGTH — Term used to denote the wave-length at which the inductance and capacity of a coil or antenna would be in resonance. In referring to antennas the fundamental wave-length is the wave-length corresponding to the frequency at which free oscillations will occur. This is often referred to as the natural wave-length and the corresponding frequency is referred to as the natural frequency of the antenna.

For practical purposes the fundamental wave-length of an aerial (antenna) may be computed from the dimensions. Where no loading inductance is used, a single wire flat top antenna (T or inverted L type) will have a fundamental wave-length approximately four times the distance from the ground connection to the extreme end of flat or horizontal portion as measured in meters. Thus, if the antenna is of the L type with a top one hundred feet long and a lead-in and ground connection sixty feet long, the fundamental wave-length will be about $4\times(100+60)\times1.1$, the result being given in feet. Now as wave-length is always stated in meters it will be necessary to divide this result by 3.28 which is the rough conversion factor from feet to meters. The multiplier 1.1 adds ten per cent to the figures for necessary correction of length. If the antenna is of the T type, the length of the flat portion would be considered as half of the total horizontal length or 50 feet instead of 100 feet. The illustration shows method of measuring length. (See *Wavelength Calculation for Antennae.*)





FUSE—A device used in electrical circuits to prevent the passage of excessive currents. Generally a strip of fusible metal, commonly lead with a small percentage of tin, enclosed in a fiber or insulated and fireproof container and inserted in the circuit. When the temperature, due to excessive current, reaches a certain limit, the fuse "blows" causing a break in the circuit. It is thus possible to limit the current flowing in a circuit to a definite maximum in order to protect instruments from excessive charges. The most common use is in commercial lighting and heating systems where the current on any line is generally limited to ten or twenty amperes for the protection of the lines leading in to the building.

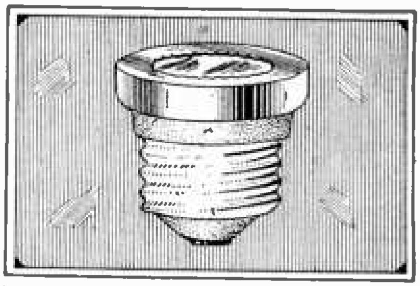


Fig. 1. A common type of fuse used in lighting, heating and power circuits.

Fig. 2. A fuse used to protect the filament of a vacuum tube from damage by excessive voltage.

G

GALENA—A natural crystal sulphide of lead. Chemical symbol PbS. It is an ore of lead, grey in color and showing brilliant metallic lustre when fractured in cubical form. Galena crystals are used either alone or in conjunction with other minerals as *crystal rectifiers* (*detectors*) in radio reception. When used in combination it is generally in conjunction with *graphite* or *zincite.* Used alone, the contact may be a fine wire or *cat whisker.* (q.v.) (See *Crystal Detector.*)

GALVANIC BATTERY—The term, now obsolete, formerly applied to a primary battery or group of primary cells.

GALVANI, LUIGI. Born 1737, died 1798.—An Italian physician and physiologist noted as the discoverer of galvanic or current electricity. While dissecting the legs of a frog, they came by accident into contact with dissimilar metals which caused muscular action in them. Galvani thought that he had discovered electricity in animal matter. Volta attributed the action to the metallic contact and thereupon constructed his voltaic pile, the forerunner of the primary cell.

GALVANOMETER—An extremely sensitive instrument used for detecting and measuring electric currents and also for indicating the direction of the current in a circuit. In its simplest form it consists of a small iron needle pivoted in the center of a hollow coil of wire. The needle is controlled by the earth's field and points north and south when at rest. When an electric current is passed through the galvanometer winding the needle is deflected over a graduated scale the extent of the deflection depending on the force of the current. The instrument is arranged in such a manner that the needle will be deflected in one direction when the current flows through the windings in a certain direction, and when the current is reversed the needle will be deflected in the opposite direction. Thus when the connections are known the direction of the current is accurately indicated as well as its strength. The galvanometer is one of the most sensitive current measuring devices, the deflection of the needle being due to the electro-magnetic field created by the passage of electric current through the coil of wire. (See *Ammeter* or *Ampere Meter*, also *Galvanometer, D'Arsonval* and *Galvanometer, Mirror.*)

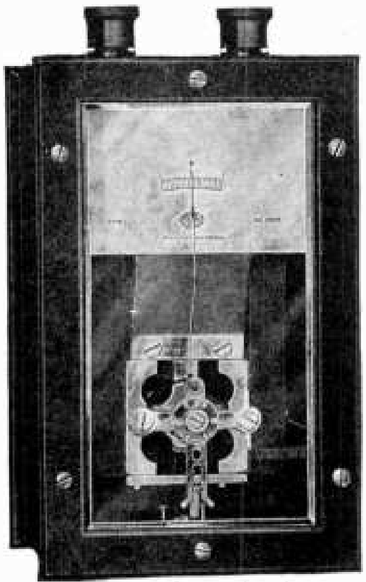

Illustration by Courtesy of the Roller-Smith Co.

A galvanometer which is used for measuring electric currents, and also for indicating the direction of flow of current in a circuit.

GALVANOMETER CONSTANT—Generally speaking, a number used to change the galvanometer reading to ordinary units. The instrument measures extremely small currents and this number times a certain function of the galvanometer reading gives the value in customary units. Technically, the strength of the field produced at the center of the coil of a galvanometer by the unit of current to be used. (See *Constant.*)

GALVANOMETER, D'ARSONVAL—A form of galvanometer having a dead beat indicator (see *Dead Beat Instrument*) in which the indicating coil is suspended in the field of a powerful horseshoe magnet. It is one of the most sensitive forms of galvanometer. The name was derived from that of the designer, A. D'Arsonval. (See *Galvanometer.*)

GALVANOMETER, MIRROR—A type of galvanometer, the moving coil or indicator of which carries a mirror which reflects a beam of light from a fixed lamp. It is so arranged that the lamp is provided with a lens and the beam is so reflected that a visible spot of light is seen on a scale and deflected when the moving element (carrying the mirror) swings with the passage of current. In the beam of light is a sharp image of fine wire stretched in front of the lamp. This type of galvanometer may also be arranged so that the reflection of a fixed scale may be observed in the mirror by means of a small telescope arrangement. (See *Galvanometer.*)

GAMMA—Γ—The third letter in the Greek alphabet. (See *Gamma Type Antenna.*) The lower case *Gamma* γ is used as a symbol for *conductivity.* (q.v.)

GAMMA TYPE ANTENNA—An alternate name for the inverted L type of antenna, so called because the third letter in the Greek alphabet, Γ, resembles an inverted "L," and a single wire antenna with lead-in from one end is in the shape of an inverted L. (See *T Type Aerial.*)

GAP—See *Spark Gap*, also *Lightning Gap.*

GAP, AIR—Term applied to the gap between sections of an iron core as in a transformer for the purpose of preventing *saturation.* (q.v.) Also applied to speak dischargers where a space is provided between the electrodes across which the spark jumps in operation. The term is used as well in referring to the radial depth of the space between surfaces of the rotor and stator in generating machines or motors. (See *Spark Gap*, also *Rotary Gap.*)

GAP ARRESTER—A form of *lightning arrester* (q.v.) in which small air gaps are provided between non-arcing metal electrodes. (See *Arrester.*)

GAP, MICROMETER—A small gap designed to protect apparatus from excessive potentials. (See *Safety Gap.*)

GASEOUS—Anything of the nature of a gas, having no natural physical boundaries but accommodating itself to the shape of the container, expanding to the dimensions of any space in which it may be confined.

GASEOUS TUBE—A term sometimes applied to a vacuum tube in which a certain amount of gas is present. Such tubes under ordinary conditions are not efficient as amplifiers in vacuum tube circuits, the minute gas atoms presenting a more or less effective obstacle to the free passage of the electrons. (See *Vacuum Tube, Theory of Operation.*)

GAS RECTIFIER—The term applied to a vacuum tube which is only partially exhausted of its residual gas. They are also known as *soft* tubes and are generally used as detectors although the tendency now is toward *hard* or highly evacuated tubes due to their adaptability to all purposes in radio receivers whereas the soft tubes do not function well as *amplifiers.* (See *Vacuum Tube.*)

GASSING—When the charging current is continued after a storage battery has taken a normal charge the free liberation of oxygen and hydrogen takes place. This is manifest in the form of gaseous emanation or liberation of bubbles from the electrolyte. The same effect may be noted when a battery is charged at higher rate than the normal charging rate stated by the manufacturer, and under certain conditions may occur at the later stages of charging, even when the battery is not fully charged. In a storage battery that is in good condition it is a fairly accurate indication of a full charge. (See *Charging*, also *Rate of Charging.*)

GAUGE, WIRE—The various systems of measurement used for denoting the physical dimensions of wire. The standard gauge in the United States is known as the B & S or Brown and Sharpe gauge. (See *Brown & Sharpe Guage.*)

GAUSS—The term adopted by the American Institute of Electrical Engineers as applying to the *magnetic flux density.* (q.v.) It is written B or $\mathcal{B}$ and is also used in conjunction with the *Gilbert* to denote magnetizing force, one gauss being one gilbert per Centimeter. It is incorrectly used to apply to *magneto motive force.* (See *Centimeter Gram Second or C. G. S.*)

GENERATOR—Any machine for producing electric energy. Usually a device for converting mechanical power into electrical energy. It may apply to a vacuum tube used to generate oscillations as in transmission or for *heterodyne action.* (See *Heterodyne*, also *Vacuum Tube Generator.*)

GERNSBACK, HUGO—Born 1884. Educated Ecole Industrielle, Luxembourg; Technikum, Bingen, Germany. President, The Experimenter Publishing Company, Publishers of Radio News, Science and Invention, Amazing Stories and Radio Internacional. President of The Consrad Company, Publishers of Radio Review, Radio Listeners' Guide and Call Book, and Money Making. Editor of Radio News, Science and Invention, Amazing Stories. Author of "Radio for All," "Wireless Telephone," "Ralph 124C-41+."

Hugo Gernsback.

GERNSBACK, SIDNEY—Born 1876. Educated College of Luxembourg, Lycee de Nancy, France. Vice-President and Treasurer of The Experimenter Publishing Company, Publishers of Radio News, Science and Invention, Amazing Stories, and Radio Internacional. Vice-President and Treasurer of the Consrad Company, Publishers of Radio Review, Radio Listeners' Guide and Call Book, and Money Making. Editor of Radio Review, Radio Listeners' Guide and Call Book, and Money Making. Author of “A Thousand and One Formulas,” “Wireless Course in Twenty Lessons,” “Experimental Electricity Course,” “Radio Encyclopedia.”

Sidney Gernsback.

GILBERT—Symbol *F*, is the unit of magneto-motive force adopted by the American Institute of Electrical Engineers. (See *Magneto-motive Force.*) It is equivalent to $4\pi/10$ or .7958 ampere turns. (See *Ampere Turns.*)

GLASS PLATE CONDENSER—A condenser, generally of the heavy duty fixed type, consisting of alternate layers of metal or foil and thin glass sheets as the *dielectric.* Glass plate condensers are mainly used for transmitting, glass having a very high dielectric constant. Such condensers may be immersed in oil to stand higher potentials without breaking down. (See *Condenser,* also *Dielectric Coefficient and Constant.*)

GLASS SILENCER—A glass tube having wooden ends with holes just permitting discharge electrodes or rods to pass, used in conjunction with spark coils and gaps to enclose the sparking surfaces and thus dampen the noise of the sparking. (See *Spark Gap.*)

GLOW DISCHARGE—See *Corona.*

GLIDING THEORY—A theory regarding the propagation of electromagnetic (radio) waves, which assumes the waves as following the curvature of the earth and not being subject to reflection due to objects in their path or by any reflecting surface above the earth. This theory has been discarded; due to observations of phenomena of transmission it now is generally assumed that there must be a reflecting surface high in the atmosphere. However, it is considered probable that the waves do not extend very high as a general rule, the exceptions being the cases of extreme distance transmission in certain directions. In the upper atmosphere, due to the rarification of the atmosphere *ionization* (q.v.) is very pronounced and the air may become a fairly good conductor. This conducting region or layer may impose severe obstacles to the electromagnetic waves and thus limit them to a certain restricted zone. In the majority of cases this ionized region may thus be regarded as damping or absorbing the waves, and in others it may conceivably intensify or concentrate them in one direction, producing instances of transmission over extreme distances with low power. For more complete discussion along these lines see *Heaviside Layer,* also *Refraction and Reflection of Electromagnetic Waves.*

GOLD LEAF ELECTROSCOPE—A very sensitive device for determining the presence and nature of an electric charge. It comprises, essentially, two strips of gold foil joined at one end by a conductor and suspended in a glass jar. When an electric charge is present the two strips of foil have a tendency to repel one another and thus, by diverging, indicate the presence of the charge. (See *Galvanometer.*)

GOLDSCHMIDT ALTERNATOR—One of the first practical *alternators* for generating *high frequency currents* suitable for *continuous wave* radio transmission. It was designed by *Rudolph Goldschmidt* in 1912 and was used mainly in Europe. This machine operated on a frequency step-up principle. A single phase alternating current was first produced, the frequency being about ten thousand cycles. This was about the highest possible frequency obtainable with an ordinary type of alternator. By means of a *cascade* effect, obtained by an arrangement of tuned circuits connected to stator and rotor of the alternator, a much higher frequency could be impressed on the antenna to radiate continuous waves. The machine had a number of disadvantages which limited its commercial value, chiefly the fact that the air gap between rotor and stator was necessarily very small—a difficult matter with a bulky machine, the rotor of which weighed several tons. (See *Alternator, Continuous Waves,* also *Goldschmidt, Rudolf.*)

GOLDSCHMIDT, RUDOLF—Born March 19, 1876, at Neu-Buckow, Mecklenburg, Germany. After finishing his education at Wiemar Municipal School, he studied engineering at Charlottenburg and Darmstadt Technical High School. In Darmstadt he obtained his degree as electrical engineer in January, 1898, and then became assistant to Professor Kittler. In 1900 he obtained the college and travelling scholarship, which enabled him to visit engineering works in Belgium, England and France. Later in the same year he was appointed engineer in the laboratory of the Allgemeine Elektrizitaets Gesellschaft in Berlin. In 1901-2 he occupied the position of chief laboratory engineer and designer to Kolben & Co., Ltd. in Prague. He came to England in connection with the Willesden Electricity Supply Station and was later appointed chief engineer to Messrs. Crompton & Co., of Chelmsford. In 1905 he joined the Westinghouse Company in Manchester. After private preparation he passed the German abitur-examination and obtained the degree of Dr. Eng. In 1907 he returned to Germany as lecturer at Darmstadt Technical College. Here he practiced as a consulting engineer, and also pursued the development of several inventions, chiefly occupying himself with the invention and design of high-frequency alternators for wireless telegraphy. In 1911 he became manager of the “Hochfrequenz-Machinen Aktiengesellschaft fur drahtlose Telegraphie” in Berlin, a company formed for the utilization of his inventions in wireless telegraphy. In this position he established two large wireless stations at Eilvesen, Province of Hanover, and Tuckerton, New Jersey, for wireless communication between Germany and America.

GOLDSMITH, ALFRED NORTON—Elec. and Radio Engr.; b. New York, N. Y., Sept. 15, 1887; B.S., Coll. of the City of New York, 1907; Ph.D., Columbia Univ., 1911; cons. radio expert, U. S. Dept. of Justice, 1912; cons. radio engr., Atlantic Communication Co., 1914; cons. engr., Gen. Elec. Co., 1915-17; dir. of research, Marconi Wireless Telegraph Co. of America, 1917-19; associated professor of electrical engineering, College of City of New York, since 1924; dir. of research dept., Radio Corp'n of America, 1919-1922; Chief Broadcast Engineer, Radio Corp'n of America, since 1922; editor, Proceedings of the Institute of Radio Engrs., since 1912. Made investigations in simplex and duplex radio telegraphy and telephony, transmission of canal rays, precision measurements in radio eng. Author: “Radio Telephony” (Wireless Press), 1918; “Radio Measurements,” “Radio Frequency Changers” (Proc. Inst. Radio Engrs.), 1915; “World Communication” (Jour. A. I. E. E.), 1921. Technical director, U. S. Signal Corps School of Communication, 1917-18; U. S. Naval Radio School, 1917-18. Fellow, A. I. E. E., I. R. E., American Association for Advancement of Science. Hon. mem., Radio Club of America, Radio Society of Great Britain, Am. Physical Soc.

Dr. Alfred N. Goldsmith.

GONIOMETER—A device used in radio reception to determine the direction from which the electromagnetic waves (signals) are coming. The term is also used at times to designate any system of directional transmission or reception. The device was originally designed as an aid to navigation.

The original goniometer was designed by Messrs. Bellini and Tosi (see *Bellini, Dr. Ettore,* also *Tosi, A.*), but numerous changes have since been made, notably by Marconi and his associates, to adapt it to the requirements of ships at sea. The form most used is based on the original Bellini-Tosi machine and is essentially a special form of *oscillation transformer* used in conjunction with a special aerial or loop. As an example of the use of a goniometer in connection with ships at sea, suppose a ship is in distress at a point about two hundred miles off the eastern coast. Perhaps the ship's radio apparatus is working, but for some reason the mariner does not know the ship's position. The radio signals are then received, let us say, by three different land stations at widely separated points. The receiving stations use their goniometers and determine more or less accurately the direction from which the signals are coming. The three stations compare notes on the respective directions and any one of them can readily plot out lines running on a chart from each station in the directions indicated by the goniometers. Then by simple triangulation the location of the ship can be figured, enabling other ships in the vicinity to be instructed accordingly and go to their rescue. There are, of course, many other uses that occur in everyday practice. Goniometers are also much used by radio inspectors to locate stations that are interfering, using an unlicensed transmitter, or are otherwise not complying with the regulations.

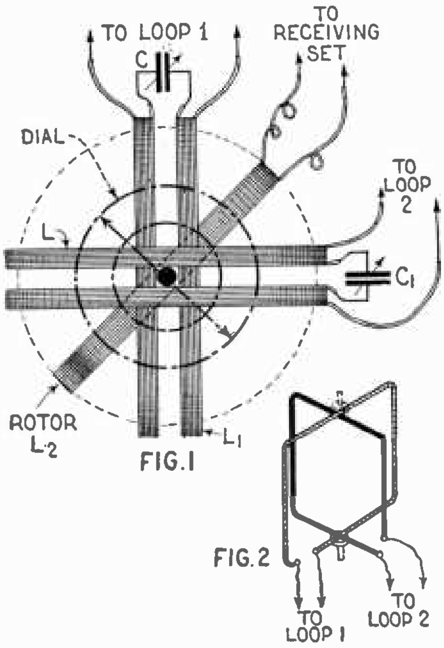

Fig. 1 shows the general arrangement of a goniometer and Fig. 2 shows the loops to which coils L and L-1 are connected.

The illustration Fig. 1 shows the general arrangement of the instrument. Here, coils L and L1 are the main windings of the goniometer. They are wound in two sections with condensers C and C1 inserted between the sections of the two windings for purposes of tuning. Coil L2 is the *exploring coil.* This is connected to the receiving apparatus, which is the customary detector circuit. Coils L and L1 are connected to the two loop aerials shown in Fig. 2. Here it will appear that the loops are placed at right angles, their relation in this respect being variable. In operation the coils L and L1 have minimum *mutual induction*, as they are placed at right angles. The exploring coil L2 can be rotated through a complete circle and the pointer indicates the angle with relation to the fixed coils. When one of the two loops points in the direction of a transmitting station it will pick up the signals, the other being at that moment inoperative, as it is at right angles to the first, as previously explained. If the exploring coil L2 is now turned until maximum signal strength is obtained, the pointer will be in the direction of the plane of the loop. If the advancing wave strikes the two loops simultaneously at any angle, a resulting magnetic field will be set up in the coils L and L1 of the goniometer, the field having a direction at right angles to the direction from which the waves are advancing. Now when the exploring coil L2 is turned to allow maximum signal strength due to this field (permitting maximum inductive transfer), the pointer will be in the direction of the transmitting station. The direction indicated by the pointer is, of course, not the geographical direction, but this can readily be determined by means of a compass. It also appears from the foregoing description that the pointer will indicate two directions, which, however, will be on the same geographic plane. In other words, the pointer may be, for example, exactly north and south.

GRAMME ARMATURE—A form of ring type *armature* (q.v.) used in generators, named for its originator. (See *Generator.*)

GRANULAR CARBON—The carbon grains used in a telephone transmitter to vary the resistance between the electrodes. The highest grade is made by carbonizing pure anthracite coal in an electric furnace, after which it is screened and graded. (See *Microphone, Carbon.*)

GRANULAR COHERER—A form of *coherer* (q.v.) used in the early days of wireless. It employed carbon granules between two electrodes, the whole enclosed in a glass tube. (See *Detector.*)

GRAPH—The presentation in diagrammatic form of facts, formulae, etc., particularly in the electrical and mechanical fields. Graphs are much used in radio to give graphic illustrations of various functions, such as the relation of currents and voltages. For this purpose ruled and squared paper is used. One of the most common and useful forms of graph is known as a characteristic curve of a vacuum tube. These curves may show the relation of changing values, such, for instance, as the relation of grid voltage to plate current, indicating certain of the operating characteristics of the vacuum tube. (See *Characteristic Curve*, also *Sine Curve.*)

GRAPHITE RESISTANCE—A form of resistance composed of graphite, used in any of several ways in radio circuits. The most common usage is in the form of a *grid leak* (q.v.). Here it may take the form of a thin sheet of paper coated with graphite or a glass tube filled with graphite and some binding medium. Such resistances are also used in *resistance coupled amplifiers* (q.v.), in which case they are interposed between the plate and "B" battery and couple the successive stages of amplification. (See *Resistance*, also *Resistance Coupled Amplifier.*)

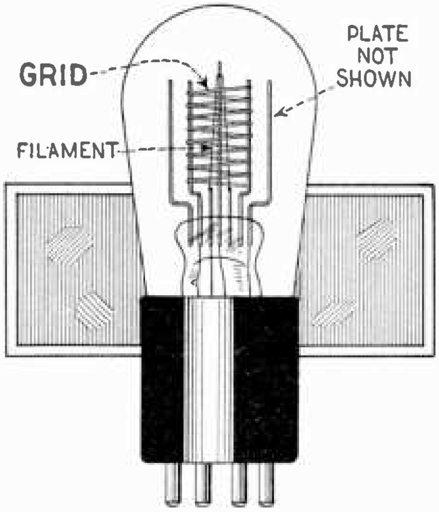
GRASSOT FLUXMETER—An instrument used to measure the strength of magnetic fields and the regions around magnetic poles. It is of particular value in measuring the relative strengths of various magnets. The instrument comprises a very sensitive galvanometer of the moving coil type with a special exploring coil. This coil is introduced into the magnetic field to be measured and readings of the proportionate strength of the field are obtained directly from the scale of the galvanometer, which is appropriately divided. The field strength is obtained by dividing the deflection value in *Maxwell turns* (q.v.) by the area of the search or exploring coil in square centimeters and the number of turns of the coil. (See *Galvanometer*, also *Flux Density.*)

GRAVITY BATTERY—A combination of gravity cells. A group of cells, each cell having two different electrolytes which remain separated without use of a diaphragm due to their difference in specific gravity. (See *Gravity Cell.*)

GRAVITY CELL—A type of *primary cell* (q.v.) in which the specific gravity of one electrolyte is less than the other, which causes this lighter electrolyte to float on top of the heavier fluid. One of the typical examples of gravity cells is the *Daniell's Cell* (q.v.). (See *Secondary Cell.*)

GRID—Generally, any system of wires placed parallel to each other and in the same plane, as a mesh. Specifically in radio usage, the fine network of wires interposed between the filament and plate elements in a vacuum tube. It may be in the form of a flat network of wires or in the form of an oval cylindrical mesh completely surrounding the filament and in turn surrounded by a similarly shaped plate of metal. The illustration shows the form taken by a typical grid member in a modern type of vacuum tube. Here the plate is not shown in order to permit the grid member to show more clearly.

In receiving circuits the grid acts as a valve to control the flow of electrons from hot filament to cold plate. When signals are impressed on the aerial they are tuned by the customary agencies and passed to the *grid circuit* (q.v.). As the incoming signals are in the form of *high frequency oscillations* (q.v.) changing their polarity (direction) many thousands of times each second, it will be apparent that the grid is altered rapidly from positive to negative and back. As the electrons flowing from the filament are negative, the grid will thus have a tendency to retard or increase the flow. That is to say, at the instant the grid is positive it will attract more electrons, but when it is momentarily negative the like charges will repel each other and less electrons will flow, some of them being held back to the filament. (See *Grid Battery, Grid Bias*, also *Vacuum Tube, Theory of Operation of.*)



Showing the form taken by a typical grid in a modern vacuum tube.

GRID BATTERY—A battery of small cells connected in the grid circuit of a vacuum tube to place a negative or positive bias or charge on that element. The illustration Fig. 1 shows a small four and one-half volt battery inserted in such a manner that a negative potential is impressed on the grid. In this case the *characteristic curve* (q.v.) of the tube is assumed to indicate that more difference in current occurs between points B and C than between A and B in Fig. 2. For this reason a negative potential is applied as shown in Fig. I. (See *Grid Bias.*)

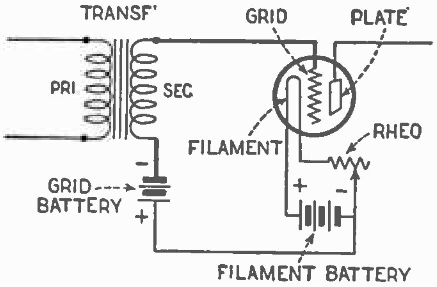


Fig. 1. Method of a 4½ volt battery to impress a negative potential on the grid of a vacuum tube.

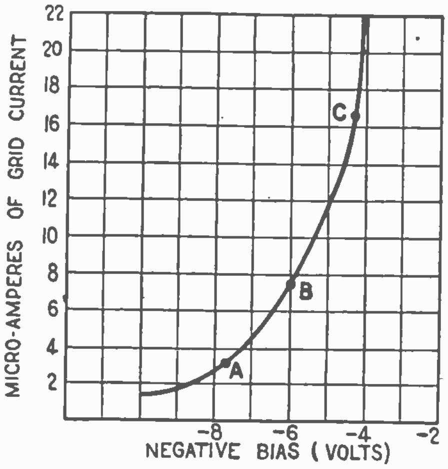

Fig. 2. Characteristic curve of a vacuum tube indicating more difference in current occurs between "B" and "C," than between "A" and "B."

GRID BIAS—A potential of a few volts, generally from four to six, applied to the grid of a vacuum tube to influence its operation by making it more or less negative. The grid bias is usually negative and determines the point of the *characteristic curve* at which the tube will operate. In a sensitive receiver, and particularly where a tube is used as an *amplifier* (q.v.), it is essential to obtain as great a change of grid current as possible. (Note: The greater the change of grid current, the greater the change in plate current and hence the more powerful will be the output.) By applying a negative potential on the grid it is possible to hold it at the point of maximum response. (See *Grid Battery,* also *Vacuum Tube, Theory of Operation of.*)

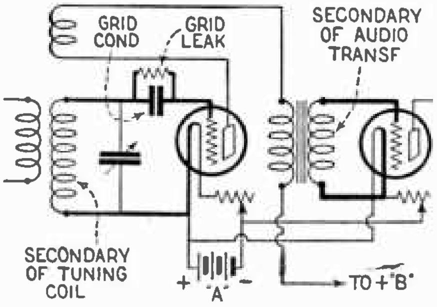

Diagram in which heavy lines at left show the grid circuit of the detector, while those on right indicate audio amplifier grid circuit.

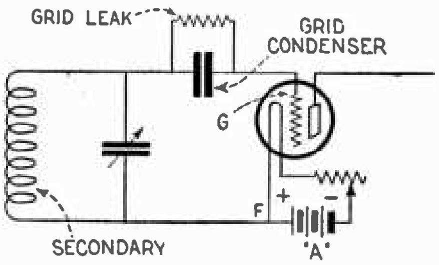
GRID CIRCUIT—In a receiver employing vacuum tubes, the part of the circuit containing the grid of the tube or tubes, but generally referring to the tuning circuit or that part of the system which contains the tuning elements. In the illustration is shown a standard arrangement of a regenerative detector and one stage of audio-frequency amplification. The heavy lines at the left of the diagram represent the tuning circuit or detector *grid circuit,* while the section with heavy lines at the right is the grid circuit of the amplifier tube. The grid circuit of a detector tube may generally be distinguished by means of the grid leak and condenser (so marked in the illustration), which controls the incoming signals and permits the tube to function as a rectifier. (See *Detector, Grid Control,* also *Grid Condenser* and *Grid Leak.*)

GRID CONDENSER—A small fixed condenser, generally from .00025 to .0005 microfarad capacity, inserted in the circuit of a detector tube between the tuning coil and the grid member of the tube. The illustration shows the manner of connecting the grid condenser in a conventional detector circuit. This condenser insulates the grid from the filament by breaking the path F to G and permits the tube to act as a rectifier or detector. A resistance (called *grid leak*) is usually placed across this condenser to allow the accumulated charges on the grid to leak off. (See *Grid Leak,* also *Grid Control* and *Vacuum Tube, Theory of Operation of.*)



Showing how grid condenser is connected in a detector circuit.

GRID CONTROL—The general term used to designate the various devices and associated connections placed in or allied with the grid circuit of a vacuum tube for the purpose of controlling to a greater or lesser extent the potential of the grid, or to tune or control the incoming oscillations. In the case of a vacuum tube used as a rectifier (detector) the grid condenser and grid leak are placed in series with it. (Note: the grid leak is often connected from the grid directly to the filament instead of across the grid condenser, the operation, however, being approximately the same in either case.) Here the controls permit the tube to function as a detector of the incoming oscillations. Where the tube is used as a radio-frequency (high-frequency) amplifier, the radio-frequency transformer or other amplifying unit controls the grid of the following tube by influencing the fluctuating potential differences impressed on it. (See *Amplifier, Radio-Frequency.*) The most important example of a grid control is by using some means to control the potential applied to the grid, such, for example, as a grid bias or grid battery. (See *Grid Bias, Grid Battery,* also *Vacuum Tube, Theory of Operation of.*)

GRID CURRENT—The current present in the grid circuit of a vacuum tube. This is generally very small, perhaps of the order of fifteen to twenty *micro-amperes* (q.v.). (See *Plate Current,* also *Grid Bias.*)

GRID LEAK—A high resistance placed in the grid circuit of a vacuum tube to permit the electrons forming the grid current to leak off after each charge, thus preventing their accumulating on the grid in such numbers as to stop the flow from the filament. The electrons being negative, a surplus of them on the grid member of the tube would act as a barrier to the free flow of other electrons from the filament through the grid to the plate, thus diminishing the plate current toward zero. It will be understood that a heavy negative charge on the grid will repel a like or negative charge, in this case the negative electrons being thrown off by the hot filament.

The grid leak may have a value ranging from about 250,000 ohms to several million ohms. The value of a grid leak is generally stated in *megohms*—one megohm being one million ohms. Thus a grid leak of 250,000 ohms resistance would be referred to as a ¼-megohm leak and, similarly, one having a resistance of two million ohms would be referred to as a two-megohm grid leak.

Such resistances are furnished in many forms, the most common being a strip of paper impregnated with graphite or some similar high resistance preparation, placed in a glass tube and sealed to prevent moisture from affecting the value. The illustration, Fig. 1, shows a tubular type of grid leak.

Courtesy of Chas. Freshman Co.

Fig. 1.—A tubular type of grid leak.

For experimental work a fairly satisfactory grid leak can be made by the simple expedient of drawing a line on a piece of cardboard with a soft pencil—the graphite mark acting as the resistance. At each end of the cardboard is placed a binding post in contact with the graphite, each binding post being connected to opposite sides of the grid condensers. Variable grid leaks, the resistance of which can be changed at will, are also furnished in an infinite variety of types, two of which are shown in Fig. 2. (See *Variable Grid Leaks,* also *Grid Control* and *Resistance.*)

Fig. 2.—Two types of variable grid leaks with condenser incorporated.

GRID POTENTIAL, MODULATION OF—In the transmission of *undamped waves* (q.v.) generated by a vacuum tube, the process of varying or modulating the potential of the grid element of the tube with respect to the filament. In this method an alternating potential may be applied to the grid circuit, the frequency of this varying potential being within the audio band—possibly about 500 cycles—supplied by a generator of that freqnency. (See *Modulation.*)

GRID POTENTIOMETER—A potentiometer—a variable resistance unit—Fig. 1, used in the grid circuit of a vacuum tube for the purpose of controlling the potential applied to the grid. The conventional method is to place the potentiometer across the "A" battery with the center or variable contact arm connected to the grid of the tube in place of the usual connection to either positive or negative filament lead. This is shown in the illustration, Fig. 2, Here the customary circuit is shown for the "A" battery to light the filament of the tube. Pri. and Sec. are respectively primary and secondary of the transformer (either radio-frequency or audio-frequency) and C the center arm of the potentiometer. The center arm may be moved either to the right or left, permitting either negative or positive potential to be applied to the grid. This system is much used in amplifying tube circuits to control the action of the tube as an amplifier. Another method would be to connect one of the ends of the potentiometer to the negative lead of the "A" battery and the center arm to the grid leak. In this way the potentiometer would be acting as a pure variable resistance, the potential applied to the grid being always negative, but susceptible of variation within the limits of the ressitance and the voltage of the "A" battery. (See *Grid Bias, Grid Battery,* also *Grid Control.*)

Fig. 1.—A type of potentiometer.

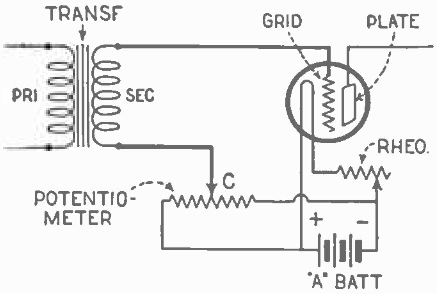

Fig. 2.—Method of connecting potentiometer in grid circuit.

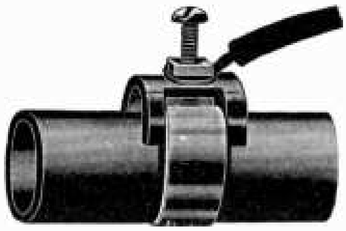
GRINDER—Term occasionally applied to one of the various forms of atmospheric disturbance known under the general heading of *static.* This form of static is more prevalent in warm weather and does not appear to have its origin in local electric storms. Its effect is to produce rattling sounds of no definite pitch. (See *Strays,* also *Static.*)

GROUND—The earth considered as an electric conductor. In radio it is considered as the return circuit for electromagnetic waves. (See *Ground Connection,* also *Theory of Propagation of Electromagnetic Waves.*)

GROUND CLAMP—A strip of metal, generally copper, having some sort of arrangement for fastening rigidly to a water or steam pipe to form the ground connection for a radio receiver. The illustration shows a conventional form of clamp. (See *Ground Connection.*)



A ground clamp for fastening the ground lead to a water or steam pipe.

GROUND CONNECTION—In radio reception or transmission, the connection between the earth and the apparatus whereby the currents set up by the electromagnetic waves are returned to the earth as one side of the assumed circuit. The ground or earth connection from a radio receiver or transmitter should be as short as possible and preferably a heavy wire as shown in the illustration. Such a connection for receiving purposes may be one or more heavy metal plates sunk in the ground and connected by a heavy wire to the apparatus. The more common method is to connect the set to a convenient water or steam pipe, such pipes being almost invariably well grounded, especially the former. (See *Earth,* also *Ground* and *Transmission.*)

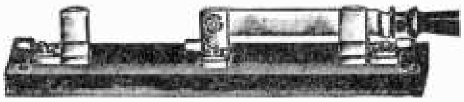
GROUND CURRENTS—Electric currents present in the ground due to the grounding of commercial electric machines. These currents very often prove a disturbing factor in radio reception. (See *Ground.*)

GROUND DETECTOR—A device for indicating an accidental ground on a power transmission line or for any conducting systems for electric currents. (See *Detector,* also *Ground.*)

GROUND RESISTANCE—See *Resistance of Ground Connection.*

GROUND SWITCH—A switch, generally of rugged construction, connected to the aerial, ground and apparatus in such manner that at one position the aerial is connected to the set, which in turn is connected to the ground, and in the other position the aerial being connected directly to the ground to protect the set from excessive static when not in use. (See *Lightning Switch,* also *Aerial Switch, Down Lead.*)



Switch having a break distance of not less than 4 inches.

GROUND WIRE—The wire connecting a receiving or transmitting set to the earth. The underwriters specify not less than No. 14 B & S gauge copper wire. (See *Ground Connection.*)

GROUNDED ROTOR—See *Rotor, Grounded Connection.*

GROUP FREQUENCY—The number of separate trains or groups of waves per second in a damped or undamped system of radio transmission. This frequency is to be distinguished from the frequency of the individual waves. Thus in a spark transmitter, for example, the condenser in the transmitting circuit will be momentarily charged and discharged. The discharges will occur in the form of trains of oscillations, each oscillation having a certain definite frequency, but the trains or groups occurring at definite intervals, the frequency of these intervals being called the group frequency. (See *Frequency,* also *Spark Transmission* and *Undamped Waves.*)

GUARD LAMP—An incandescent lamp having a straight filament, sometimes shunted across the armature and field leads of a rotary converter used in radio transmission. Its purpose is to protect the windings from injury due to the inducing of oscillatory surges from the high-frequency circuits. (See *Rotary Converter.*)

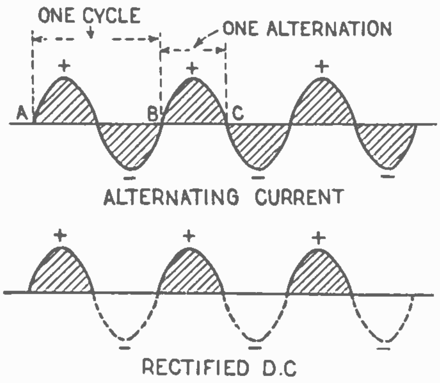
GUTTA PERCHA—An insulating material derived from the milky secretion of certain trees, used as an insulation for submarine cables on account of its ability to resist the action of salt water. It is used to a lesser extent as a general insulating medium for wires, but owing to its scarcity and limited field of usefulness, rubber or rubber compounds are more widely used. (See *Insulating Materials.*)

GUY WIRE—Wires used to brace aerial masts for receiving or transmitting stations. Such guys are generally heavy galvanized wires attached to the mast at various points and extending radially downward and anchored to surrounding rigid objects or by means of some form of anchor in the ground. (See *Aerial.*)

H

H—The chemical symbol for *hydrogen.* In electrical and radio usage it is the symbol for *magnetizing force* or *magnetic field intensity*, adopted as such by the International Electrotechnical Commission and by the American Institute of Electrical Engineers. It has also been adopted by the I. E. C. as the symbol for *Henry* (q.v.). (See *Magnetic Field.*)

HALF WAVE RECTIFICATION—The process of changing alternating currents to pulsating direct currents wherein only one-half of the full alternating current wave or cycle is rectified, the other portion being blocked by the action of the rectifier. In the illustration is shown a typical half wave rectification process. The upper graph shows the sine wave representing an alternating current, such as supplied from an ordinary alternating current house lighting system. Here A-B represents one complete cycle or two alternations, one positive and the other negative. In the lower graph is shown the form taken by the current after passing through a half wave rectifier. It now appears as a pulsating or intermittent direct current, only the upper or positive alternations having passed through the rectifier. The shaded portions below the line represent the negative or unused alternations. (See *Full Wave Rectification, Sine Wave of Alternating Current or E M F*, also *Charger, Storage Battery.*)



The upper graph represents an alternating current, and the lower graph shows the form taken by the current after passing through a half wave rectifier.

HALF WAVE RECTIFIER—Any system for rectifying or changing alternating currents to pulsating direct currents, wherein only half of the full alternating current wave is used. Essentially such a device is a uni-directional conductor, permitting current to pass in one direction only and submerging or blotting out the surges in the opposite direction. A typical example of a half wave rectifier is the crystal detector used in simple receiving circuits. Here the nature of the crystal is such that the currents are permitted to pass only in one direction. In half wave rectifiers used for charging storage batteries the effect is much the same. Where tubes such as the Tungar or Rectigon are employed, one tube is more commonly used, allowing the current to flow in one direction but submerging half of each cycle. (See *Rectifier, Full Wave*, also *Rectifier and Charger, Storage Battery.*)

HAMMER BREAK—A magnetically operated device for making and breaking contact in an electrical circuit. Hammer breaks are essentially the same as a vibrator or buzzer break but are made to withstand heavy currents without undue arcing, and hence are much slower in action. (See *Buzzer*, also *Spark Coil.*)

HAMMOND, JOHN HAYS, JR.—Inventor. Born San Francisco, Calif., April 13, 1888. B.S., Sheffield Scientific School (Yale), 1910; Sc.D., George Washington University. Inventor of type of torpedo for coast defense, controlled by wireless energy from coast fortifications, which was recommended to Congress for exclusive purchase by U. S. by Board of Ordnance and Fortifications, U. S. A.; invented system of automobile torpedo firing; aluminothermic incendiary projectiles employed by Allied armies in World War; radio system of control of ships, employed on U. S. S. Iowa for target practice; a system of coastal patrol by aeroplane; a system of selective radio telegraphy, adopted by the U. S. Navy, U. S. Signal Corps, and U. S Army; system of aerial coast surveying adopted by the Bartlett Expedition for Polar exploration. President Radio Engineering Company of New York; director Hammond Radio Research Labs.; director Radio Corp. of America; consulting engineer to Radio Corp. of America and General Electric Co. Has licensed the American Tel. & Tel. Co., and the Radio Corp. of America under his electrical patents in U. S. and S. A. for commercial purposes only, U. S. Gov't retaining option on military uses. Has applied for over 224 patents in U. S. and Europe relating to Radio Telegraphy and Telephony and Wirelessly controlled torpedoes and various improvements in pipe organ mechanisms. Formerly member Advisory Board, U. S. Naval Board of Inventors, member Advisory Com. Langley Aerodynamic Lab. of Smithsonian Inst., co-operating with Third Naval Dist.; member Conf. Com. on National Preparedness (Sub.-Com. on Finance); Gov. Aero Club America (mem. Aerodynamic, Tech., Pub. Safety and Map and Landing Places Coms.); v.-p. Am. Soc. Aeronautic Engineers; mem. Inst. Radio Engineers (ex-treas., etc.), Am. Inst. E. E., Royal Soc. Arts (London); asso. mem. Am. Soc. M. E.; hon. mem. Nat. Inst. of Inventors, Harvard Aeronaut. Soc.; Fellow Am. Geog. Soc.; U. S. del. Radio-Telegraphic Com., London, 1912.

John Hays Hammond, Jr.

HAND CAPACITY—See *Body Capacity.*

HARD DRAWN WIRE—In radio usage generally confined to hard drawn copper wire, i. e., copper wire that has been hardened by repeated drawing without being annealed. It is used chiefly for aerials. (See *Aerial.*)

HARD TUBE—A vacuum tube is said to be hard when it has been evacuated of all gases to a high degree. The opposite is a soft tube, one in which the vacuum is not of a very high order and more or less gas particles are present. Hard tubes are used for amplifiers, both audio and radio frequency, while the soft tubes are used mainly as detectors or oscillators. Hard tubes may be used with high plate voltages, whereas soft tubes require comparatively low plate voltages, the tubes having a tendency to turn blue (see *Blue Glow*) under the influence of high plate potentials. (See *Detector*, also *Amplifier.*)

HARMONIC CURRENT—An alternating current which can be represented by a simple harmonic or sine curve. It may be considered as an alternating current, the waves of which are sinusoidal or uniform. (See *Simple Harmonic*, also *Sine Curve.*)

HARMONIC MOTION—A term signifying any periodic oscillatory motion, as, for example, the vibration or beating of a pendulum. The illustration shows the manner of indicating simple harmonic motion. The distance A-B represents 360 degrees of a circle, or, if it is assumed to represent a sine wave of alternating current, it will represent one complete cycle. Curves representing harmonic motion are used extensively in radio engineering to illustrate, in graphic form, the oscillations of an alternating current. (See *Sine Wave*, also *Simple Harmonic Vibration* and *Oscillations.*)

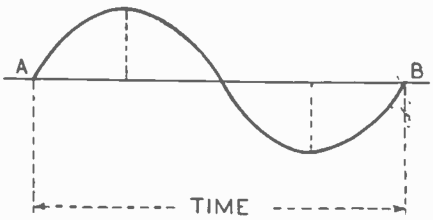


Illustration showing method of indicating simple harmonic motion.

HARMONICS—Oscillations to which a circuit will respond in addition to the basic or fundamental oscillations. The effect is similar to that in sound, where, for instance, the primary or fundamental tone struck by an instrument may be accompanied by notes or tones of a higher pitch. In sound these harmonics are principally the third, fifth, seventh and the octave. In radio, a circuit may respond to oscillations of a frequency either higher or lower than the fundamental frequency, as, for example, one third, one fifth or one seventh, or, again, double or treble the original frequency. As a concrete example, with a fundamental wave-length of 240 meters, the harmonics might be

40 meters or 80 meters. The corresponding frequencies would be approximately 1,250,000 cycles, 7,500,000 cycles and 3,750,000 cycles. (See *Harmonic Suppressor, Side Bands,* also *Harmonic Motion, Oscillations, Wave-length.*)

HARMONIC SUPPRESSOR—A device used in radio transmission and in laboratory work, for the purpose of eliminating undesired frequencies (wavelengths). Essentially such a device is a *filter* (q.v.) so arranged as to suppress or eliminate certain frequencies or *harmonics* (q.v.). In radio broadcasting it is particularly essential that all undesired frequencies or *harmonics* be suppressed. Basically the system involves a special coil shunted by a condenser and tuned to the frequency of the interfering wave, the main tuning circuit at the same time being adjusted to the desired frequency. (See *Broadcasting, General Treatise on Methods,* also *Transmission* and *Radio Telephony.*)

HAZELTINE NEUTRODYNE RECEIVER—The radio receiver designed by Professor Hazeltine, employing the Neutrodyne circuit. Essentially these are five-tube receivers employing two stages of tuned and neutralized radio-frequency amplification with the conventional detector and two audio-frequency stages. In addition to the five-tube Neutrodyne receiver there are numerous types involving the Neutrodyne principle in conjunction with *reflex systems.* (See *Neutrodyne.*)

HEAD TELEPHONE OR HEADPHONES—Telephone receivers arranged with a band to fit over the operator's head, thus leaving him free use of both hands. Head-phones are used in commercial radio work, the operator being free to handle a key or the controls of the receiver or transmitter. They are also used in broadcast reception where the strength of signals is not sufficient to permit the use of a loud speaker, and also in some cases to tune in distant signals before attaching a loud speaker. (See *Watch Case Receivers.*)

HEAVISIDE, DR. OLIVER. — Born in London on May 13, 1850, Dr. Heaviside was engaged in telegraph work for a few years, but after 1874 he lived in retirement studying Clerk-Maxwell's theory and applying it to telegraph and wireless problems. Elected a Fellow of the Royal Society in 1891, he was also Faraday Medallist of the Institution of Electrical Engineers and Hon. Ph.D. of Gottingen University. The name of Dr. Heaviside is primarily associated with the theory, propounded by himself, of the existence of a permanently ionized layer in the upper atmosphere capable of deflecting electro-magnetic waves and thus permitting wireless communication round the earth.

HEAVISIDE LAYER—An assumed layer or stratum of the atmosphere supposed to exist from fifty to one hundred miles above the earth's surface according to the Heaviside Theory. Heaviside's theory supposes this stratum to consist of heavily ionized gas which is conductive and acts as a gigantic reflector of electromagnetic waves (radio waves). It is this layer which is supposed to reflect the electric waves and force them to follow the curvature of the earth. This theory partially explains—if true—why radio signals are transmitted over great distances instead of being radiated off into space and lost. It has been accorded the support of many eminent scientists. Elihu Thompson has propounded an alternative theory which assumes the waves as attached to the earth and gliding along over the surface. (See *Gliding Theory.*)

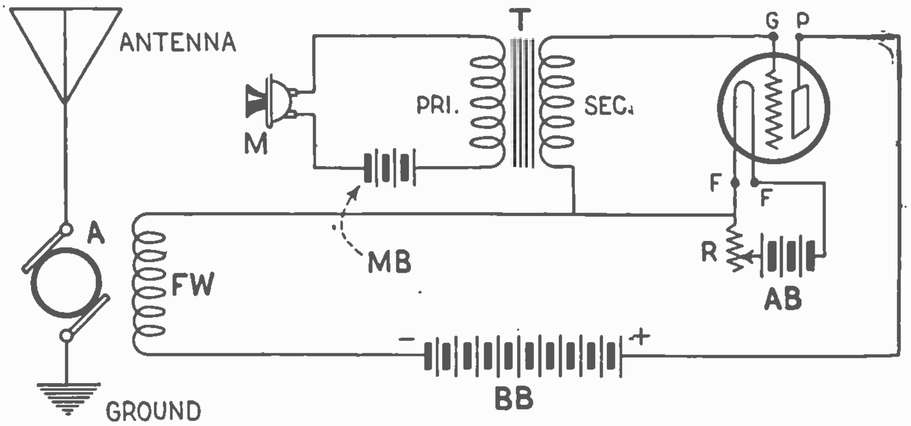
HEAVISIDE LAYER THEORY—The theory of an upper ionized stratum from fifty to one hundred miles above the earth's surface, which is assumed to act as a reflector of radio waves and thus force them to follow the curvature of the earth. None of the theories thus far advanced has been proven, but it has been definitely established that these waves do follow the curvature of the earth. (See *Heaviside Layer,* also *Gliding Theory.*)

HEDGEHOG TRANSFORMER—A type of audio transformer so called because of its peculiar construction. The core is cylindrical in shape and consists of a great number of soft iron wires around which is a bobbin holding the primary and secondary windings. After the windings are completed the wires forming the core are bent back over the form and held in place, completely surrounding the windings. (See *Audio-Frequency,* also *Transformer.*)

HEIGHT OF AERIAL—The elevation of an aerial system as used in radio transmission or reception. The effective height is roughly considered as the height above the earth or surrounding objects. The range of a station having constant power is dependent upon the height of the aerial, other factors of radiation being unchanged. In other words, increase of height increases the range within certain limits. (See *Radiation from Antenna,* also *Transmission.*)

HEISING, RAYMOND A.—Electrical Engineer, born Albert Lea, Minn., August 10, 1888. Educated University of N. D., Elec. Engineer, 1912; University of Wisc., M.S., 1914 Grad. Work in Physics, Research and Development of Radio Tel. since 1914; Trans-Atlantic test in 1915; for Army and Navy use during War, aeroplane, chaser, intership communication; since War continued research and development ship to shore use, trans-Atlantic test, 1923. Author of several technical papers; numerous inventions widely used in present broadcasting stations.

HEISING MODULATION—A system of modulating radio currents for radio transmission, such as broadcasting, developed by *R. A. Heising.* The fundamental principle is shown by the illustration. Here the customary antenna and ground are connected with a high-frequency alternator, A; the field of the alternator, FW, is connected to the grid return and filament of the vacuum tube circuit, and through the "B" battery BB to the plate P of the tube. The microphone circuit comprises a microphone M connected to the primary of a transformer T through the battery MB. The secondary of the transformer is connected to the grid G of the vacuum tube and the filament F. R is the usual rheostat to control the filament of the tube and AB is the filament lighting battery. In operation the speech or sound vibrations are impressed on the microphone M, thus varying the resistance of the current flowing from the battery MB and through the transformer T. This serves to vary the potential of the grid G, and as this potential changes, the current in the plate circuit will also be varied, the same characteristics being maintained. As the field winding FW is in the plate circuit, it is evident that the antenna current will be modulated in accordance with the variations of the speech or sounds introduced at M. (See *Grid Control,* also *Modulation* and *Broadcasting, General Treatise on Methods.*)



Circuit illustrating the fundamental principle of the Heising system of modulation.

HELIOGRAPH—An instrument involving a movable mirror, by means of which the sun's rays are reflected and made use of as a signalling device. In practice it is usually arranged with a blind or shade to cover the mirror at rapid intervals by pressing on a key device. In this manner the flashes may be made at definite intervals, as in the case of the Morse light. (See *Code,* also *Morse Light.*)

HELIX—The shape assumed by a line or wire wound in a single layer around a cylinder. Generally speaking, a *solenoid* (q.v.). A device in the form of a helix was formally used in transmitting circuits to vary the inductance, or, practically speaking, the wave-length. It usually was a number of turns of heavy copper or aluminum wire wound on an insulating form. Clips were provided to permit a variation in the contact point and hence any necessary change in the value of the inductance. (See *Oscillation Transformer.*)

HENRY, JOSEPH—Born in 1797, died in 1878. An American Physicist, noted for his researches in electromagnetism. He developed the electromagnet which had been invented by Sturgeon in England, so that it became an instrument of far greater power than before. In 1831 he employed a mile of fine copper wire with an electromagnet, causing the current to attract the armature and strike a bell, thereby establishing the principle employed in modern telegraph practice. He was made a professor at Princeton in 1832 and during his experimenting there he devised an arrangement of batteries and electromagnets embodying the principle of the telegraph relay which made possible long distance transmission. He was the first to observe magnetic self-induction, and performed important investigations in oscillating electric discharges (1842), and other electrical phenomena. In 1846 he was chosen secretary of the Smithsonian Inst. at Washington, an office which he held until his death. As chairman of the U. S. Lighthouse Board he made important tests in marine signals and lights.

Joseph Henry.

In meteorology, terrestrial magnetism and acoustics he carried on important researches. Henry enjoyed an international reputation and is acknowledged to be one of America's greatest scientists.

HENRY—The unit of inductance, named after the American physicist, Joseph Henry, who first produced high-frequency oscillations in 1832. A coil of wire is said to have an inductance value of one henry when a current passing through it changes at the rate of one ampere per second and an electromotive force of one volt is produced. As the henry is too large a unit for practical purposes, the thousandth part of a henry, known as the *milli-henry*, or the millionth part, known as the *micro-henry*, are more commonly used. Another much-used term is the centimeter, which is the thousandth part of a micro-henry. The abbreviation for henry is H, and for micro-henry μH. (See *Centimeter Gram Second*, *Centimeter*, also *Inductance.*)

HERTZ, HEINRICH RUDOLF—Born 1857, died 1894. A German physicist noted as the discoverer of electromagnetic waves (1888) which form the basis of wireless telegraphy. He found that waves produced by the spark of a simple device called the oscillator could be detected by a loop or square of wire known as the resonator, and he was able to show the reflection, refraction, diffraction and poralization of the waves. These remarkable discoveries demonstrated the practical possibilities of radio-telegraphy. He also made valuable experiments with electric phenomena in vacuum tubes.

Heinrich Rudolf Hertz.

HERTZIAN WAVES—Term occasionally applied to radio or electromagnetic waves, they being named after Dr. Heinrich Rudolf Hertz owing to his extensive researches into electromagnetic waves. (See *Hertz*, also *Clerk-Maxwell*, and *Ether Theory.*)

HETERODYNE—The term originally applied by Fessenden to a method of reception of electromagnetic waves, wherein the principle of *Beats* (q.v.) was employed. It is derived from the words "hetero," meaning other or different, and "dyne," meaning power.

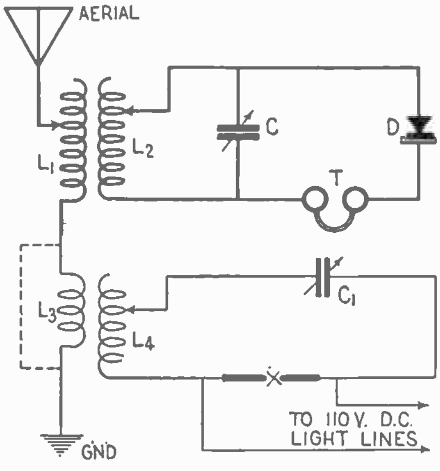


Fig. 1.—The original form of heterodyne receiver.

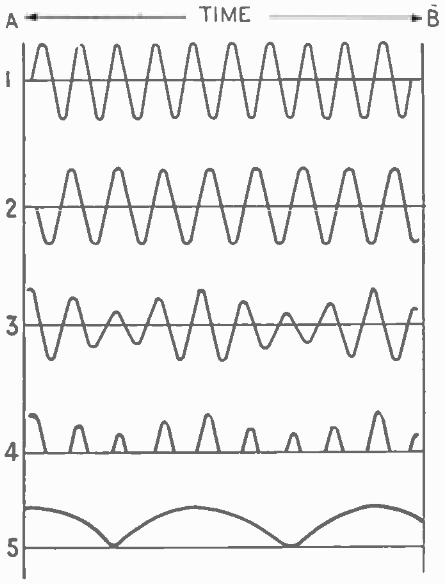
In its original conception by Fessenden, before the widespread use of vacuum tubes, it was used in conjunction with crystal receivers for the reception of *undamped waves* (q.v.). The heterodyne principle involves production of a local series of oscillations which are tuned to a frequency differing from the frequency of the incoming oscillations from the antenna. The difference between the two is known as the *beat frequency*. (See *Beats*, also *Heterodyne Receiver.*)

HETERODYNE RECEIVER—A receiver for electromagnetitc (radio) waves employing the *heterodyne* principle. The illustration Fig. 1 shows the original form of heterodyne receiver, wherein the local oscillations were produced by means of a direct current arc gap and associated circuits, and combined through a coupling medium, with the oscillations in the antenna circuit. Here the heavy lines represent a conventional crystal receiver circuit. L1 and L2 are respectively primary and secondary of a vario-coupler, C is a variable tuning condenser, D the crystal detector and T the head phones. If the dotted line is assumed as a connection to the ground, this will constitute a complete receiver. For the heterodyne purpose, however, a special coil L3 is employed in the ground circuit. Coupled to this is the secondary L4. C1 is another tuning condenser and A is an arc gap fed by 110 volts direct current. In operation the circuit represented by the light lines acts as a generator of undamped oscillations, these oscillations being supplied to the antenna circuit and the frequency varied by means of the condenser C1 and the coil L4. If the receiving tuner is tuned to a certain wave-length corresponding to incoming signals, and the generator system tuned to a different frequency, the difference between the two frequencies will be a *beat* frequency which will be present in the detector circuit. This new series of oscillations will be rectified by the detector D and will be audible in the head phones, T. The action of this system is shown by the series of curves given in Fig. 2. Here the incoming oscillations (signals) from the antenna are shown in graph 1 at the top of the illustration. These oscillations are of continuous amplitude or *undamped* (q.c.). Graph 2 shows the local oscillations. If we assume that the distance from A to B represents the time, it will be apparent that there are more oscillations per unit of time in the case of the incoming signals—



Series of graphs showing the action of a heterodyne receiver.

hence the second graph indicates that the local oscillations have a lower frequency. Graph 3 represents the *beat* resulting from interaction of the two upper series of oscillations and the frequency corresponds to the numerical difference. When the two upper groups of oscillations are opposed, the beat current is zero, and when they are in phase, or assisting each other, the beat current is maximum. When rectified by the crystal detector action the beats take the form shown in graph 4, the lower half of each cycle having been submerged. The telephone current of a periodic nature is indicated by the bottom graph, the original signals being represented in the phones by a series of contractions of the diaphragm. (See *Heterodyne*, also *Beats* and *Super Heterodyne.*)

HETERODYNE, SELF—See *Self-Heterodyne.*

HETERODYNE WAVE-METER—A wave-meter—device for measuring the wave-length of coils, circuits or incoming and outgoing signals—which utilized the heterodyne principle. Briefly the action is as follows: It has already been explained under Heterodyne Receiver that when the local oscillations and the incoming oscillations are opposed, the beat current is zero. It follows, then, that with a pair of phones connected in the circuit, the beat signals will be audible only when the two frequencies are different. Now if a suitable means is present for varying the frequency of the local oscillations, in practice a combination of coil and condenser, the local circuit can be tuned to a point where the two frequencies concur or are similar and no beat is audible. As the frequency is proportional to the capacity and inductance in a circuit, and as wave-length can easily be figured when the frequency of the local generating system is known, the wave-length of the incoming signals must be that of the local circuit when the beat is zero. The condenser dial on the heterodyne wave-meter can thus be calibrated directly in meters and a nearly true reading of the wave-length of incoming signals obtained. (See *Beats*, also *Heterodyne* and *Wave-meter.*)

HIGH FREQUENCY—A very general term applied to alternating electric currents. As a rule, alternating currents having frequencies above one thousand *cycles* (q.v.) per second are referred to as high frequency currents. When the frequency is extremely high, of the order of hundreds of thousands of cycles, the current is usually referred to as high frequency, oscillatory current. There is no definite level or line of distinction between high and low frequency currents. In radio practice, the audio frequency currents are generally considered below twenty thousand cycles per second and known as low frequency currents. The radio frequency or frequencies above twenty thousand are considered as the high frequency currents, although here again there is no definite level or line of demarcation between the two areas. (See *Audio Frequency*, also *Radio Frequency* and *Frequency.*)

HIGH FREQUENCY ALTERNATING CURRENT—See *High Frequency Current.*

HIGH FREQUENCY ALTERNATOR—An alternating current machine or alternator, designed to produce currents having high frequencies, generally above one thousand cycles per second. Such machines are used in high power radio telegraph transmission (not broadcasting) producing undamped or continuous waves. (See *Alternator*, also *Alexanderson Alternator.*)

HIGH FREQUENCY AMPLIFICATION—The process of stepping up or amplifying currents of high frequency. In radio circuits, the high frequency currents are known as radio frequency oscillations. In radio circuits the audio frequency (low frequency) currents and the high or radio frequency currents are usually in different parts of a circuit. When we consider alternating currents having a frequency above, say, twenty thousand cycles per second as radio frequency, and those below that limit as audio frequency, it is easy to consider the radio frequency currents as existing in all stages between the aerial and the detector. Beyond the detector, the alternating currents having become uni-directional surges, we can consider these currents as being audio frequency currents.

Thus we have a definite dividing line in any radio receiver using but one detector, the detector or rectifier marking the transition from radio frequency to audio frequency. Thus, any means of amplifying the signals before they reach the detector will be known as high frequency amplification. (See *Audio Frequency*, also *Amplifier.*)

HIGH FREQUENCY BUZZER—A *buzzer* (q.v.) designed to produce a very high note. The term "high frequency" in this case merely indicates that the pitch or frequency (vibration) is high in comparison with the ordinary buzzer, the sounds of course being actually of audible frequency. The general scheme of such a buzzer is about that of the ordinary type as used in conjunction with electric bells or signal systems, the armature, however, being very thin and thus permitting rapid make and break for the current. Such buzzers are used extensively in connection with crystal receivers for the purpose of testing and also for code practice. (See *Buzzer* also *High Frequency* and *Armature.*)

HIGH FREQUENCY COMPONENT OF PLATE—The high frequency currents present in the plate circuit of a vacuum tube receiver, as distinguished from the audio or low frequency currents. (See *Feed-Back*, also *Plate Component, High Frequency*, and *Regeneration.*)

H.F.C.—Abbreviation used abroad and occasionally in the United States for high frequency current. The more common term is radio frequency current and no abbreviation is used as a rule. (See *Radio Frequency Current*, also *High Frequency.*)

HIGH FREQUENCY CURRENT—Alternating currents having frequencies above certain limits, as, for example, the radio frequency currents employed in radio transmission, which are usually of a frequency above one hundred thousand cycles per second. (See *High Frequency*, also *Low Frequency* and *Radio Frequency.*)

HIGH FREQUENCY OSCILLATION—The term oscillation is generally applied to an alternating current of very high frequency. Thus radio frequency currents, which may run into hundreds of thousands of cycles per second, are called high frequency oscillations. (See *Oscillation.*)

HIGH FREQUENCY RESISTANCE—Resistance to the passage of alternating currents of high frequency. Said of wires, coils, circuits and apparati. The resistance of a certain conductor or part of an electrical circuit, as in radio, may be comparatively higher in the case of high frequency currents than to alternating currents of a low frequency. This is due to the "*skin effect*" (q.v.) it being a phenomenon of radio frequency (high frequency) currents that they have a tendency to concentrate near the surface of the conductor. For this reason, small wires are more apt to have high radio frequency resistance, as obviously the surface on which the currents can travel is restricted. (See *High Frequency.* also *Skin Effect* and *Resistance.*)

HIGH PASS FILTER—An arrangement of electric circuits designed to permit ready passage of high frequency alternating currents while at the same time presenting high resistance or impedance to alternating currents of low frequency, generally within certain definite limits. (See *Filter* also *Filter, High Pass.*)

HIGH PRESSURE—A term occasionally used to denote high potentials or voltages. (See *High Tension*, also *High Potential.*)

HIGH POTENTIAL—One of the several terms used to indicate high voltage. (See *High Potential Battery*, also *High Voltage.*)

HIGH POTENTIAL BATTERY—Another term for "B" battery, the battery used to supply potential to the plate of a vacuum tube. The term "high potential" is used here, only in a comparative sense, the voltage of the battery being high in proportion to that of the filament or "A" battery. High potential batteries for radio usage are generally furnished in blocks of 22½ or 45 volts. (See *High Voltage, High Tension* and *"B" Battery.*)

HIGH RESISTANCE—The property of any circuit whereby it offers considerable opposition to the flow of electric currents. There is no very distinct line of demarcation between high and low resistance. One of the common applications of the term is in the case of a *grid leak* or grid resistance. Here the resistance may be upward of a half million ohms, running into several million ohms in certain cases. An example of low resistance elements is that of a *rheostat* for controlling the filament current. Here the resistance is relatively low, rarely more than thirty ohms. The average resistance of the magnet windings in headphones (as used in radio) is one thousand ohms. The term "high resistance" is also used in a comparative sense in respect to various instruments or parts of radio circuits. Here the resistance in most cases should be as low as possible, and therefore a resistance of even a few ohms may be referred to as *high*. While resistance to direct currents is generally the feature of resistance coils and units, the opposition to currents of an oscillatory nature (high frequency alternating currents) may be of the utmost importance, and it is often the case that a circuit has little direct current resistance but very high resistance or *impedance* (q.v.) to high frequency currents. (See *Resistance, Impedance*, also *Skin Effect.*)

HIGH RESISTANCE JOINT—Any connection between two wires or conductors which offers resistance to the passage of current due to defective contact or imperfect connection through solder or any other medium. When bare wires are joined they should be carefully scraped and soldered. Too much solder is a bad feature, as the resistance of solder is naturally far higher than that of the copper wire. (See *Corrosion*, also *Soldered Joints.*)

HIGH RESISTANCE TELEPHONES—Headphones or telephones used in radio reception, having high resistance windings. In the ordinary telephone receiver used with the commercial telephone systems, the windings of the telephone magnets have a relatively low resistance, generally less than one hundred ohms. Such phones would not be sufficiently sensitive for radio usage, the average resistance in this case being about one thousand ohms. The resistance here refers to the ohmic resistance of the many turns of wire wound around the magnets. This resistance is not a required feature, the factor of importance being the number of turns. Inasmuch as space is a factor to be considered, it is necessary to use very fine wire in order to permit use of the thousands of turns essential. The resistance of this fine wire is of course high. Where very high resistance windings are used—and this indicates small wire—it is sometimes advisable to use a by-pass for the heavy plate potentials to protect the windings. (See *Ampere Turns*, also *Output Transformer* and *High Resistance.*)

HIGH SPEED RECEPTION AND TRANSMISSION—The reception or transmission of radio messages by automatic means in order to obtain much greater speed than would be possible under the manual system or hand opereating and recording. The general practice is to record the messages to be transmitted on a tape by means of a punching machine. They are then sent automatically through a high speed automatic transmitter and received automatically at the same high speed by a machine which punches the messages or records them on some form of tape or sheet. The more common of these methods is the *Wheatstone Transmitter.* (q.v.).

HIGH TENSION—One of the numerous terms used to denote high voltage. "B" batteries as used in radio reception are generally known as high tension batteries to distinguish them from the low voltage storage battery or dry cells used to light the filaments. Abbreviation H. T. mostly used in magazines and books printed in England.

HIGH TENSION BATTERY—Term applied to "B" batteries used in radio reception to supply potential to the plates of the vacuum tubes. These batteries usually are in blocks of twenty-two and a half or forty-five volts. (See *"B" Battery.*)

HIGH TENSION CIRCUIT—Term occasionally applied to the part of a radio circuit in which high potentials are present, as in the plate circuit of a vacuum tube. Here the "B" battery is in the circuit. (See *High Tension*, also *"B" Battery.*)

HIGH TENSION INSULATOR—Insulators of large dimension and rugged design, possessing unusual insulating properties in order to withstand high voltages. As a rule such insulators are made of high grade porcelain and arranged with annular ridges or "petticoats" to give greater surface and reduce the possibility of surface leakage. The illustration shows a form of high tension or high potential insulator. (See *Insulator*, *High Tension*, also *Petticoat Insulators.*)

A high potential insulator.

HIGH VACUUM—A term applied to vacuum tubes when they have been highly exhausted of air. That is, an almost perfect vacuum. When a vacuum tube has a very good vacuum—has been highly evacuated of gases—it is generally called a "hard" tube. A high vacuum is essential in tubes to be used as amplifiers or for transmission. (See *Vacuum Tubes, Theory of Operation.*)

HIGH VOLTAGE—A very indefinite term, used in ordinary electrical practice to denote voltages above 600, but applied in radio practice to much lower potentials, as, for example, a "B" battery, which is generally referred to as a high voltage battery in spite of being generally below 100 volts. The term used in this sense is one of comparison with the low voltage of a storage or other type of "A" battery. (See *Voltagee*, also *Potential.*)

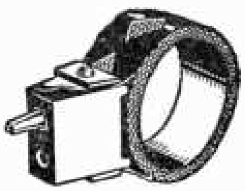
HIGHLY DAMPED WAVES—An expression applied to waves or trains of waves wherein the amplitude or strength of each succeeding oscillation or train of oscillations is greatly decreased. If the progressive decrease in amplitude or strength is very gradual, that is, if the waves die out slowly, they are said to be feebly damped, but if they die out rapidly they are referred to as being highly damped. (See *Damped Waves*, also *Decrement* and *Amplitude.*)

HOGAN, JOHN V. L.—American radio expert. Born at Philadelphia, Pa. He was educated at Sheffield Scientific School, Yale University, where he made a special study of physics and mathematics. In 1906 he became assistant to Dr. Lee De Forest, and in 1909 he joined the National Electric Signalling Co. In 1914 he was appointed chief research engineer to the International Radiotelegraphic Company. Hogan has written many articles on radio and is a past president of the Institute of Radio Engineers, member of the American Institute of Electrical Engineers, of the American Association for the Advancement of Science, of the Radio Club of America and other societies.

John V. L. Hogan.

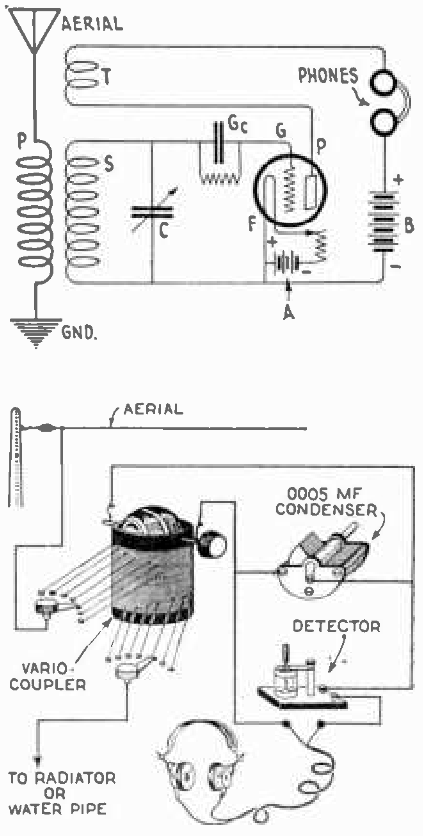
HOMOPOLAR—Synonymous with unipolar. Having but one pole. Said of a dynamo having its conductor or armature rotating around a single pole of a field magnet. (See *Multi-Polar.*)

HONEYCOMB COIL—A coil used in radio, having a peculiar construction, somewhat similar to a honeycomb. The illustration shows a typical honeycomb coil used as an inductance in receiving circuits. The object of this staggered winding system is to reduce the self-capacity between wires to a minimum without reducing the inductive value. The chief value of such a winding method is that it permits the retaining of high inductance value in a limited space, without undue *high frequency resistancee* (q.v.). (See *Inductance, Distributed Capacity* and *High Frequency Resistance.*)



Honeycomb coil used in radio reception.

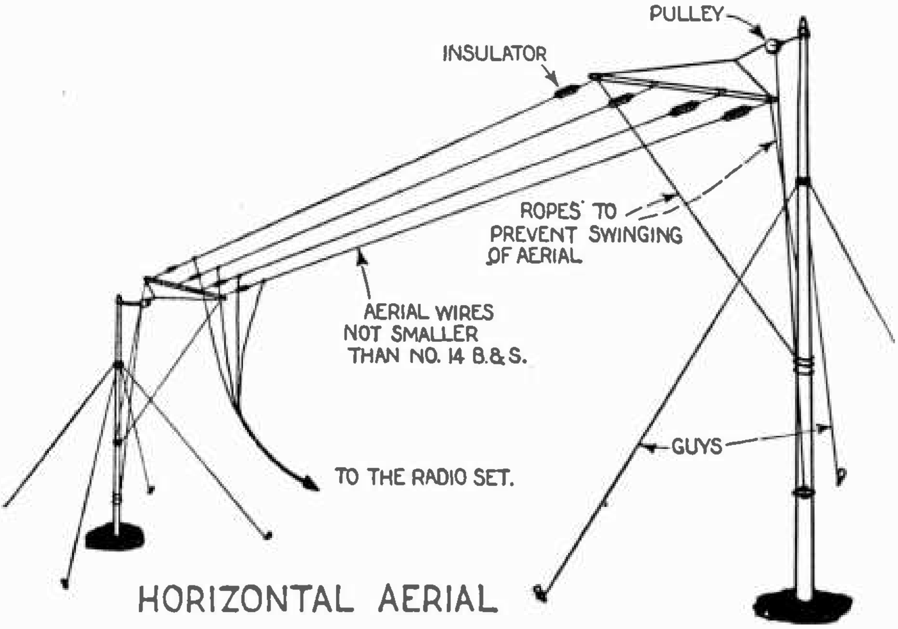
HOOK UP—The general term in the United States to designate the diagram for any complete radio receiver or transmitter, or for any specific part of such a circuit. Thus, when we refer to a hook-up for Radio receiver, we mean a diagram, either schematic (using symbols for the parts) or perspective (showing pictures of the parts) which gives the various parts necessary and the manner of connecting them to each other to form the complete circuit. Similarly we may use the term "hook-up" to describe a sketch or circuit for connecting various instruments such as *ammeters*, or *voltmeters*, *wavemeters* and the like. (See *Circuit*, also *Diagram.*)



The upper diagram is in schematic form and shows a single tube regenerative receiver, and the lower diagram is in perspective form and shows a crystal receiving set.

HOOPER, STANFORD C.—American Naval wireless expert. Born August 16, 1884, at Colton, California, and educated at San Bernardino, California. He joined the Southern Pacific Company as a telegraph operator. In 1901 he entered the Naval Academy at Annapolis, and entering the Navy was advanced to Commander in 1918. From 1910-11 he was instructor in electrical engineering, physics and chemistry at the U. S. Naval Academy, and in 1912-13 Fleet Radio Officer of the United States Atlantic Fleet. During the great war he was responsible for the supply of wireless instruments, etc., for the American Navy, and he was also responsible for the construction of many of the larger American wireless stations including those at Annapolis, San Diego and Pearl Harbor. Hooper was one of the chief men concerned with the radio-compass system now used in the American Navy.

HORIZONTAL AERIALS—Aerials—overhead wire systems—for the reception or transmission of radio signals, wherein the major portion of the aerial is horizontal—parallel to the earth's surface. Typical examples are the "T" and inverted "L" aerials. In the former type, the flat portion suspended horizontally between two supporting structures and a lead-in wire is attached to the center and thence to the apparatus. In the latter type, the lead-in is attached to either end, giving a shape somewhat similar to an inverted L, from which the name is derived. The more common term is "flat top." This term is now somewhat ambiguous, as single wire aerials are used more or less extensively for receiving purposes, whereas formerly a system of several horizontal wires was employed. (See *Flat Top Aerial or Antenna*, also *Aerial T Type* and *Inverted Γ Aerial.*)



PULLEY
INSULATOR

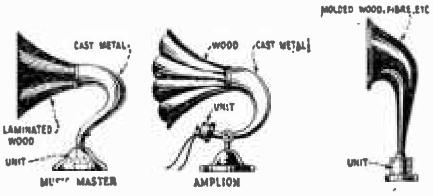
AERIAL WIRES NOT SMALLER THAN NO. 14 B.&S.
GUYS
TO THE RADIO SET.
HORIZONTAL AERIAL

A horizontal aerial of the inverted "L" type.

HORN, LOUDSPEAKER—A device, generally in the shape of a horn, used in conjunction with a heavy duty telephone receiver or loudspeaker unit, to reproduce loudly the signals or music from a radio receiver. In operation, the horn has attached to it at its small end a unit or telephone receiver. When the diaphragm of the unit is actuated by the signals, speech or music, the column of air in the open tube is displaced, creating audible sounds which can be heard at a distance or throughout a room. Assuming other conditions equal, the volume will be more or less in proportion to the size of the norn, or more specifically to the amount of air displaced by the signals. When a telephone receiver is used without horn, the opening above the diaphragm being unconfined, only a small column of air is displaced and the volume will not be great under ordinary circumstances. When a horn is attached, however, the sound being confined will displace a relatively greater amount of air—depending mainly on the shape and size of the horn—and the volume will be measurably greater. (See *Loudspeaker*, also *Acoustics* and *Loudspeaker Units.*)



Three types of horn loudspeaker.

HORSE POWER—The unit of power used in the United States and Great Britain. It is defined as the power required to lift 550 pounds to a height of one foot in one second, or similarly, 33,000 pounds to that height in a minute. The term "foot-pounds" is derived from this value. Thus, one horsepower is the power required to perform 550 foot-pounds of work per second of time. (See *Horse Power, Electrical.*)

HORSE POWER, ELECTRICAL—The unit of electrical work similar to the mechanical horse power. It is actually mechanical horse power expressed in *watts* (q.v.). One electrical horse power is equivalent to 746 watts. In the *centimeter gram second* (q.v.) system of units, the unit of work is the *erg.* This unit is too small for ordinary usage and the customary unit is the watt, which is equal to 10^7 ergs per second. The unit used in electrical power work is still larger; it is the *kilowatt* or one thousand watts. (See *Units*, also *Watts.*)

HORSESHOE MAGNET—A *magnet* (q.v.) in the shape of a horseshoe or letter U, both poles being brought nearer together so that they may act on the armature or "keeper." Generally a magnetized steel bar which retains its magnetism for a long period. The illustration, Fig. 1, shows a permanent horseshoe magnet. Such magnets are also used with external power, then being termed *electromagnets.* In this case the magnet is made of soft iron. The illustration, Fig. 2, shows a horseshoe *electromagnet.* Here the magnetic attraction is supplied by application of an external electric force to the windings WW, and the magnet being of soft iron, loses its magnetic attraction almost immediately upon withdrawal of the electric current, magnetizing force. (See *Telephone Receiver*, also *Electromagnet.*)

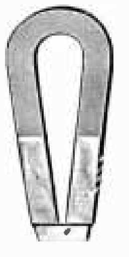


Fig. 1. A permanent horseshoe magnet.

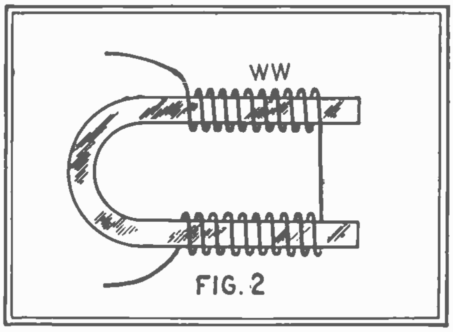

Fig. 2. A horseshoe electromagnet.

HOT-WIRE AMMETER—An ammeter, or instrument for measuring electric current amperes, which depends for its action on the expansion of a fine wire under the influences of the heat produced in it, by the passage of the electric current to be measured. In the illustration the current to be measured is passed through the fine resistance wire A-B. P is a pointer moving over a graduated scale, and attached at its other end to a coiled spring S, which in turn is attached to the wire A-B by the silk thread T. The tendency of the spring is to move the pointer to the right, but owing to the pull of the thread in the normal position of the wire A-B, the pointer rests at zero at the left of the scale. As current is passed through the wire A-B, it heats and expands, thus permitting more or less slack to occur in the thread T and allowing the spring S to move the pointer over the scale toward the right, As soon as the current is withdrawn, the wire cools and contracts to its former size, thus again restoring the tension to the thread and returning the pointer to zero. Hot Wire ammeters are used extensively for measurement of currents at *radio frequency*, that is, extremely high frequency as in radio transmission. The average ammeter using a coil of fine wire would not be adaptable to this use, as the high voltage, high frequency current would burn out the coil. In addition to this, the length of these windings would affect the circuit and probably throw it out of *resonance* (q.v.). (See *Ammeter* or *Ampere Meter, Frequency, Resonance,* also *Instrument Shunts.*)

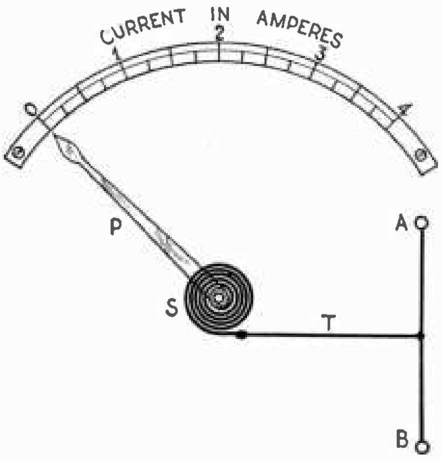

Illustration showing operation of a hot wire ammeter.

HOT WIRE INSTRUMENTS—Current measuring instruments which utilize the tendency of a fine wire to sag or expand under the heat caused by passage of an electric current through it. Such instruments may be used for direct or alternating current. (See *Hot Wire Ammeter.*)

HOT WIRE OSCILLOGRAPH — See *Oscillograph.*

HOT WIRE TELEPHONE—See *Thermal Telephone.*

HOT WIRE WATTMETER—An instrument used to measure combined volts and amperes, i. e., watts in a circuit. It comprises essentially a mirror, which is deflected according to the difference in expansion of two fine wires. (See *Hot Wire Instruments,* also *Wattmeter.*)

HOUR METER, AMPERE—An instrument used extensively in connection with storage batteries, to measure the input or output in amperes per hour. (*Ammeter* or *Ampere Meter.*)

HOUSE MAINS—A term much used in connection with storage battery charger and battery elimination devices. The term implies the main circuit of any standard house lighting system, either direct or alternating current. Thus in the case of a rectifier for charging storage batteries from alternating current, a lead is provided for connecting to the house mains, offering a means for introducing the required current into the device. (See *Current Direct,* also *Alternating Current* and *Chargers, Storage Battery.*)

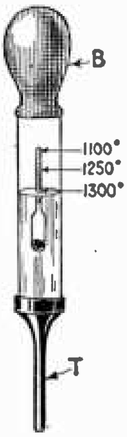
HOWLING—The general term used to imply any undesired sounds produced in or by a radio receiver. Howling is usually caused by *feed-back effects* (q.v.). The most common example of howling is in the case of a regenerative receiver. Here the detector tube may have a tendency to generate its own oscillations As long as these oscillations are equal in frequency to any incoming signals there will be no howling, but should these local oscillations differ in frequency from the incoming series of signals, the result will be a howl resulting from the *beats* (q.v.) established owing to the difference between the two sets of oscillations. This is essentially the principle of *heterodyne* or "beat" reception, but in the case of a heterodyne, the effect is utilized, whereas in the case of a regenerative receiver it is undesirable. Interaction between various parts or different parts of a circuit may often lead to howling. (See *Feed-Back,* also *Regeneration, Reflex, Beats* and *Re-Radiation.*)

H. P.—Abbreviation sometimes used in radio for *high potential* or *high pressure.* In mechanics it is the standard abbreviation for *horse power.*

HOZIER-BROWN DETECTOR—A form of electrolytic detector, which, however, does not use a liquid electrolyte. It consists of a small pellet of lead oxide held more or less rigidly between two electrodes, one platinum and the other lead. (See *Detector,* also *Electrolytic Detector.*)

HYDROGEN—A gaseous chemical element. The symbol is H and its specific gravity is taken as 1, that of air being 14.4. It is colorless, tasteless and odorless and is the lightest known body. Hydrogen is a constituent of water, which is composed of one atom of oxygen and two atoms of hydrogen according to the chemical formula for water, H_2O. Hydrogen is used in radio transmission in connection with *arc generators.* (q.v.) (See *Poulsen Arc.*)

HYDROMETER—An instrument used to measure the *specific gravity* (q.v.) of a liquid. In radio it has an extensive use in connection with storage batteries. Various types of hydrometers are used to indicate the specific gravity of the electrolyte of a storage battery and hence in a manner, to indicate the state of charge of the battery. The illustration shows the standard form of hydrometer using a weighted float. In the illustration the float is shown inside the barrel of the instrument. In operation the bulb B is compressed and the tube T inserted in the open vent of a storage battery. When pressure on the bulb is released some of the electrolyte is drawn up inside the barrel and the float rises more or less within the barrel in proportion to the specific gravity or density of the electrolyte. With the hydrometer held in the manner shown, that is, upright, the numbers just at the level of the liquid in the barrel indicate the specific gravity. Thus, if the reading is 1250° or higher the battery is considered in fairly good operating condition —full charge being 1280° to 1300°. If the reading is below 1200° it indicates the need of charging, these levels not being arbitrary, a discharged condition being indicated by a reading of 1150° or lower. The use of a hydrometer is generally advisable and the reading accurate under ordinary conditions. If, however, water has just been placed in the battery, the reading may not be accurate for several hours due to the fact that the water and acid may not mix immediately. (See *Storage Battery Tests,* also *Electrolyte.*)



Hydrometer used to test the specific gravity of liquids.

HYGROSCOPIC EFFECT — The effect in any substance which permit it to absorb moisture. In the case of forms or tubes for radio coils and inductances this feature is particularly undesirable, as obviously, moisture lowers the dielectric value of the form and may cause it to warp. (See *Bakelite,* also *Tubing.*)

HYSTERESIS—The tendency of magnetization to lag behind the magnetizing force as, for instance, in an iron core in a *transformer* (q.v.). When the core of such a transformer is undergoing rapid reversals of magnetism, there is often an expenditure of energy which is not useful and which is converted into heat, thus representing a loss in power. This effect is more noticeable with certain qualities of iron. In other words, when rapid reversals of magnetism take place in a poor quality of iron core it may display a certain sluggishness. This is actually the lagging of the magnetic flux behind the magnetizing force producing it. This loss of energy is assumed due to the work required to alter the position of the molecules of the iron composing the core and the less energy expended in this manner the less the hysteretic losses. In designing transformers or armature cores, hysteresis must be taken into consideration and the iron must be of high quality to hold these losses at a minimum. (See *Eddy Currents,* also *Core, Transformer.*)

HYSTERESIS COEFFICIENT — The amount of energy wasted or lost in the process of magnetizing and de-magnetizing a unit volume of magnetic material is referred to as the hysteresis coefficient of that material. (See *Hysteresis,* also *Coefficient.*)

HYSTERESIS LOOP—Graphic illustration of losses due to hysteresis in any sample of core material. Loops are plotted in graphic curves of cycles of magnetization. (See *Curve,* also *Hysteresis.*)

HYSTERESIS LOSSES — The energy wasted or lost through hysteresis. (See *Hysteresis.*)

HYSTERETIC LAG — The lagging of magnetization due to the effect of hysteresis. (See *Hysteresis,* also *Magnetization.*)

I

I—The abbreviation adopted by the *International Electrotechnical Commission* (q.v.) and American Institute of Electrical Engineers, to denote current in amperes. The small or lower case (i) may also be used where the capital letter is not advisable. (See *Current.*)

I ARMATURE—An armature used in generating machines, having a core resembling the letter I in shape. (See *Armature,* also *Core.*)

I.C.W.—The customary abbreviation for "interrupted continuous waves." This is a system of radio transmission wherein the waves are modulated at a constant low frequency. (See *Interrupted Continuous Waves,* also *Modulation.*)

IDLE CURRENT—A name often applied to the component of an alternating current which contributes nothing to the power. This is also known as the *wattless component* (q.v.) or the *wattless current* (q.v.). It represents the component which, being in quadrature with the electromotive force in the circuit, thus has no active value—adds nothing to the total power. (See *Current,* also *Electromotive Force* and *Alternating Current.*)

I.E.C.—The abbreviation for *International Electrotechnical Commission,* the body which suggested the international electrical and magnetic abbreviations and symbols. (See *Symbols,* also *Units.*)

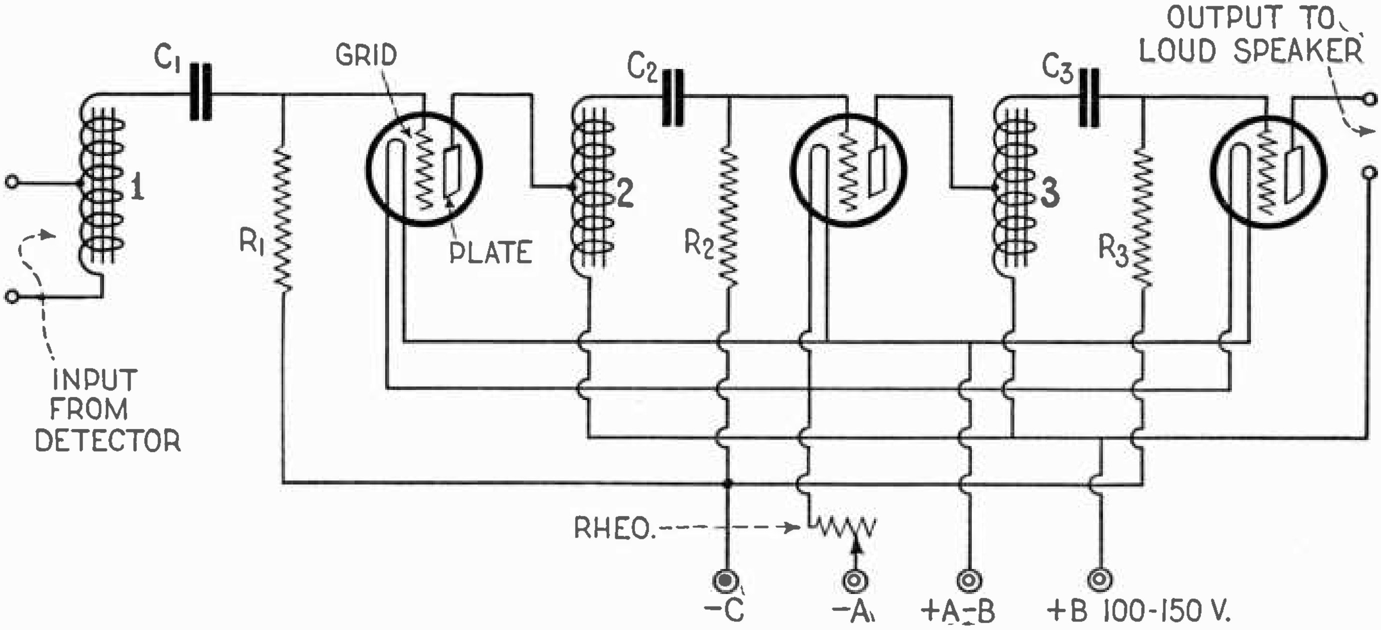
IMPACT OR SHOCK EXCITATION—The method of producing *free oscillations* (q.v.) in a circuit by means of an exciting current of short duration compared to that of the resultant oscillations. The term is a general one and broadly covers the various methods of generating oscillations in which an oscillatory circuit is thrown into electrical vibration at its natural or fundamental frequency by means of an electromotive shock or exciting force of short duration. Also covers the term *Impulse Excitation.* (See *Oscillations,* also *Fundamental Frequency.*)

IMPACT TRANSMITTER—Apparatus for transmitting radio waves wherein the transfer of energy from the primary or exciting circuit to the oscillatory circuit takes place during one pulse or vibration of the exciting current. (See *Impact or Shock Excitation,* also *Transmitter.*)

IMPEDANCE—The total resistance to the flow of alternating current in a circuit. Impedance combines the ohmic resistance and the apparent resistance due to self-induction. When a direct electromotive force is impressed on a circuit, the current flowing in that circuit depends directly on the ohmic resistance of the circuit. The formula is according to Ohm's law $I = \frac{E}{R}$, I representing the current in amperes, R the resistance in ohms and E the electromotive force in volts. Now if this direct electromotive force is replaced by an alternating EMF (electromotive force) and the ohmic resistance remains the same, the total resistance of the circuit to the alternating EMF will nevertheless be greater than in the case of direct current. Now the ohmic resistance is still the same but we have added to it the apparent resistance due to the self-induction of the circuit. In other words the inductance of the circuit has a marked effect on the current flowing in the circuit. What actually occurs is that the self-induction sets up a *counter-electromotive force* (q.v.) which continues to act against the impressed EMF as long as the flow of current persists. The result is a reduction in the current flowing in the circuit, the EMF having been, in effect, reduced, and hence according to the law above, $I = \frac{E}{R}$, the current is less. This added resistance, due to self-induction, is referred to as *reactance* and the flow of current in an alternating current circuit is thus governed by the ohmic resistance and the reactance. The application of the term "apparent resistance" to describe the added resistance due to self-induction, is a concession to the fact that it is not actually resistance in the proper sense of the word. In a direct current circuit, the resistance actually wastes or dissipates a certain amount of energy. In the alternating current circuit, the ohmic resistance has the same effect. The reactance, however, does not dissipate energy. It merely reduces the effective EMF by means of the counter EMF and thus necessitates the application of a higher impressed voltage in order to maintain the same flow of current.

This is one of the major advantages of alternating over direct current. Alternating current can be transformed readily and can also be readily controlled by means of a reactance or choke coil, which by creating a counter EMF limits the current flowing in the circuit without dissipating any great amount of energy. (See *Alternating Current, Current Direct, Choke Coil,* and *Reactance.*)

IMPEDANCE COIL—A coil of wire or inductance coil, generally wound on an iron core, used in alternating current circuits to limit the current flowing in the circuit. In action such a coil serves through the medium of its self-induction, to create a counter electromotive force which acts against the impressed EMF (electromotive force) and thus reduces the current in the circuit according to ohm's law that the current is equivalent to the EMF in volts, divided by the resistance in ohms. An impedance coil is also known as a choke coil although the two may have somewhat different meanings. For example, a choke coil might be used in either direct or alternating current circuits, whereas an impedance coil as its name indicates, offers impedance, an effect only present in alternating current circuits. The simplest formula for impedance of a coil is the following: Impedance $= \sqrt{R^2+P^2L^2}$. Here it is assumed that the current takes the form of a *sine wave* (q.v.), then R is the resistance of the coil, L the coefficient of self-induction in henries and p is 2 π times the number of alternations per second. (See *Choke Coil, Alternating Current, Current Direct, Reactance, Impedance,* also *Impedance Coupled Amplifier.*)



Schematic diagram of an impedance coupled audio frequency amplifier. (*See Impedance Coupled Amplifier.*)

IMPEDANCE COUPLED AMPLIFIER—A system of amplifying radio signals, voice or music, whereby the successive stages are coupled or joined by means of impedance coils. This system is much used in audio amplifiers, the amplification being much more uniform over the necessary range of frequencies than in the case of the ordinary audio frequency transformer. This is also known as choke coil coupling or choke coil amplification. The illustration on the preceding page shows a typical impedance coupled amplifier for audio frequency currents. It will be noted that three stages are used. This is necessary owing to the lower amplification per stage. Using this system, then, three stages are necessary in place of the customary two stages of transformer coupled amplification. In the illustration, which is a schematic diagram of the circuit for such an amplifier, the impedances 1, 2 and 3 are in the form of *auto transformers.* (q.v.) R1, R2 and R3 are grid leaks ranging in value between one quarter megohm and one and one-half megohms. C1, C2 and C3 are stopping condensers of about 1 micro-farad capacity each. The variations in potential are transferred successively from stage to stage, the amplification factor being roughly the sum of the individual factors of the tubes. In other words the ratio of the windings of the impedances is one to one, or unity, and therefore no voltage amplification takes place. The resistances are the usual grid leaks and the condensers C1, C2 and C3 are to block the high plate voltages from the grids of the succeeding tubes. (See *Tuned Impedance,* also *Amplifier* and *Vacuum Tube Amplifiers, Theory of.*)

IMPEDANCE FACTOR—The ratio of the impedance to the ohmic resistance in an alternating current circuit. (See *Impedance,* also *Resistance.*)

IMPEDANCES, MATCHED—Arrangement of an amplifying circuit and the choice of an audio transformer or loudspeaker with due regard for the impedance of the circuit. Thus if the impedance of a certain amplifier tube is 10,000 ohms, and the resistance of a loudspeaker unit being used is 2,500 ohms, then for maximum response when used with an *output transformer* (q.v.) the impedance of the primary of the transformer should be equivalent to the total or 12,500 ohms. (See *Matched Impedances.*)

IMPREGNATED INSULATING MATERIALS—Cloth or paper impregnated with an oily or resinous substance to render it moisture proof and improve the insulating properties. Cardboard is sometimes treated in this manner and used for tubing to wind inductance coils. (See *Empire Cloth or Paper,* also *Insulating Property.*)

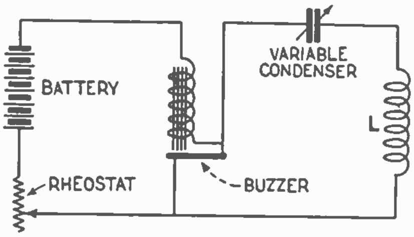
IMPRESSED ELECTROMOTIVE FORCE—The term used to distinguish the EMF (electromotive force) impressed on or applied to a certain part of an electrical circuit from the counter or back-electromotive force due to constants of the circuit. The term is sometimes used where a direct current is applied in a circuit, but it should be confined to use where a counter EMF (electromotive force) is present. (See *Counter Electromotive Force,* also *Choke or Choking* and *Reactance.*)

IMPRESSED FIELD—An electric or magnetic field of force impressed on or applied to a body or region (area) for the purpose of producing other fields of force. (See *Field.*)

IMPULSE—Electrically, an electromotive force which produces an impulsive rush or discharge of electricity. The term is used to distinguish between this form and an electromotive force producing a steady flow of current. (See *Current,* also *Electromotive Force.*)

IMPULSE E.M.F.—The more specific term designating an EMF (electromotive force) which produces an impulsive rush or discharge of electricity. It is defiined technically, as having a maximum value which is large compared with its average value, the average value being taken over a time equivalent to the *time-constant* (q.v.) of the circuit on which the EMF is impressed. (See *Current, also Electromotive Force.*)

IMPULSE EXCITATION—Method of exciting or starting oscillations in a circuit, such as the aerial circuit of a transmitter, by a sudden surge of impulse EMF (electromotive force) rather than by application of oscillations of the frequency of the circuit.



Connections of buzzer for generating damped oscillations suitable for testing by impulse excitation.

This system of impulse or shock excitation may be used for transmission and also has application in connection with testing or comparing of wavemeters. The illustration shows a buzzer connected with the necessary components to form a source of high frequency oscillations. This system is capable of producing through coupling from the coil L, currents by shock excitation. These currents can be used in a variety of ways for testing purposes. In operation the condenser is charged to the voltage of the battery at the instant the buzzer contact is open and when the contact closes, discharges through the coil L thus furnishing a series of oscilations to surge through the coil and by inductive coupling to any other coil placed in proximity to it. (See *Buzzer Exciter.*)

INCANDESCENCE—The glowing of any substance when brought to a white heat. The term is used in radio to signify the condition of the heated cathode or filament in a vacuum tube. In order to produce *electrons* (q.v.) it is necessary to cause the filament to become white hot, the condition being known as incandescence. (See *Filament.*)

INCONDUCTIVITY—A little used term signifying the condition of a substance by virtue of which it will not act as a conductor for electric currents. (See *Conductivity, Specific.*)

INDEPENDENT UNIT—A unit of a quantity, such as length, mass or time, chosen arbitrarily and without having any relation to any other unit. (*Centimeter Gram Second, or C. G. S.,* also *Fundamental Units.*)

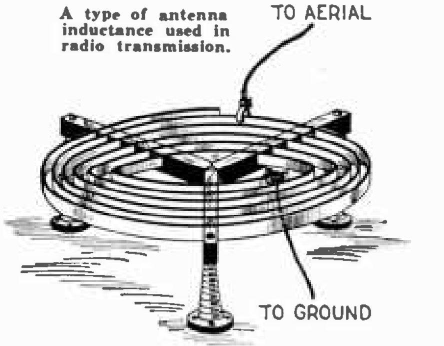
INDICATING INSTRUMENTS—Any instrument or device which indicates values, as for example, a *voltmeter* or *ammeter.* (q.v.) (See *Instruments, Measuring.*)

INDIRECT CURRENT—Term for alternating current—now obsolete. (See *Alternating Current.*)

INDUCED CURRENT—The current in a circuit due to an induced EMF (electromotive force). The current produced by an EMF induced in a circuit due to a change in the magnetic flux linking the circuit with another. (See *Induced EMF,* also *Induction.*)

INDUCED E.M.F.—The electromotive force induced in a conductor or body. The phenomena of induced EMF (electromotive force) is the basis of operation of generating machines. Here a conductor is rotated or moved in a field of force, the action causing a change in the flux lines linking the circuits or the conductor. An EMF may also be induced by placing a coil in inductive relation to another coil through which alternating current is passing. Here the transfer is caused by induction. (See *Induction.*)

INDUCTANCE—The broad term used to designate any wire wound coil as used in radio practice for tuning units, inductive couplers and any variety of purpose. Actually the term is derived from self-induction or self-inductance, a property of a coil of wire by virtue of which it sets up a counter EMF (electromotive force) which serves to oppose the original EMF passing through it. When a certain circuit has inductance, it is to say that a number of turns of wire possessing self-induction are present in the circuit. The greater the inductance in a circuit the greater its opposition to the passage of an alternating current. The unit of inductance is the Henry. This is defined as the self-induction of a circuit or coil when the induced EMF is one volt with the inducing current varying at the rate of one ampere per second. (See *Alternating Current, Henry,* also *Inductance Coils.*)



A type of antenna inductance used in radio transmission.

INDUCTANCE, ANTENNA—Inductance (coil) placed in antenna circuit of transmitting set for purpose of increasing wavelength of the open or antenna circuit to any desired level. It is generally referred to as an antenna loading inductance or loading coil. In high power transmitting stations it is very often the case that the natural period or fundamental wavelength of the antenna is not as great as the intended operating wavelength. In this case a loading inductance is used to bring it up to the desired value. In some instances the fundamental wavelength is too high, in which case a condenser is placed in series to reduce the wavelength and then a few turns of inductance placed in series with the condenser and antenna for the purpose of tuning. Such inductances must be of a very rugged nature when high power is used, generally consisting of a comparatively few turns of heavy copper ribbon mounted on high tension insulators. The illustration shows a common form of antenna inductance used in radio transmission. (See *Loading Inductance,* also *Tuned Antenna.*)

INDUCTANCE COILS—Any coil of wire wound in such a manner as to possess the property of self-induction. Such a coil may be in almost any conceivable form, providing the turns are separated or insulated from each other. Inductance coils are a very necessary part of radio circuits, being used in conjunction with condensers to obtain resonance or desired wave-length. Such coils can also be arranged as separate circuits and placed in inductive relation to each other, thus permitting energy present in one to be transferred through induction to the other. The most common example of inductance in a receiving set is that of a tuning coil or vario-coupler. The illustration shows several forms of inductances known as tuning inductances. (See under separate headings as follows: *Inductance, Loading, Tuning, Tapped,* also *Inductance, Units of.*

Honeycomb type inductance coils.

Low-loss air-wound inductance coil made especially for tuned radio frequency work.

INDUCTANCE, DISTRIBUTED—Added inductance distributed throughout the length of a cable or telephone line to compensate for the capacity of the line. (See *Distributed Inductance.*)

INDUCTANCE, LOADING—Literally an inductance to load a circuit. The term is used to designate any inductance coil or unit used in series with the antenna for the purpose of increasing the wave-length of the circuit. (See *Inductance, Antenna.*)

INDUCTANCE, MEASUREMENT OF—Any process or means of determining the inductance value of a coil or circuit. The usual method is by formula. (Fully described under *Measurement of Inductance.*)

INDUCTANCE, MUTUAL—Symbol M. The number of linkages of flux lines or the flux that is common or mutual to two circuits which are adjacent to each other or inductively coupled. It is generally defined as the amount of the *flux* (q.v.) which is common to two linked circuits per unit of current flowing in the inducing circuit. In the illustration circuit A contains an inductance L_1 which is being traversed by an alternating electromotive force. Circuit B contains merely an inductance L_2 and a measuring device, M. Now, as the alternating E.M.F. passes through coil L_1 it sets up a field of force, or rather flux lines as shown. These lines link with the coil L_2 and an alternating E.M.F. is set up. Now, suppose that the inducing current flowing in circuit A is changing at the rate of one ampere per second and an E.M.F. of one volt is induced in the circuit B, or rather in coil L_2. We then say that the mutual inductance of the two circuits will be one henry. This is the same unit used for self-inductance and in fact, mutual inductance and self-inductance are virtually the same thing.

The effect of mutual inductance must be taken into consideration when measuring the fundamental wave-length, capacity or inductance of an antenna. That is to say, where a number of parallel wires are used, the mutual inductance between them must be taken into consideration as well as other values or constants. (See *Self-Inductance, Mutual Inductance, Induction, Coupling* and *Induced E.M.F.*)

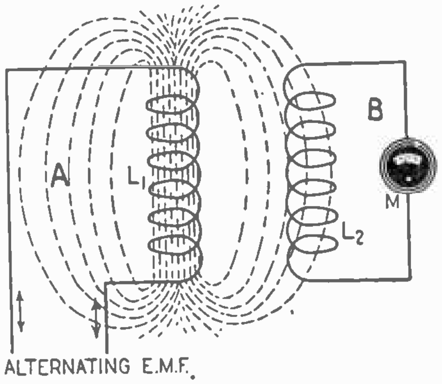


Diagram which illustrates the mutual inductance between coil L_1 in circuit A and coil L_2 in circuit B.

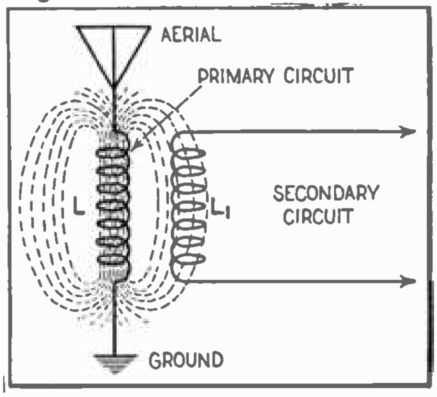
INDUCTANCE, REACTANCE—Symbol x—The *reactance* present in a coil possessing self-inductance. The self-inductance in such a coil opposes the flow of alternating current due to the back *electromotive force* set up as a result of the changing magnetic field of the current. *Inductance reactance* (or *inductive reactance*) is the term used to define this opposition. *Inductance reactance* acts similarly to *resistance* (q.v.) in that it opposes the flow of an electric current. It is measured in *ohms* (q.v.), just as *resistance* is measured. It should be noted, however, that *inductance reactance* only opposes the flow of alternating currents, whereas resistance opposes the flow of both direct and alternating currents. Furthermore, resistance in offering opposition to current flow consumes power, while *inductance reactance* merely takes up energy from the circuit momentarily while current is increasing and thereafter gives it back while the current is decreasing.

The combined opposition offered to the flow of alternating current by the resistance and the inductance reactance of a circuit is called the *impedance* (q.v.) of that circuit. The voltage drop due to resistance is in *phase* (q.v.) with the current. The voltage drop due to *inductance reactance* is 90 degrees in advance of the current.

Expressed as a formula, $x = \sqrt{Z^2 - R^2}$, where x is the inductance reactance, Z is the impedance and R is the resistance, all measured in ohms.

Knowing the *frequency* (q.v.) of the alternating current and the inductance of the circuit through which this current flows, it is possible to calculate the *inductance reactance* by using the formula $x = 2\pi fL$, where π is a constant equal to 3.1416, f is the frequency in *cycles* per second, and L is the *inductance* of the circuit in *henry's* (q.v.). This formula is sometimes abbreviated by substituting the symbol ω (omega) for $2\pi f$. From the formula it can be seen that the *inductance reactance* increases directly both with the inductance of the circuit and with the frequency of the current flowing. (See *Current,* also *Electromotive Force, Resistance, Reactance.*)

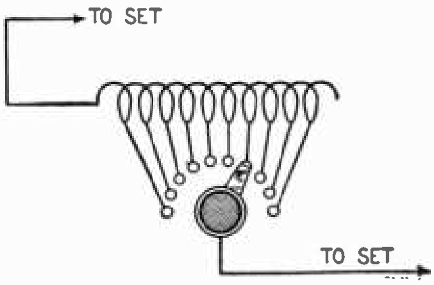
INDUCTANCE, RECEIVING—Broadly, any form of inductance used in receiving circuits. The term thus includes all types of coils for tuning purposes, such as couplers, tuned transformers, variometers, etc. The illustration shows a common form of tuning inductance. Here the coil L is an inductance in the aerial circuit and L_1 the coil in the secondary circuit. Here the energy from the aerial traverses coil L and by induction is transferred to coil L_1. (See *Tuning Coil, Vario-Coupler, Receiving Circuit.*)



A form of tuning inductance sometimes used in radio receiving sets.

INDUCTANCE, SELF—Symbol L—An alternate term with self-induction for the *inductance* (q.v.) due to the field of force produced by the circuit itself. It is virtually the same as mutual inductance. For example, in a coil of wire being traversed by alternating currents the adjacent turns may act upon each other on the principle of mutual induction between two separate adjacent circuits. The induced currents are the result of self-induction. (See *Self-Induction,* also *Mutual Inductance* and *Induction.*)

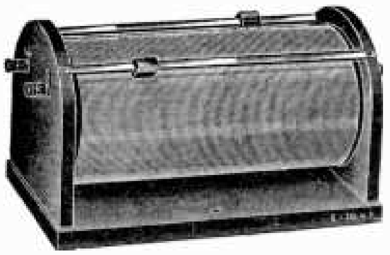
INDUCTANCE, TAPPED—Any type of inductance having taps for connecting at different points on the coil in order to vary the inductance value. The illustration shows a form of tapped inductance. Here the taps at different portions of the coil are connected to switch points and the switch lever permits instant change to any of the available values. (See *Inductance Coils,* also *Tuning Coil.*)



A tapped inductance which permits inductance to be added or taken out of the circuit by rotating the lever switch.

INDUCTANCE, UNITS OF—The measuring units for inductance. The practical unit is the henry (H), the value of inductance which, if current varies at the rate of one ampere each second, results in an *induced electromotive force* (q.v.) of one volt. When we speak of an induced E.M.F. of one volt, the volt is used as a practical unit. Under the electromagnetic system of units, the absolute unit of induced E.M.F. is known as the abvolt. This unit is very small, 100,000,000 of them being required to equal one volt. We thus say that the volt of induced E.M.F. is equal to $1x10^8$ abvolts. The electromagnetic unit of E.M.F., or the abvolt, is defined as the E.M.F. induced in a conductor cutting one line of magnetic force each second. As we have shown that one volt is equal to $1x10^8$ abvolts of induced E.M.F., and since one ampere is equal to $1x10^{-1}$ abamps of current (see *Units, Electromagnetic*) then the unit of inductance or one henry $= \dfrac{1x10^8}{1x10^{-1}}$ or) $1x10^9$ abhenrys. The unit of inductance (the henry) being too large for practical purposes, the *milli-henry* (one-thousandth henry) or the *micro-henry* (one-millionth henry) are commonly used. Occasionally the *centimeter* is used as a measure of inductance, being the thousandth part of a micro-henry or a *milli-micro-henry*. The milli-henry is written as $1x10^{-3}$ henry, the micro-henry as $1x10^{-6}$ henry, and the centimeter as $1x10^{-9}$ henry. (See *Induced Current, Induced E.M.F., Induction, Electromagnetic,* also *Units.*)

INDUCTANCE, VARIABLE—Any coil possessing self-inductance and being arranged in such a manner that the value of the inductance can be changed at will. The simplest form of variable inductance is the sliding contact tuner. This is merely a coil of wire of any predetermined value (maximum) mounted and arranged with a sliding contact moving over the wires, which are bared of insulation at a certain point to permit contact. By using the sliding contact as one connection and either end of the coil as the other lead, the effective value of the inductance in the circuit may be varied within the limits of the coil itself. Other forms of variable inductance include the variometer, vario-coupler and various modifications. The illustration shows the two more common forms of variable inductance. (See *Inductance,* and *Inductance Coils.*)



A sliding contact tuner formerly used in radio receiving sets.

Variable inductance known as a variocoupler.

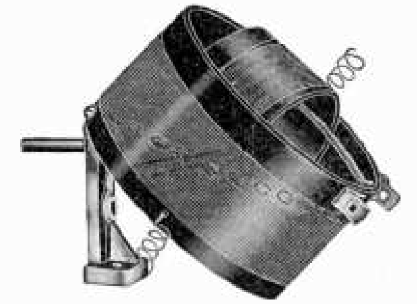

Illustration by courtesy of Radio Specialty Co.
Another type of variocoupler.

INDUCTANCES IN PARALLEL—Coils possessing the property of self-induction or self-inductance, connected in parallel or shunt to each other. The illustration shows two standard coils connected in a circuit in this manner. The effective inductance is less than that of either coil alone. (See *Inductance Coils.*)

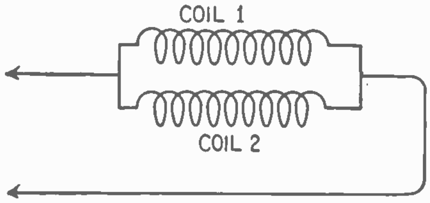

Diagram showing connection of two inductance coils in parallel in a circuit.

INDUCTANCES IN SERIES—Coils possessing the property of self-induction, connected in series in a circuit. The illustration shows two coils connected in series in a circuit. Here the effective inductance value is the sum of the separate inductances. (See *Inductance Coils.*)

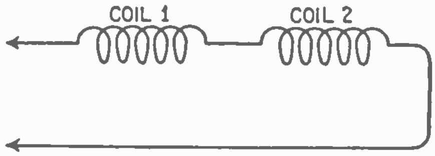

Diagram showing two inductance coils in series in a circuit.

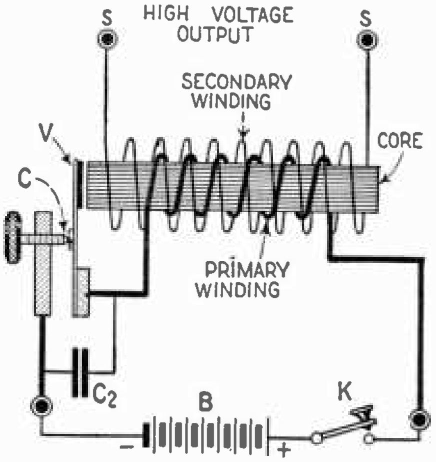
INDUCTION—The influence exerted by one field of force (electromagnetic or electrostatic) on another or on a conductor. Whenever a magnetic field interlinked with an electric circuit is changed, an *electromotive force* (q.v.) is induced in that circuit. The magnetic field is considered to originate from the heart of the conductor, spreading out concentrically from the conductor as the current increases and shrinking back into the center of the conductor as the current decreases. In either case, the conductor is cut by the magnetic field, and in accordance with the *law of electromagnetic induction* (q.v.) an electromotive force is induced in the circuit proportional in amount to the rate of change of the magnetic field and acting in a direction which would, by producing a current, tend to oppose the change.

A bothersome type of electromagnetic induction sometimes occurring in radio takes place when a radio aerial is run parallel to a high-tension line or even a trolley line. The varying field of force about the high-tension line sets up, by induction, a corresponding field in the parallel aerial, thus causing a disturbing hum in the loud speaker. Such a condition can usually be eliminated by running the aerial at right angles to the power line. By doing this, induction between the two conductors is reduced to a minimum.

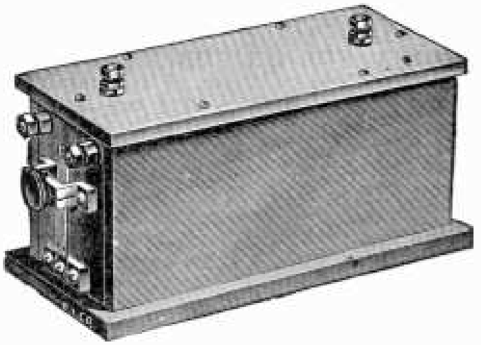
Electrostatic induction is a re-arrangement of an electrostatic field whereby a body in the neighborhood of a charged body will have an opposite charge induced on it. An *induction machine* (q.v.) known as the Wimshurst utilizes the principle of electrostatic induction.

INDUCTION BRIDGE—Also called inductance bridge. A balance arranged similarly to a *Wheatstone Bridge* (q.v.), used in induction measurement. (See *Induction, Measurement of Inductance,* also *Induction Density.*)

INDUCTION COIL—A form of transformer, having a primary winding arranged with a means of making the direct current applied to it, pulsate. Essentially a transformer with open magnetic circuit, carrying a pulsating direct current which induces a high voltage, alternating current in the secondary by means of the step-up effect of the windings. The illustration shows a typical form of induction coil and the associated circuits for producing high voltages. Here, there are two windings, a primary and a secondary, over and insulated from a core, composed of a number of soft iron wires. The primary is arranged with a key, K, and a battery, B, to supply direct current to the circuit. When the key is depressed the current flows through the primary circuit, including the contact C and the vibrator V. The core becomes *saturated* (q.v.) or magnetized and attracts the armature or spring V. As this spring is drawn toward the core it breaks the contact between the spring and the contact post. This, of course, breaks the circuit from the bat-



A typical form of induction coil showing diagram of connections, vibrator, core, battery, condenser and key.



A form of spark coil.

tery and the flow of current stops, resulting in the collapse of the flux through the core. When the magnetic attraction ceases the spring goes back into normal position and the contact is once more complete, allowing current to flow through the windings. This make-and-break process is more or less rapid and is repeated continuously. By induction, an alternating E.M.F. (electromotive force) is created in the secondary windings, and as these windings have many more turns than the primary winding the induced E.M.F. will be proportionately greater. If the breaks occur at a rate of from thirty to one hundred per second, the key can be used to interrupt the primary current and produce at the secondary terminals a high voltage suitable for spark transmission. (See *Induction, Transformer, Spark Coil.*)

INDUCTION COIL, PRIMARY—The simplest form of induction coil. It consists of an iron core wound with a relatively large amount of low resistance copper wire, which is well insulated. The iron core increases the effect of self-induction and the size or length of the core and the number of turns of wire determine the efficiency of the coil. Such coils are used extensively for low tension ignition. (See *Induction Coil.*)

INDUCTION COIL, SECONDARY—A type of induction coil employing a primary and secondary winding. The primary is wound over an iron core and the secondary is generally wound over the primary. (See *Induction Coil.*)

INDUCTION DENSITY—A term occasionally used to refer to the density of flux in a magnetic or electromagnetic field of force. It is synonymous with flux density, under which heading it will be found more fully defined. (See *Induction, Electromagnetic,* also *Gauss,* and *Induction, Magnetic.*)

INDUCTION, ELECTROMAGNETIC—The production or *inducing* of electric currents in a conductor when it is moved in a magnetic field of force in such manner as to cut magnetic lines of force. The simplest example of this phenomena is the Faraday experiment in which he discovered that a wire with its ends joined, when moved rapidly in the field of a magnet, would result in current being induced in the wire or conductor. All dynamo electric machinery is based upon this principle of electromagnetic induction, as are also alternating current transformers and various other electrical devices.

In the illustration is shown the theory of production of current by electromagnetic induction. Fig. 1 shows a coil of wire placed in a uniform magnetic field of force between two magnets. Here the coil is assumed to have been moved from A to B in the same plane. This is known as a *motion of translation,* and the field being uniform at all points the same number of lines pass through the coil at both points. Therefore no current is induced in the coil and a sensitive instrument placed across the leads, C, C, would show no current present. In Fig. 2 the same coil is shown at A in its original position. Here, however, it is rotated, and when in position B it is apparent that less lines of force pass through it. We have thus fulfilled the conditions for inducing current, and if the instrument is placed across the leads, C, C, the presence of electric current will be indicated. If the motion of rotation is continued the number of lines of force passing through the coil will continue to increase and decrease and current will be produced in the coil as long as the motion persists. From the above it will appear that current can be induced either by rotating the coil around any axis in its plane, or by tilting it in its motion across the field. The coil of wire in this case is known as an *inductor* because the current is induced in it. It is also referred to as a *conductor* when describing the production of alternating currents.

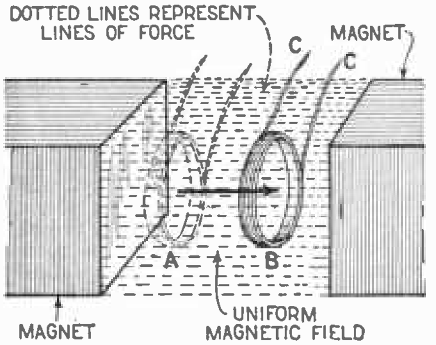


Fig. 1. Coil of wire in a uniform field moving parallel to direction of the field.

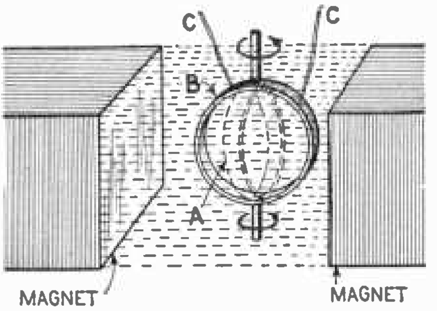

Fig. 2. Same coil, showing cutting of field due to the rotation of the coil.

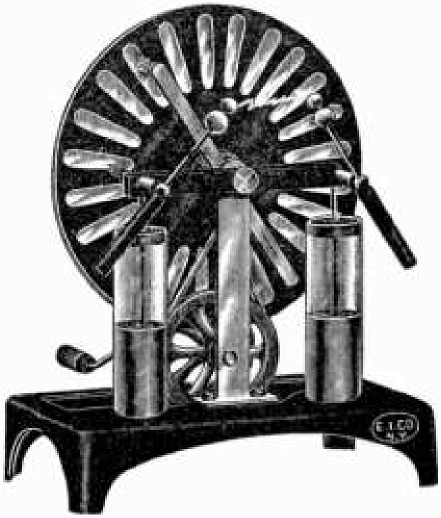
Now it was stated that current is induced in the inductor whether the lines of force through it are *increased* or *decreased* by its motion through the field. We can reduce the action to two simple rules. First, the relative motion between an inductor and a magnetic field must be such that the number of lines passing through the inductor are altered, i.e., increased or decreased. Second, the electromotive force induced in the inductor circuit will be proportional to the rate of increase or decrease in the number of magnetic lines embraced by the inductor circuit. We know from the *Lenz Law* (see *Alternating Current, Theory of Production of*) that current will flow in the inductor in a direction dependent upon whether the lines of force through it are being increased or decreased, and as the inductor is being rotated continuously the current will change direction with each change in the number of lines. (See *Alternating Current, Alternator, Electromotive Force, Fleming's Rule, Laws of Electromagnetic Induction, Lenz's Law.*)

INDUCTION, ELECTROSTATIC—The production of an electric charge in a body due to the presence of a nearby conductor having an opposite charge. The effect is known as a displacement of electric charge. (See *Electrostatic Induction,* also *Induction.*)

INDUCTION INSTRUMENTS—Measuring instruments used in electrical and radio practice, which make use of the principle of electromagnetic induction. Such instruments are used for measuring alternating currents, the torque or actuating force for the indicator being produced by the effect of a rotating field on a metal disc or drum which is not connected to the circuit carrying the currents. The instruments operate on the same basic principle as the *induction motor* (q.v.).

INDUCTION MACHINE—A machine wherein the primary and secondary windings rotate with respect to each other. Examples of induction machines are induction motors, certain types of frequency converters and induction generators. An entirely different kind of induction machine is one which generates low potentials, utilizing the principle of *electrostatic induction* (q.v.). The most common form of this type is known as the Wimshurst (q.v.).



A common type of induction machine known as the Wimshurst.

INDUCTION, MAGNETIC—The communication of magnetism to a metal by the presence of a magnet without any actual contact. The effect of the presence of a magnet in the neighborhood of a piece of magnetic material is to induce magnetic poles in it. (See *Magnetism, Magnetic Poles, Induction,* also *Induction, Electromagnetic.*)

INDUCTION MOTOR—An alternating current motor in which the input current is passed through the field coils only, the armature not being connected to the external circuit. Here the armature is rotated by currents induced by the varying field set up through the field coils. The induction motor is the most widely used of the alternating current types, maintaining a practically constant speed from no load to full load and being simple and rugged in construction. This type of motor has two windings, the primary and secondary, and two members called stator and rotor. The primary winding is usually on the stator and the secondary winding, which is therefore customarily on the rotating member, is not connected electrically to the primary. Current to operate the rotor is induced in the secondary windings by the magnetic action of the current circulating in the primary windings. (See *Alternating Current,* also *Induction, Electromagnetic.*)

INDUCTION, MUTUAL—The interference or mutual effect between two electric or magnetic fields, due entirely to their proximity and without electrical contact. The mutual induction or electromagnetic influence of one circuit upon another is measured by the coefficient of mutual inductance or induction. (See *Mutual Induction,* also *Mutual Induction Coefficient,* and *Mutual Inductance.*)

INDUCTION REACTANCE—The value in ohms of the inductance in an electrical circuit as distinguished from the capacity or capacitive reactance. It is the part of the total impedance in an alternating current circuit that is due to the presence of inductance in the circuit. (See *Inductance Reactance, Ohm, Impedance.*)

INDUCTION REGULATOR—A system of regulating the voltage in alternating current circuits, employing a choke coil with removable core, or some form of variable ratio transformer which will assist or oppose the current by readjustment of the ratio. (See *Choke Coil, Reactance,* and *Variable Ratio Transformer.*)

INDUCTION SCREEN—A metal screen or shield placed between two electrified or magnetic bodies to reduce the effect of induction between them. A common example of this in radio usage is the placing of a sheet of metal between two coils, the sheet being generally grounded, or the provision of a metal *shield* (q.v.) entirely around each coil. This reduces the interaction of the fields of the coils, which leads to losses or howling, especially in *tuned radio frequency amplifiers* (q.v.). (See *Shielding.*)

INDUCTION UNIT—The *henry,* defined as the induction in a circuit when the electromotive force induced in that circuit is one *international volt* (see *volt*) while the inducing current varies at the rate of one ampere each second. (See *Henry,* also *Self-Induction.*)

INDUCTION VOLTMETER—See *Induction Wattmeter,* also *Induction Instruments.*

INDUCTION WATTMETER—An instrument for measuring the power delivered to a circuit. The induction type wattmeter operates on a principle used in the induction motor, a magnetic body attached to a pointer being rotated by a changing magnetic field. (See *Induction Motor,* also *Wattmeter.*)

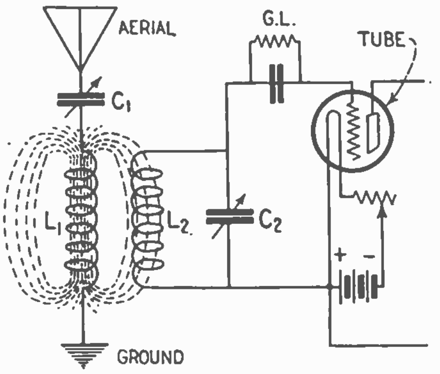
INDUCTIVE CAPACITY—Generally referred to as the specific inductive capacity in rating the dielectric qualities of a substance. It is the quality of any dielectric substance by reason of which it permits electrostatic induction through it. The term is more or less synonymous with *Dielectric Constant,* the latter, however, being generally given in terms of a numerical value representing its comparative specific inductive capacity with some material taken as a standard. (See *Dielectric Coefficient and Constant,* also *Specific Inductive Capacity.*)

INDUCTIVE CIRCUIT—An electrical circuit possessing inductance but not capacity. (See *Inductance,* also *Capacity.*)

INDUCTIVE CONNECTION—A connection between two circuits entirely through the property of induction and without any metallic contact. The two coils, primary and secondary, of a vario-coupler as used in radio receiving circuits, are said to have inductive connection where the windings are separate. Thus, the primary coil will be in one electrical circuit and the secondary coil will receive energy from it by means of induction. (See *Induction, Coupling, Vario-Coupler.*)

INDUCTIVE COUPLER—The inductances or coils placed in inductive relation or inductively connected with each other for the purpose of transferring energy by electromagnetic coupling. Any device consisting of a primary and secondary inductance and used to transfer energy from one circuit to another by means of induction. (See *Coupler, Induction, Vario-Coupler.*)

INDUCTIVE COUPLING—The coupling or connection between two circuits by means of electromagnetic induction.



The utilization of a vario-coupler to inductively couple the aerial system with the rest of a receiving circuit.

The most common example of inductive coupling is in radio receiving circuits where coupling coils are used to associate the primary or aerial circuit with the secondary circuit. In the illustration L_1 is the primary of a vario-coupler and L_2 the secondary. The primary is inserted between the ground and aerial and the secondary is connected to the grid and filament of the detector tube. The variable condenser C_1 tunes the primary circuit, the primary coil also being variable by means of taps if desired. The variable condensed C_2 tunes the secondary inductance and the condenser and grid leak GL are the customary elements in the detector grid circuit. As the high frequency currents traverse the primary circuit, passing through coil L_1, lines of force are set up as shown and some of these lines embrace the secondary coil L_2, inducing similar currents in the secondary or vacuum tube circuit. The balance of the circuit is not shown for obvious reasons. This type of coupling between circuits is much more selective than the straight coupling or conductive coupling. (See *Coupling,* also *Conductive Coupling.*)

INDUCTIVE DISTURBANCE—The disturbing effects sometimes experienced in radio broadcast or telegraph reception due to induction from nearby power or telephone lines. This sometimes occurs when an aerial is strung close to and parallel with a line carrying high voltages, and occasionally is experienced with telephone wires near the receiver. (See *Induction.*)

INDUCTIVE DROP IN VOLTAGE—The drop or diminution of voltage in an alternating current circuit due to the presence of inductance. Inductance in a circuit carrying alternating current tends by reason of the self-induction to set up a counter-electromotive force which opposes the original E.M.F. (electromotive force), thus reducing the effective voltage in the line. (See *Inductance,* also *Inductance Reactance.*)

INDUCTIVE EMF—The electromotive force due to induction. That is to say, the electromotive force induced in a circuit. (See *Induction, Induced EMF.*)

INDUCTIVE REACTANCE—The reactance or portion of the total impedance in a circuit, due to the presence of self-inductance. (See *Inductance Reactance,* also *Impedance.*)

INDUCTIVE RESISTANCE—A resistance element possessing inductance, as for example a resistance coil, which also has the property of self-inductance. (See *Resistance,* also *Inductance.*)

INDUCTIVE RISE—The rise in voltage noted in transformers or other alternating current apparatus due to the presence of a *leading current* (q.v.). (See *Inductance,* also *Transformer* and *Angle of Lead or Lag.*)

INDUCTIVITY—Another term used alternately with dielectric constant and conductive capacity, referring to the dielectric properties of materials. (See *Dielectric Coefficient or Constant,* also *Inductive Capacity.*)

INDUCTOR—The coils or conductors in which current is induced through electromagnetic induction, as in an induction motor. Any conductor in which current is induced due to a change in magnetic flux may be called an inductor. (See *Induction, Inductor Alternator,* and *Induction Motor.*)

INDUCTOR ALTERNATOR—An alternator for producing high frequency currents. It employs the *armature* and *field windings* on projections inside the *stator,* the rotor consisting of a drum carrying a magnetic material. By using a *rotor* of solid steel, very high speeds and consequently high frequency currents are obtainable. The *Alexanderson Alternator* (q.v.) is an inductor type alternator. (See *Alternator,* also *Inductor.*)

INDUCTOMETER—A device or instrument used to measure self or mutual inductance. The basic principle depends on the relation of two coils, a primary and secondary, one of which can be moved in its relation to the other, the inductance, either self or mutual, being registered on a scale calibrated in units of inductance. (See *Inductance, Mutual,* also *Inductance, Self.*)

INERTIA—In physics, the property of a body which tends to keep it in a state of rest or to resist any change of motion. (See *Inertia, Electric.*)

INERTIA, ELECTRIC—Term occasionally applied in place of *self-inductance* (q.v.). When a current flows in a circuit possessing inductance and the circuit is broken, current continues to flow for a short time. It thus appears that in this instance the resistance alone will not stop the flow of current on the instant of breaking the circuit, an interval of time being required as in the act of bringing to rest a moving material. (See *Inertia, Inductance, Self,* also *Resistance.*)

INERTIA, ELECTROMAGNETIC—The same as electric inertia, being, in effect, the energy required to start or stop a a current in a circuit possessing self-inductance. (See *Inertia.*)

INFERRED ZERO—A term used in connection with certain instruments having extremely high sensitivity, where the zero is removed from the scale. In a galvanometer, for example, the zero position on the scale may be merely assumed, an electrical or mechanical force being applied to bring the zero off the scale entirely, only a part of the full range of the full scale being utilized. (See *Galvanometer.*)

INFLUENCE—A broad term signifying action at a distance, as by electrostatic induction, without any actual physical contact. It is considered as the effect of a charged body on a neutral body or conductor coming within its field. (See *Field*, also *Induction.*)

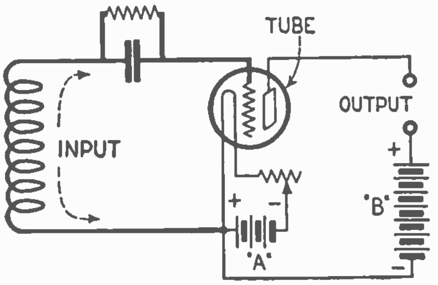
INFRA-RED RAYS—The heat waves or rays which lie between light waves and electromagnetic (radio) waves. The infra-red lies at the extreme low frequency end of the invisible spectrum, the wave-length being extremely high and the frequency conversely low. (See *Wave*, also *Ether Waves.*)

INFRA-SATURATION PART OF CHARACTERISTIC—In a characteristic curve of a vacuum tube, this is the portion over which the tube is operable, or the operating portion of the curve. (See *Characteristic Curve*, also *Vacuum Tube, Theory of Operation.*)

INITIAL MAGNETIZATION — The initial stages of magnetization as distinguished from the effect after saturation has been approached or reached. (See *Saturation, Magnetic.*)

INPUT—Generally speaking, the energy absorbed by a machine as distinguished from the output energy. (See *Input Voltage*, etc.)

INPUT CIRCUIT OF VACUUM TUBE—Vacuum tube circuits are generally divided into three separate classes or circuits. The first is the circuit including the filament, i.e., the "A" battery circuit through the filament. The second is the circuit between filament and grid and the third is the circuit between filament and plate. The filament grid circuit is called the input circuit because the incoming oscillations are impressed on this circuit. The filament plate circuit is known as the output because the rectified or amplified currents are taken from across the plate and filament. The illustration shows both input and output circuits, the former in heavy lines and the latter in light lines. The input circuit of a tube is also known as the *grid circuit.* (See *Grid, Filament, Plate,* also *Vacuum Tube, Theory of Operation.*)



Input and output circuits of a vacuum tube receiver. Heavy lines show the former, light lines the latter.

INPUT VOLTAGE — The voltage impressed on a circuit or machine as distinguished from the output voltage. (See *Input.*)

INSTANTANEOUS CURRENT — The value of current in an alternating current circuit measured at any instant, as distinguished from the average current value. (See *Instantaneous Values.*)

INSTANTANEOUS VALUES—The actual value of an alternating current, E.M.F. (electromotive force), etc., measured at any instant. This value may be anything from zero to maximum or peak It must be remembered that in an alternating current the current and voltage are both variable factors, rising to a maximum in one direction, then falling to a minimum, and then rising to a maximum in the other direction. Thus, a wattmeter measures the actual value of current and voltage at each instant and the instantaneous torque at each instant is proportional to the instantaneous power. The average torque acting on the moving element during each cycle of the current and voltage is then proportional to the average power. If we measure an alternating current with an ammeter, and then measure the voltage with a volt-meter, the product of the two will be the apparent power, (apparent watts). It should be noted that these instruments measure effective and not instantaneous values. In order to ascertain the true *watts* (q.v.), it is necessary to multiply the apparent watts by the power factor. A wattmeter measures true watts. (See *Effective Electromotive Force, Power Factor,* also *Wattmeter.*)

INSTANTANEOUS VOLTAGE OR PRESSURE—The voltage or pressure in an alternating current circuit measured at any instant, as distinguished from the average value of E.M.F. (electromotive force). (See *Instantaneous Values.*)

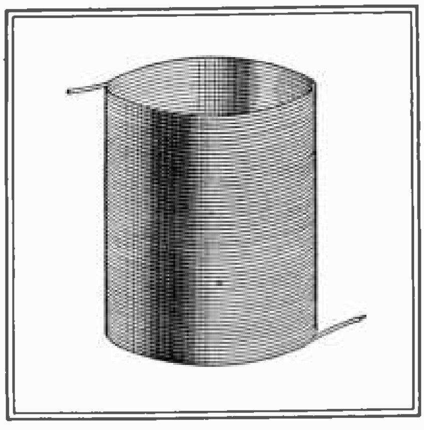
INSTRUMENTS, MEASURING — In electricity or radio, any device or instrument for recording or indicating values, such as an ammeter for indicating the current in amperes, or a voltmeter to indicate the electromotive force in volts. (See *Ammeter* or *Ampere Meter, Voltmeter, Wattmeter.*)

INSTRUMENT SHUNTS—In electrical measuring instruments, a branch conductor, generally of relatively heavy wire or metal strip, joining the meter circuit at two points and forming a parallel circuit, thus dividing the current and protecting the delicate windings of the instrument. (See *Shunt,* also *Ammeter,* or *Ampere Meter, Hot Wire Ammeter.*)

INSULATE — To provide a protective covering or shield for a part or conductor, preventing flow of electricity from it or the passage of electricity through it. A conductor of electric currents is generally insulated to prevent the flow of the electricity through contact with other parts or conductors except where contact is intended to be made. (See *Insulated Wire.*)

INSULATED WIRE — Wire, generally copper, covered with insulating material to prevent leakage of the electric current. Standard insulated wire of the heavier gauges is usually covered with a layer of rubber and an outer covering of braided cotton. (See *Lead-In,* also *Insulation.*)

INSULATING COMPOUND—Liquid or easily liquifiable mixture of some insulating material, used in radio to coat cardboard tubes and to cover any open point of contact in an otherwise insulated conductor or part. Coils are very often coated with shellac or some other liquid and quick-drying substance. This serves to hold the windings in place and also acts as a protective covering. A very valuable application of an insulating liquid is shown in the illustration. Here an inductance is wound on a form of stiff paper or cardboard tube and after being completed is coated with one or two treatments of collodion or similar liquid. (Shellac introduces losses through the medium of *distributed capacity.*) The form is then cut away and the coil remains self-supporting as shown. This method produces a coil having the least possible dielectric and distributed capacity loss for a cylindrical shape. (See *Dielectric, Inductance Coil, Low Loss Coils, Collodion.*)



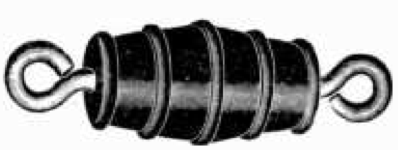
Air core coil made rigid by use of insulating compound.

INSULATING MATERIALS—Non-conducting substances, for example, glass, hard rubber or porcelain, which do not conduct electric currents. Strictly speaking, there are no perfect insulating materials. The most perfect insulators are certain gases, although at low pressure these may act as very good conductors. The more common insulating materials in radio are the following: mica, glass, bakelite and hard rubber, the insulating values being in that order. When we speak of the insulating property of a material we are actually referring to its resistance, a good insulator offering infinite resistance to the passage of electric currents and poor ones being relatively good conductors. The term *specific resistance* is used extensively in connection with the insulating properties of materials. This term is defined as the resistance of a piece of material of unit length and unit cross-sectional area at a given temperature, the value being given in ohms. (See *Dielectric Coefficient and Constant, Table of,* also *Ohms, Resistance* and *Insulate.*)

INSULATING PROPERTY—The ability of any material to *insulate* electric currents. Accepting mica as an insulator, we say that its insulating properties are superior to glass or hard rubber. (See *Insulating Materials,* also *Dielectric Coefficient and Constant* and *Insulation of Aerial.*)

INSULATION—Broadly any material or gas used to insulate electric currents. In radio, insulation plays a most important part, providing protective coverings or separators between conductors of the electric current and between the conductors and the ground. Insulation is really a material or gas having extremely high specific resistance; the better the insulating property, the higher the resistance to passage of electricity. There is no clearly defined line of demarcation between an insulator and a conductor, a poor insulator being to some extent a conductor. (See *Bakelite, Conductor, Dielectric Coefficient and Constant, Insulations of Aerial, Panel.*)

INSULATION OF AERIAL—The means used in connection with an aerial for reception or transmission of radio waves, to prevent leakage or ground-



Aerial Insulator.

ing of the currents. The insulation of an aerial for reception purposes should be given very careful consideration. The wires may be suspended by means of small glass or porcelain insulators and the lead-in rubber covered wire, entering the building through a *lead-in insulator* (q.v.). The aerial for transmission must be accorded specially careful attention as far as insulation is concerned. The bare wires must be suspended with heavy duty insulators, capable of withstanding high voltages without *"breaking down."* The lead wire must be conducted into the building through a high-tension insulating tube or other lead-in device to prevent leakage of the current to the ground. (See *Aerial, Insulation of Aerial* and *High Tension Insulators,* also *Lead-In Insulator.*)

INSULATION RESISTANCE—The actual resistance in ohms, generally megohms, of the insulation of any conductor or piece of apparatus. If we assume two conductors, carrying separate currents and crossed so that the only protection would be the actual insulation of the wires, the insulation resistance would be the actual resistance in megohms from one path to the other. Conceivably a small current might leak from one conductor to the other, this current, of course, depending on the resistance of the insulation. The term "insulation resistance" is more easily understood when it is considered that an insulator or insulating material is merely a very poor conductor, or one having extremely high resistance to electric currents, there being actually no perfect insulator. (See *Insulation, Insulated Wire,* also *Conductor* and *Resistance.*)

INSULATION TESTER—An instrument or set of meters for testing the resistance of an insulator in fractional ohms, generally megohms. (See *Insulation Resistance.*)

INSULATOR—Any substance having insulating properties. *Insulators* are used to keep electric currents flowing in predetermined paths. It is necessary to use insulators on all electric circuits in order to prevent *grounds, leakage* and *short circuits.* Insulators are of the utmost importance in radio. At the transmitting end, where high voltages as well as high frequencies are used, the insulators must be specially designed to prevent leakage. A typical installation of insulators in use on the aerial system of a modern broadcasting station utilizes a 12-inch pyrex insulator at each end of each wire between the spreaders. A standard porcelain strain insulator is used every 14 feet on each guy wire. At each end of each guy wire a standard 24-inch porcelain insulator is used.

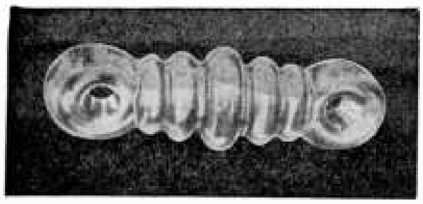


Illustration by courtesy of Corning Glass Works.
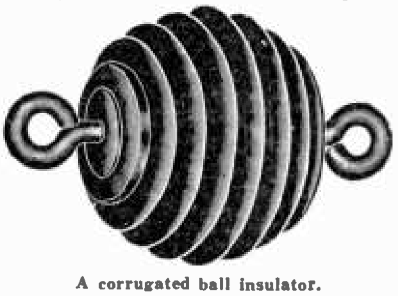
A typical small antenna insulator, showing corrugated surface.

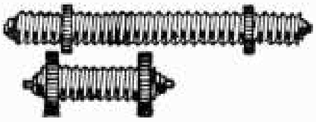


A corrugated ball insulator.

Insulators used on receiving antennas are made of porcelain, pyrex, rubber and composition. These are usually about 4 inches in length. Sometimes porcelain tubes are used as insulators to bring a *lead-in* (q.v.) into a building, but these have been generally superseded by flat *window lead-ins.*

INSULATOR, LEAD IN—The insulating tube through which a lead wire from a radio aerial enters a building, used to prevent grounding or leakage of the current by contact with another conducting surface. (See *Lead-In Insulator.*)

A flat window lead-in which permits entrance of lead-in into building without the necessity of boring holes.



Lead-in insulators of conventional type.

INTEGRATING DETECTOR—The name sometimes given to any detector which yields a response proportional to the total energy received from a spark train rather than to the maximum value of the current or voltage in the train.

INTEGRATING INSTRUMENTS—Meters so designed as to record the total quantity of electricity (ampere hours) or the total energy (watt-hours) passing in a circuit in a given time. (See *Ammeter* or *Ampere Meter,* also *Integrating Wattmeter.*)

INTEGRATING WATTMETER—An instrument which measures and records the total amount of electrical energy being consumed in a circuit. These instruments are also known as *recording watthour meters* (q.v.), *integrating watthour meters,* and sometimes are simply referred to as *watthour meters* (q.v.).

Broadly speaking the *integrating wattmeter* is a type of small motor whose rotations are counted by means of a worm on the armature shaft engaging a set of cogs working a counter. The construction is such that the average *torque* (q.v.) exerted by the motor is proportional to the average power taken by the load. In other words, the motor rotates at a speed directly proportional to the energy being expended. For direct current work, *integrating wattmeters* are either of the commutator type, such as the Thompson, Westinghouse and Duncan meters or of the no-commutator type, such as the Sangamo. The commutator type instruments operate on the *dynamometer* (qv.) principle. Meters of the no-commutator type are essentially motors whose armatures always cut the same direction flux. That is to say, they are essentially *homopolar* (q.v.) motors. The principle of operation of these meters is the law of motor action which states that a conductor, free to move and carrying a current whose direction of flow is at right angles to a fixed magnetic field, will be moved out of this field, and in a direction at right angles both to the direction of current flow and to the field. For alternating current work, *integrating wattmeters* are of the *induction* (q.v.) type. The principle of operation of these meters is identical to that of *induction motors* (q.v) having shunt and series windings stationary and so related and located as to produce a rotating field acting upon a closed rotable secondary. In the induction meter the secondary consists of a light aluminum disc. These meters may be either of *single phase* (q.v.) or *polyphase* (q.v.) construction. (See *Electro-dynamometer.*)

INTEGRATOR—A device which automatically, by means of clockwork, adds up and records on a dial items of calculation or measurement. The system used in a recording or integrating wattmeter. (See *Integrating Wattmeter.*)

INTENSIFICATION—Broadly an intensifying or increasing of the density of electric current, but specifically in radio it refers to the tendency of radio signals to increase in intensity under certain conditions. The phenomena of intensification is naturally closely related to fading, as obviously the intensification process must necessarily follow or be followed by a fading process. The tendency toward intensification is more pronounced toward night and generally on the shorter wavelengths, it being noted that quite often signals from a distant station will be increased in volume or intensity as much as fifty per cent or more between the late afternoon and late evening. While the periodic *fading* of signals and the subsequent increase in volume over regular periods, usually of a few minutes' duration, may be considered as *fading* and *intensification,* it is preferable to think of fading as one operation together with the subsequent increase in volume, and the term *intensification* as referring strictly to the change to greater volume that takes place toward night. (See *Fading,* also *Phenomena of Electric Wave Propagation.*)

INTENSITY OF ELECTRIC CURRENT—A term more or less in use to imply the strength of an electric current in amperes, the symbol I for current being derived from it. (See *Ampere, Current Density,* also *Intensity of Field.*)

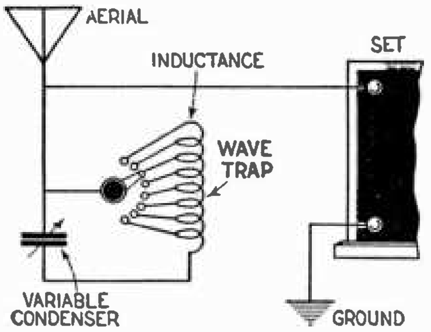
INTENSITY OF FIELD—The intensity or strength of the force exerted in a magnetic field. It is measured by its action or effect on a unit pole placed at any point in the field, the intensity of the field, of course, varying at different points. (See *Flux Density, Intensity of Magnetic Flux.*)

INTENSITY OF MAGNETIC FLUX—The strength of the force exerted in a magnetic field. (See *Intensity of Field,* also *Flux Density.*)

INTENSITY OF MAGNETIZATION—The density of force per unit cross-sectional area of a magnetized material. The extent of the magnetizing effect on a material placed in a magnetic field of force. This applies only to material in a magnetic circuit and should not be confused with the lines of force due to a field arising from the presence of neighboring currents or magnets. (See *Magnetization,* also *Intensity of Magnetic Flux.*)

INTERFERENCE—The interruption or interference with desired electromagnetic waves by undesired or extraneous waves. The interference of undesired broadcast or radio-telegraph signals with the desired signals. Also, broadly, the detrimental effect of power lines and other electric circuits on radio communication. Interference is encountered chiefly in receiving sets having poor *selectivity* (q.v.). In some instances interference may be due to the fact that another transmitter is operating on the desired wave-length, and being sufficiently close as to make it practically impossible to obtain clear signals from the desired station. Ordinarily, and where the effect is due to lack of sharp resonance or tuning, certain changes can be made in the receiver to sharpen the tuning, or if the disturbance is due to the transmitting stations and the receiver is normally sharp, various circuits can be employed to filter out the undesired signals. (See *Interference Preventer*, also *Wave Trap.*)

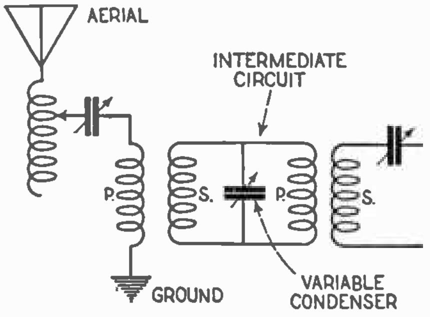
INTERFERENCE ELIMINATOR—A device or system as shown in the illustration for reducing or preventing reception of undesired signals in radio work. Practically all *interference eliminators* make use of a separately tuned inductance across the aerial and ground and in parallel with the receiving set. The inductance is usually tuned by means of a variable condenser which allows it to be tuned to the wave-length of the interfering signal. The interference can thus be by-passed to the ground. *Interference eliminators* of the kind described are generally known as *wave traps* (q.v.). A special form of interference due to atmospheric and electrical disturbances is known as *static* (q.v.). (See *Static Eliminator.*)



A wave trap or interference eliminator which dispenses with the ground connection.

INTERFERENCE PREVENTERS—Any arrangements either within the receiving set, or external to the set, for limiting or preventing interference. In addition to *interference eliminators* (q.v.) and static *eliminators* (q.v.) various other methods are utilized in radio to prevent interference. Thus the arrangement of a receiving set to give sharp tuning and great selectivity, results in the prevention of much interference. A method of preventing interference which has been used, is the utilization of filter circuits which can be tuned to pass any desired frequency and exclude all others. The use of the *loop aerial* (q.v.) results in great selectivity. The loop has a very pronounced directional effect and this in itself acts to narrow the field of stations offering possible interference. For example, if stations of very nearly the same wave length are in opposite or different directions and are sending at the same time, the loop permits selection of the station wanted, with no interference from the others.

INTERMEDIATE CIRCUIT—A closed circuit consisting of two inductance coils shunted by a variable condenser. One coil acts as primary to the secondary coil of the detector circuit and the other coil acts as secondary to the primary of the aerial circuit. A circuit such as this is sometimes referred to as a *multiple tuner intermediate* circuit and may be used as an interference eliminator.



A multiple tuner intermediate circuit.

INTERMEDIATE FREQUENCY—This is a frequency higher in number of oscillations than *audio frequency* (q.v.) but lower than *radio frequency* (q.v.). It is generally around 30,000 cycles or 10,000 meters wave-length. In the *super-heterodyne* (q.v.) the incoming signal is converted from the broadcast frequency to the so-called *intermediate frequency* at which it can be amplified by means of fixed winding transformers to almost any extent desired. The method of converting the incoming signal in a *super-heterodyne* from radio frequency to *intermediate frequency* is by the *beat* method. In this case an oscillating circuit controlled by means of a variable condenser so as to obtain any desired frequency, is brought into interference with the first detector and produces a *beat note* (q.v.) for the *intermediate frequency* which has all the characteristics of the original signal. In this way, no matter what the frequency of the intercepted signal may be, the intermediate frequency amplification is always carried on at a fixed wave-length, thus making for high efficiency. (See *Beat Frequency; Beats.*)

INTERMEMEDIATE FREQUENCY AMPLIFIER—An arrangement of tubes and transformers for stepping up the current, used in the *super-heterodyne* (q.v.) circuit. The intermediate frequency amplifier is located between the first detector and the second detector. (See *Intermediate Frequency.*)

INTERMEDIATE TRANSFORMER—The name given to the transformers used in the *intermediate frequency amplifier* (q.v.) of the *super-heterodyne* circuit. *Intermediate transformers* are often referred to as *intermediate frequency transformers*. They are *radio frequency transformers* (q.v.) but have an iron core and instead of tuning to a maximum of 550 or 600 meters they are designed to cover wave-lengths of 10,000 meters or higher. (See *Intermediate Frequency.*)

INTERMITTENT CURRENT—A current which flows irregularly or which is interrupted at intervals, or without continuity. The current obtained from a *magneto generator* (q.v.) is an interrupted or *intermittent current.* Such a current may be either alternating or direct. A magneto generator constructed to give direct current is equipped with a two segment commutator having a stationary brush in contact with it. (See *Pulsating Current.*)

INTERNAL RESISTANCE—Resistance within an electric source. In the case of a primary cell such as a dry battery, the internal resistance causes an interference with the flow of current. This varies in amount with the construction and materials of the battery.

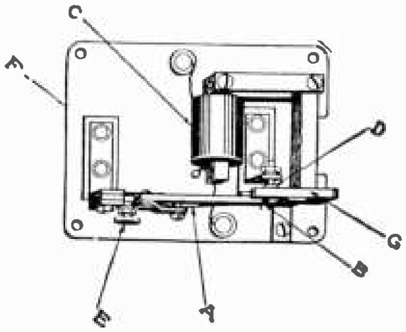
INTERNATIONAL MORSE CODE—This is also known as the *Continental code.* (See *Code.*)

INTERPOLE—A small magnetic pole placed between the main field poles of an electric generator for the purpose of obtaining better commutation. Interpole windings are connected in series with the armature winding and the load. The action of the interpole is exactly analogous to the shifting of the brushes, but when interpoles are used, brush shifting is dispensed with and the magnetic flux is shifted instead.

INTERRUPTED CONTINUOUS WAVES—abbreviation I.C.W.—These waves are obtained by the modulation at audio frequency, during signalling, of an otherwise *continuous wave* (q.v.). (See *Continuous Waves Key Modulated*, also *Continuous Waves Modulated at Audio Frequency.*)

INTERRUPTED WAVES—abbreviation I.W.—Interrupted waves are waves produced by modulation at audio frequency, of otherwise continuous waves. (See *Interrupted Continuous Waves.*)

INTERRUPTER—A combination of an electro-magnet with a vibrating armature which carries a contact point on a piece of spring steel fastened to the armature. When the electro-magnet attracts the armature the contact points are drawn apart thus interrupting the circuit. This action is only momentary for the spring again brings the circuit back to its original condition. The most important use of the interrupter in radio is as a *rectifying valve* (q.v.) in mechanical chargers. A typical vibrator panel is shown in the illustration. The armature, A, is the moving element. This carries at its outermost end a heavy Tungsten contact, B, which is caused to vibrate in synchronism with the supply current, by the actuating coil, C. When the current from the transformer is of the correct polarity and value the actuating coil attracts the armature, closing the charging circuit to the battery through the fixed contact, D. The contact end of the armature, A, vibrates within the air gap of the pole shoe, G.

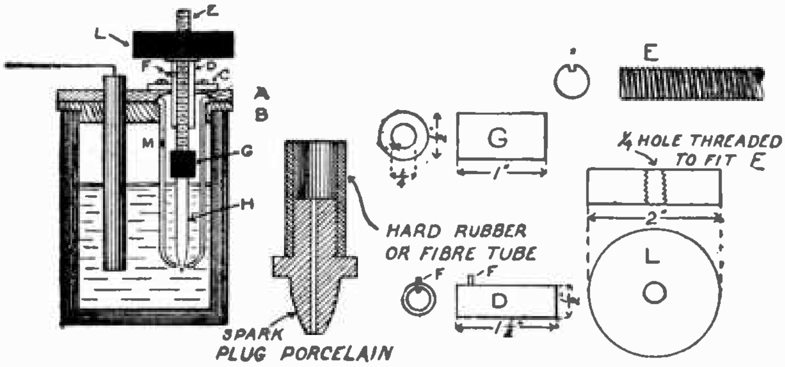


The vibrator panel of an efficient type of mechanical charger.

A common use of the *interrupter* is in the ordinary electric bell. In this apparatus, the electromagnet pulls the armature carrying the spring and contact point, breaking contact and opening the circuit. This immediately de-energizes the magnet since its coils are in series with the circuit. The spring tension pulls the armature back to its original position thus again closing the contact. As soon as the contact is closed, the electromagnet is again energized and it again attracts the armature, opening the circuit. This action keeps on indefinitely as long as a difference of potential is maintained at the terminals of the bell.

The *interrupter* is used in the *induction coil* (q.v.) for breaking up the direct current into a series of impulses, thus producing an intermittent current. (See *Circuit Breaker.*)

INTERRUPTER, ELECTROLYTIC—A jar containing diluted sulphuric acid as the electrolyte, a large sheet of lead as one electrode and a platinum needle point introduced through a glass tube as the other electrode. If these electrodes are connected through an inductance to a source of current supply, the current in the circuit will be rapidly interrupted. *Electrolytic interrupters* are suitable for radio transmitters using small spark coils and are also used in X-ray work. (See *Electrolytic Interrupter.*)



A simple type of Wehnelt interrupter. The positive pole of the direct current supply is connected to the brass part C, while the negative pole is attached to the lead rod. L is a fibre handle; E is a threaded rod, which is constructed to fit the threaded handle, but slotted so as to engage the pin F and prevent it from turning; H is a copper or platinum rod; D is a brass tube; M. is the overflow hole in the fibre tube, into the lower end of which a portion of an old spark plug porcelain part has been driven; finally C is a small brass block as shown. This is the adjustable type of Wehnelt interrupter, since the fibre handle can be operated to allow more or less surface to be exposed to the acidulated water.

INVERTED "L" AERIAL—A flat top aerial (antenna) in which the down lead is tapped off one end of its horizontal span. (See *Length of Aerials, Horizontal Aerial.*)

INVERSE DUPLEX CIRCUIT—A circuit in which the vacuum tubes are utilized both for radio frequency and for audio frequency amplification as in the *reflex* (q.v.) circuit with this important differentiation that the first radio frequency tube is utilized as the second audio frequency tube and the second radio frequency tube is used as the first audio frequency tube. In the ordinary reflex circuit the first radio frequency tube is also the first audio tube and the second radio frequency tube is the second audio tube. The *inverse duplex* circuit has the advantage over the reflex in that the tubes which are reflexed operate more efficiently since the relatively weak radio currents pass through the same tube as the stronger audio currents and vice-versa. The *inverse duplex circuit* is the invention of David Grimes.

ION—An atom of matter carrying an *electron* or an *atom* deprived of electrons. *Monad-ion* refers to a unit charge, *dyad-ion, divalent* carries two units, the *triad-ion* carries three unit charges. The positive *ion* is an *atom* minus an *electron.* A negative *ion* is an *atom* plus an *electron.* (See *Anion,* also *Cathion, Electron, Electron Theory.*)

IONIZATION—sometimes spelled **IONISATION**—The splitting up of *molecules* into *ions* (q.v.). *Ionization* may apply either to a chemical compound or to a gas. When a electric current is passed through an *electrolyte* (q.v.) the constituents of the electrolyte which are liberated or deposited at the *electrodes* (q.v.) are called *ions* and this process is called *ionization.* Gases at or near atmospheric pressure are normally good insulators. They are said to undergo *ionization* when they are made conductive, that is when they allow the flow of electricity. A gas may be made conductive by passing *X-rays* (q.v.) through it, by the action of ultra-violet light, by subjecting it to radium rays, by passing it close to a flame or hot piece of metal or by forming in it a brush discharge or *corona* (q.v.). Gases which have been made conductive carry current because of their dissociation into *ions,* which carry positive or negative charges of electricity. (See *Electrolysis, Electrolytic Action,* also *Valve Detectors.*)

I.R. DROP.—The voltage drop due to the resistance in a current-carrying conductor. It is directly proportional to the current flowing in the circuit multiplied by the resistance of that circuit.

I^2R LOSS—The power loss in any circuit due to the resistance offered to current flow. It is proportional to the square of the current flowing in the circuit multiplied by the resistance of the circuit. Whenever current flows there is an I^2R loss. This is measured in *watts* (q.v.) or *kilowatts* (q.v.).

IRON PYRITES—Formula FeS_2—This is a mineral, a disulphide of iron, found in large quantities. It was formerly used in radio as a crystal detector mineral but has been almost entirely superseded by vacuum tube detectors. *Iron pyrites* is flaked with shiny spots which have the appearance of gold, and for this reason it is sometimes called "fools gold." *Iron pyrites* is very hard and brittle. The present commercial use of *iron pyrites* is in the production of sulphuric acid. Ferrous Sulphide, FeS, has also been employed in the past as a radio detector. This substance is chemically formed by fusing equivalent quantities of sulphur and iron together. The resultant substance has a smooth surface. (See *Crystal Detector.*)

ISOCHRONOUS—A term applied to two or more oscillatory circuits, meaning that they have the same *natural frequency* (q.v.). Stated in another way, two or more radio frequency circuits are isochronous when they are in electrical *resonance* (q.v.). Circuits are said to be in resonance when they have the same *oscillation constant* (q.v.). The *oscillation constant* of a circuit is equal to the square root of the product of the inductance multiplied by the capacity of that circuit. Circuits having equal oscillation constants will have the same discharge frequency.

ISODYNAMIC LINES—Lines on a magnetic map connecting all parts of the earth where the magnetic intensity is the same. In other words, these lines pass through points of equal horizontal component of the earths magnetic field.

ISOGONIC LINES—Lines on a magnetic map passing through points of equal *declination.* Lines connecting all points of equal variation of the magnetic meridian from the geographic meridian.

ISOTHERMS—Lines on a meteorological chart joining all points having the same temperature.

ISOTROPIC CONDUCTIVITY—Equal conductivity in every direction. A conductor is said to be *isotropic* when it offers the same resistance to the flow of an electric current in every direction through its mass.

J

JACK—An arrangement of spring terminals as shown in the illustrations which can be connected together or separated thus closing or opening circuits through the insertion of a *plug* which also forms a part of the circuit. The *plug* (q.v.) has a tip and a sleeve at one end (that is at the end inserted into the jack) and at the other end it has the two terminals for connecting the apparatus to be cut into the circuit. As an example, the terminals of the plug may be connected to a *loud speaker* (q.v.). The jack in this case is of the *open circuit* variety. That is to say, the springs of the jack are separated when not in use and the circuit is normally open. When the plug is inserted, the tip of the plug makes contact with one spring and the sleeve makes contact with the other thus closing the circuit through the *loud speaker*. In cases where the plug is used to open a circuit, that is to make the *jack* springs break contact with each other, the *jack* is called a *closed circuit jack* since its spring terminals are normally making contact. In cases where the jack is used not only to put the loud speaker in the circuit, but also to act as a filament switch, it is known as an *automatic filament control jack.* Jacks which are used to control a single circuit only, are referred to as *single circuit jacks.* Those controlling two or more circuits simultaneously are known as *multiple circuit jacks. Jacks* are usually mounted on a panel so that the plug can be inserted from the outside of the panel while the spring terminals are concealed behind the panel.

The jack shown at the left is a four-spring double circuit jack. At the right is a five-spring automatic jack.

JAMMING—An expression denoting interference at a receiving station caused by a transmitting station not desired to be heard. More specifically, such interference, prevents the reception of signals, *jamming* the receiving station by drowning out with stronger signals or noises the station desired.

JANET, PAUL—Born in Paris, January 10, 1863. Educated at Lycee Louis-le-Grand and at the high school. He was Professor of Physics at the University of Paris and University of Grenoble. Professor Janet was the author of several important works, and first to make the experiments in electrical resonance successful. The results of these experiments are applied in present day wave meters.

JAR—A unit of electrostatic capacity. It is mainly used in the British Naval service. One *jar* equals 1000 *centimeters* which equals .0011 *microfarads* (q.v.).

JIGGER—A term generally accepted to denote an *oscillation transformer* (q.v.). Used for transforming trains of oscillations from one circuit to another. Dr. J. Erskine Murray refers to high frequency oscillations as *Jigs. Jiggers* are also known as *magnetic coupling transformers* (q.v.). They are also sometimes referred to as *auto-jiggers.*

JOULE—symbol J—The practical unit of electrical energy. It is equal to 10^7 *ergs* (q.v.). The *joule* is also the unit of electrical work. It is equal to the work done or the heat generated by a *watt second* (q.v.); or an *ampere* (q.v.) flowing for a second through a resistance of one *ohm* (q.v.). Expressed another way the *joule* is the work done by one *coulomb* (q.v.) flowing under the pressure of one *volt* (q.v.). One *joule* is equal to .73732 foot pounds, or .24 calories (q.v.).

JOULE EFFECT, or **JOULEAN HEATTING**—This occurs when an electric current traverses a resisting conductor. The rate of generation of heat in the conductor by a steady current equals the square of the current multiplied by the resistance.

JOULES EQUIVALENT—The amount of energy equal to a heat unit.

JOULES LAW—The heat produced in an electric circuit is directly proportional to the square of the current, to the resistance of the conductor and to the time of current flow.

K

KANALSTRAHLEN—A German word meaning Rays of Canal. It has been found that by perforating the cathode of a tube producing *cathode rays* (q.v.), faint luminous streaks will come through these perforations in a direction opposite to that of the *cathode* rays. These are called *kanalstrahlen.* They communicate a positive charge to an insulated conductor. In terms of the *electron theory* (q.v.) they are positively charged *ions* (q.v.) The cathode particle is an electron traveling in one direction, and the kanalstrahlen particle traveling in the opposite direction is what remains of the atom which has lost an electron.

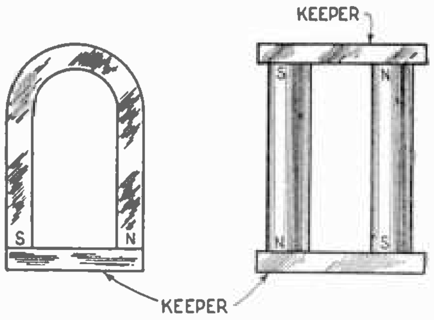
KATHODE—This is a negative *electrode* (q.v.). (See *Cathode,* also *Electrolysis.*)

KATHODE OF CELL—The positive pole of a cell. This is indicated by the plus (+) sign. (See *cell.*)

KATHODE RAYS—The stream of *electrons* (q.v.) thrown off by the *kathode* of a vacuum tube. These produce a glow when they strike the walls forming the tube. They can be deflected by a magnet. (See *Cathode Rays.*)

KATION—The charged particles or *ions* (q.v.) moving in the direction of the *cathode* (q.v.). (See *Cathion.*)

KEEPER—The piece of iron used to close a magnetic circuit to protect it from external disturbances. The term *keeper* is generally used to refer to such a piece of iron when used with a permanent magnet such as a horseshoe magnet. In the case of the piece of iron which closes the magnetic circuit of an electromagnet, this is more often referred to as an *armature* (q.v.). The *keeper* may be used with a straight bar magnet also. In this case, two bar magnets are laid side by side with unlike poles adjacent and two keepers are used, one at each end. The use of a keeper avoids the demagnetizing effect of *leakage lines* (q.v.). (See *Horseshoe Magnet.*)



At left is shown keeper used with a horseshoe magnet. At right two keepers are shown used with two bar magnets.

KELVIN, LORD (William Thomson) was born at Belfast in 1824; he entered Glasgow University as a student at 10 years of age; graduated at Cambridge in 1845. When only 22 years of age he was called to occupy the chair of natural philosophy in the University of Glasgow, a chair which he adorned by his genius for fifty years. He was for 40 years or more regarded as the acknowledged leader of British science on its physical and mathematical side. His great inventions in telegraphy, his magnetic compass and sea sounding apparatus brought him fame and fortune. He was knighted in 1866; and in 1892 was raised to the peerage as Baron Kelvin of Largs; he died on December 17, 1907.

Lord Kelvin (William Thomson)

KELVIN'S BRIDGE—A method of measuring low resistance in which the voltage drops, produced by the same current in the resistance under test and in a standard low resistance slide wire are balanced against each other. This *bridge* is a modification of the *Wheatstone Bridge* (q.v.) and was designed by Lord Kelvin to eliminate the errors introduced when measuring resistances much less than one *ohm* (q.v.). In the case of the *Wheatstone Bridge,* such resistances could not be measured accurately on account of the errors produced by the terminal and contact resistances.

KELVIN'S ELECTROSTATIC VOLTMETER—A voltmeter used for measuring high, and in some cases low, alternating current voltages. It is constructed on the principle of an air condenser. One type of electrostatic voltmeter is a high potential instrument having the needle made of a thin aluminum plate suspended vertically on delicate knife edges, with a pointer extending from the upper part to a scale. Two quadrant plates, metallically connected together, are placed on either side of the needle and parallel to its face. These serve as one terminal of the circuit to be measured. The needle acts as the opposite terminal. When there is a difference of potential between the needle and the plates, the needle is deflected out of its neutral position. The value of the scale indications can be changed by hanging calibrated weights on the bottom of the needle.

KENOTRON—A type of *vacuum tube rectifier* (q.v.) in which the vacuum is extremely high and the discharge is carried almost entirely by electrons, not by gas ions. In these tubes, the plate current is always less than that actually emitted by the hot filament. *Kenotrons* are made sufficiently large to rectify several kilowatts.

KENNELLY, A. E.—Anglo-American radio expert. Born at Colaba, Bombay, December 17, 1861, he was educated in England, Belgium, France and Italy. In 1875 he became a telegraph operator in the employ of the Eastern Telegraph Company, and in 1886 became the principal electrical assistant to Thomas Alva Edison in the laboratories at Orange, N. J., a post he held until 1892.

He was engineer-in-chief with E. J. Houston, of the Thomson-Houston Company, for the laying of the cables from Vera Cruz to Campeche, 1902. Since 1902 he has been Professor of Electrical Engineering at Harvard University, and since 1914 professor of the same subject at Massachusetts Institute of Technology.

Kennelly has written a large number of books on electricity and radio, and is the author of one of the standard elementary text-books on same. He has written a very large number of papers on radio, and he is an authority on alternating currents.

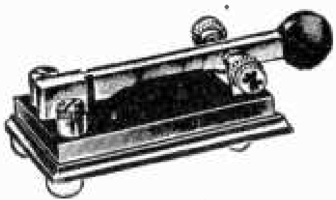
He is past president of the American Institute of Electrical Engineers, was president in 1916 of the Institute of Radio Engineers, and vice-president of the International Electrical Congresses, held in Paris and Turin. He is a member of many scientific societies, and has received many honorary degrees. In 1921 he was appointed a delegate to the Interallied Radio Technical Committee in Paris.

KEY—A form of switch for conveniently and quickly opening and closing a transmitting circuit, in the act of transmitting signals. An *operating,* or *telegraph,* so-called *Morse key* is a form of *tapping key* designed especially for the rapid sending of signals by the dot and dash code. A tapping key has one contact carried by a springy strip of metal. In signalling, this key is depressed by the fingers, thus closing the circuit by bringing the contact together with a fixed contact. A standard type of *transmitting key* (q.v.) such as used in sending wireless messages is shown in the illustration. These keys must necessarily be made with larger contacts and of more solid construction than those used to interrupt the smaller currents used in wire telegraphy.

A standard transmitting key.

KEY, ANTI-CAPACITY—This is in reality a form of switch. (See *Switch.*)

KEY, HIGH-SPEED—A transmitting key usually operated from side to side instead of downwards, which makes



High speed key.

contact both on the right and on the left side. Such a key requires only half the travel of the ordinary transmitting key and thus facilitates high-speed manual transmission of code signals.

KEY SWITCH—A type of switch adapted for operation by a removable portion in the form of a handle or key. In radio work, *key switches* are sometimes used to lock a receiving set so that it cannot be operated unless the filament circuit is closed by the insertion and turning of the key. Key switches are generally operated by a hollow slotted key, although there are other types on the market. The slot in the key fits a projection or pin on the spindle or shaft of the switch which carries the movable contact. When the key is inserted in the socket and turned, it turns the shaft and brings the movable contact against a fixed contact. *Key switches* are also used for turning on or off electric lights and for locking or unlocking the ignition systems of automobiles.

KILO—Symbol K—A prefix placed before the name of a unit to indicate the multiple 1000 or 10^3. In cases where standard units are too small for convenient use, it is customary to utilize this prefix as, for example, in stating the voltage of a high tension transmission line. This would often be given as 10 kilovolts (K.V.) rather than as 10,000 volts. In like manner, in referring to large amounts of power, it would be preferable to give the amounts in kilowatts rather than in watts. Thus the better way to express 10,000,000 watts would be to divide by 1,000, thus converting to 10,000 kilowatts.

KILOAMPERE-TURN—One kiloampere-turn is equivalent to 1,000 ampere-turns. In referring to the magnetic circuits of electrical machinery it is usual to specify the magnetomotive-forces in kiloampere-turns rather than in ampere-turns. (See *ampere-turns*, also *magnetomotive-force.*)

KILOCYCLE—1,000 *cycles*—Two immediately succeeding half waves of an alternating current constitute a *cycle* (q.v.). The number of *cycles* per second is called the *frequency* (q.v.). In house-lighting and similar circuits, where a comparatively low frequency is used, it is usual to refer to the *frequency* in cycles per second. However, in radio circuits, where currents as high as 300,000,000 cycles per second are used, it is preferable to divide by 1,000, thus converting to *kilocycles*. If the wave-length in meters is known, it is a simple matter to determine the frequency in *kilocycles*. This is calculated as follows: The speed of light is 186,000 miles per second and experiments have shown that this is practically the same as the velocity of electromagnetic or radio waves. Expressed in meters this is equal to 300,000,000 (appx.) meters per second. Assuming that a transmitting station is using a wave-length of 500 meters, the frequency will be obtained in cycles per second by dividing the velocity of the waves by the

KILOCYCLES TO METERS, OR METERS TO KILOCYCLES

Meters	Kilocycles	Meters	Kilocycles	Meters	Kilocycles	Meters	Kilocycles	Meters	Kilocycles	Meters	Kilocycles	Meters	Kilocycles

length of a single wave, which in this case would be equal to 300,000,000 (appx.) divided by 500, equalling 600,000 cycles per second or (reduced to kilocycles by dividing by 1,000) 600 kilocycles. On the preceding page is given a chart for converting kilocycles to meters, or meters to kilocycles.

KILOLINE—This is equal to 1,000 *lines of force*, or 1,000 *maxwells* (q.v.). The *maxwell* or the *line of force* is the unit used to measure *magnetic flux*. (See *Line of Force, Maxwell, Magnetic Flux.*)

KILOVOLT — abbreviated K.V. — The kilovolt is equal to 1,000 volts.

KILOVOLT-AMPERE — Abbreviated K.V.A. or kv-a.—The product of the effective volts across the terminals of a circuit by the effective amperes flowing in that circuit, divided by 1,000. Alternators are rated in *kilovolt-amperes* because their load determines the power factor. Thus with a zero *power factor* (q.v.) the *true power* (q.v.) in kilowatts would equal zero even if the alternator were delivering maximum amperes and maximum volts. At 50% power factor the kilowatt capacity would be half that at 100% power factor. On the other hand the kilovolt-ampere capacity remains the same no matter what the power factor.

KILOWATT — abbreviation K.W.—The kilowatt is a unit of electrical power having the value of 1,000 watts. One kilowatt equals 1,000 watts. To reduce the power expressed in kilowatts to watts, it is necessary to multiply the number of kilowatts by 1,000. Most electrical formulas use watts rather than kilowatts. Therefore, in solving such formulas, where the power is given in kilowatts, it is necessary to multiply this by 1,000 before using it in the formula. For example, suppose the power expended in an electrical circuit carrying 100 amperes is 20 kilowatts. The voltage will equal the power in watts divided by the current in amperes. This is $\frac{20 \times 1,000}{100} = 200$ volts. Motors are often rated in kilowatts instead of horsepower. For practical calculations, the horsepower rating of a motor is equivalent to four-thirds of its kilowatt rating. (See *watts.*)

KILOWATT-HOUR—The energy expended when work is done for one hour at the rate of one kilowatt. It is possible to calculate the energy expended in an electrical circuit over a certain period of time, knowing the current in amperes and the resistance of the circuit. Using the following formula the energy expended will be obtained in kilowatt-hours:

$$\frac{\text{Work performed or energy expended} = \text{Current}^2 \times \text{Resistance}^* \times \text{Time}^\dagger}{3,600,000}$$

$= \text{kilowatt-hours.}$

KIMURA SHUNKICHI—Japanese radio authority. Kimura was born in 1866, and educated at the Scientific College of the Tokyo Imperial University, his special study being physics, which he continued to study at Harvard and Yale Universities, United States.

In 1901 Kimura entered the Japanese Navy and first began to study wireless telegraphy, particularly for naval use. In 1906 he was appointed the Japanese delegate to the International Wireless Telegraph Conference, Berlin, and after his retirement from the Navy, 1912, he became the director of the Nippon Radio Telegraph and Telephone Company. Kimura has written largely on radio subjects for various scientific journals.

KINETICS—That branch of dynamics dealing with forces that produce or change motion. Energy is usually classified either as *potential* or *kinetic.* When energy is available for the production of work it is referred to as potential energy. Energy at work is *kinetic energy* (q.v.). The term *kinetic* refers to motion.

KINETIC ENERGY—The work a body is able to do by reason of its motion. The unit of energy is the *erg.* This unit is also used to measure work. (See *Erg.*) It should be noted that *kinetic energy* is stored in the magnetic field. It requires more energy to start a current in a circuit having great inductance than in one having small inductance. This greater amount of energy is stored in the magnetic field and is returned to the circuit when the current decreases to zero.

KINRAIDY SPARK GAP—A form of *quenched spark gap* (q.v.) consisting of two water-cooled flat terminals close together and between which discharge occurs.

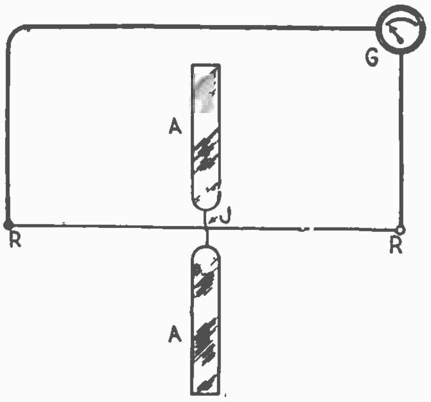
KIRCHOFF'S LAWS—These are two in number. First Law: The sum of the currents flowing to a point, in any electrical circuit, is equal to the sum of the currents flowing away from that point. Second Law: In any closed electrical circuit, the sum of the impressed *electromotive forces* (q.v.) will equal the sum of the *voltage drops* (q.v.). This statement requires modification, in so far as "addition" of voltages is concerned. Voltages are added provided that they are in the same direction, but must be subtracted if in opposite directions. These two laws depend on *Ohm's Law* (q.v.) and constitute a further application of that law to more complicated electrical circuits. In addition to simple electrical circuits, conductors may be connected in various complicated networks, all of which come under the heading of *divided circuits*. By means of *Kirchoff's Laws*, the current in any part of a divided circuit may be found, if the resistances of the various parts, and the electromotive forces are given.

KITES AS AERIAL SUPPORTS—During the early experiments with wireless, kites were successfully employed by Marconi as aerial supports.

KLEIN, RENE HENRI—Anglo-French radio expert. Born at Soults-sous-Foret, France, in 1880, he first became interested in wireless telegraphy in 1908. He was the founder and first honorary secretary of the Wireless Society of London, 1913-20, and became a vice-president of the society. He was one of the inventors with H. L. McMichael of the synthetic galena crystal Radiocite, and has written many articles on wireless subjects.

KNIFE SWITCH—A switch in which the movable arm wedges in between two parallel spring clips. Knife switches may be either of the *single pole* (s.p.) or *double pole* (d.p.) types and also may either be *single throw* (s.t.) or *double throw* (d.t.). Knife switches are often referred to as *Lever* switches They are used on direct current circuits up to 250 volts and on alternating current circuits up to 500 volts (See *Ground Switch; Double Throw Switch.*)

KLEMENCIC THERMAL JUNCTION—A device consisting of two thin sheets of brass, designated in the illustration as A, A. These are 4 inches by 11.8 inches and are placed about 1 inch apart. Soldered to one plate is a fine platinum wire and to the other plate is a fine platinum-nickel wire. These two wires are connected together at J to form a *thermal junction* (q.v.) and are then led off at right angles and are soldered at their other ends to the leads R, R, of a sensitive *galvanometer* (q.v.). This resonance system is fixed at the focal line of a suitable cylindrical metallic reflector. When electric waves, with the electric force parallel to A A fall on this receiver, electric oscillations between A and A produce heating at the junction J which is the point of contact between the two dissimilar metals. In consequence, the heat developed gives rise to a thermoelectromotive force at the junction and consequently to a current in the galvanometer. This instrument can be used to detect and measure electric waves.



Schematic diagram showing Klemencic thermal junction.

KOEPSEL PERMEAMETER—An instrument used for measuring the *permeability* (q.v.) of an iron or steel bar. In its principle of operation, this device is a movable coil milli-voltmeter in which the permanent magnet is replaced by an electromagnet. The sample to be tested forms a part of this electromagnet. The flux produced in the sample and in the pole pieces of the instrument is measured by a movable coil similar to those used in direct current voltmeters. The coil is supplied with energizing current from a small dry battery. Deflections are indicated by a pointer on a dial, the scale being calibrated directly in magnetic densities.

KOHLRAUSCH'S LAW—This law states that the rate of motion of each atom in a solution undergoing electrolysis for a given liquid is independent of the element with which it may have been in combination.

KOLSTER, FREDERICK A.—American radio authority. Born at Geneva, Switzerland, January 13, 1883, he was educated at Cambridge, Mass., and Harvard University. From 1902-08 he was assistant to J. S. Stone, the radio expert, and from 1909-12 to Dr. Lee de Forest. He was appointed chief of the Radio Section of the Bureau of Standards, a post he held until 1921, when he became research engineer to the Federal Telegraph Company.

Kolster has written a large number of articles on radio subjects, including those on the "Effects of Distributed Capacity in Coils," "Reinforced Harmonics in Radio Transmission," etc. He is the inventor of the Kolster decremeter, of a radio compass, of directional radio systems, etc., and is a member of the American Institute of Radio-Engineers.

---

*Ohms. †Seconds.

KOOMANS, NICHOLAS—Dutch radio authority. Born at Delft, 1879, he was educated there as a mechanical and electrical engineer. In 1908 he received his doctorate for his dissertation "Regarding the Influence of Self-Induction in Telephone Conducting Wires." He was one of the founders of and editor of the "Monthly Review of Telephony and Telegraphy," and was also one of the founders of the Dutch Society for Radio Telegraphy. Koomans is a member of the International Electrotechnical Commission and professor in physics and theoretical electrical engineering at the school of the Dutch Post and Telegraph Administration.

KORDA AIR CONDENSER—A variable *condenser* (q.v.) using air as the *dielectric* (q.v.) consisting of two sets of semi-circular plates, one set being connected together and fixed in position and the other set being also connected together but capable of being rotated about a central axis. Rotating the movable plates brings a greater or less area of the two sets of plates into interlapping positions, thus permitting the capacity of the condenser to be varied. This condenser was patented by Korda in Germany in 1893.

KORN, ARTHUR—German radio expert. Born at Breslau, Germany, 1870, Korn was educated at Leipzig and Paris and became professor of physics at the University of Munich, 1903-8, and afterwards professor at the Polytechnical High School, Charlottenburg, Berlin.

Korn is well known for his experiments on and the invention of a method of transmitting photographs by telegraphy, the first photograph being telegraphed from Munich to Berlin in 1907 by his methods. He is the inventor of a system of telautography and wireless phototelegraphy, and the author of a number of standard books on electricity.

L

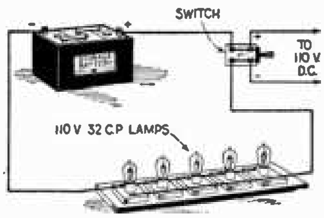
L—The symbol of *inductance* (q.v.) or the *coefficient* of *self-induction.* In general, the co-efficient *L* by which the rate of change of current in any circuit must be multiplied to obtain the value of the self-induced *electromotive force* (q.v.) is called the *coefficient* of *self-induction* or simply the *inductance.* (See *Self-induction, coefficient.*)

LAG—One *alternating current* quantity reaching its maximum at a later time than a second alternating current quantity. As an example,—the current is said to *lag* behind the impressed voltage when maximum current occurs after maximum voltage. In other words, the current and voltage in such an alternating current circuit are out of *phase* (q.v.). In the above example, since the current *lags* behind the voltage, the voltage is said to lead the current. *Inductance* (q.v.) in an alternating current circuit will cause the current to *lag* behind the impressed voltage. *Capacity* (q.v.) in such a circuit will cause the current to *lead* (q.v.) the impressed voltage. The word *lag* may be applied to magnetic quantities as well as electrical quantities. Thus, one magnetic flux may *lag* behind another as in the case of an induction motor where the induced *magnetic flux* (q.v.) *lags* behind the impressed magnetic flux. Another type of magnetic *lag* is the retardation of magnetic effects behind their causes, due to *hysteresis* (q.v.) in the magnetized substance. (See *Lead,* also *Leading Current.*)

LAMINATED—Composed of a number of thin plates, one on top of another. Examples of laminated construction are *laminated brushes, laminated cores laminated conductors,* etc.

LAMINATED CORE—An arrangement of soft iron plates or stampings forming the core of a transformer, or of an armature of a motor or generator. Cores are laminated in this way, principally to reduce *eddy current* (q.v.) losses. In the case of an armature core, this must be laminated parallel to the direction of rotation (in other words, perpendicular to the axis of rotation). Laminations are insulated from each other by means of japan, varnish, shellac or simply rust.

LAMP BANK—A bank of incandescent lamps arranged so that they can be connected in series or parallel. *Lamp banks* are used in laboratories in conjunction with electrical machinery under test. In this case, the lamps act as the *load,* the more lamps being connected in *parallel,* the greater the amount of current being drawn. *Lamp banks* are sometimes connected in *series* in a circuit for the purpose of reducing voltage. An example in this connection is the use of a lamp or bank of lamps in charging a 6-volt storage battery from a 110-volt direct current source. Lamp banks are sometimes called *lamp panels* or *lamp batteries.*

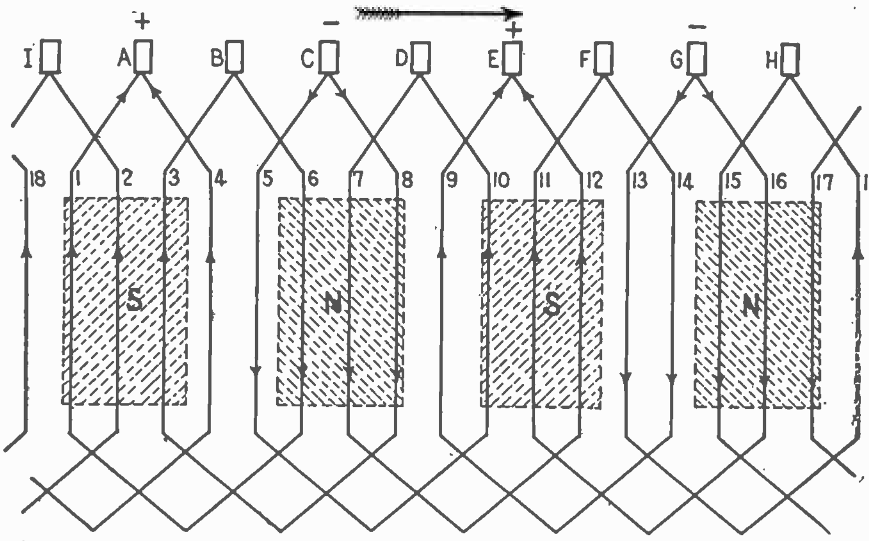


Use of lamp bank in charging storage battery.

LANGMUIR, IRVING—American radio authority. Born at Brooklyn, New York, January 31st, 1881, he was educated at the School of Mines, Columbia University, and was for some time assistant to Professor Nernst at the University of Gottingen. In 1906-9 he was instructor in chemistry at the Stevens Institute of Technology, and in the latter year he became a research assistant to the General Electric Company, at Schenectady. He has carried out a series of brilliant researches on apparatus used in wireless telegraphy and telephony, on electron discharge apparatus, atomic and molecular structure, etc.

Langmuir has paid particular attention to high-vacuum valves, and is the inventor of the Langmuir valve. To him is due the discovery that by treating the tungstic oxide used in the construction of tungsten filaments with certain compounds of thorium the filament becomes thoriated tungsten and the electronic emission is enormously increased. These filaments are the ones used in dull emitter valves, the electrons being given off at comparatively low temperatures Langmuir is the author of many papers to scientific and technical journals, including those on pure electron discharge, thermionic currents in high vacua, etc. He is also well known for his mercury condensation pump for high vacua.

LAP WINDING—An armature winding in which the opposite ends of each coil are connected to adjoining commutator segments. As a result the windings lap back and upon themselves forming loops. *Lap winding* is also called *loop winding, parallel winding* and *multiple winding.* In the elementary form of *lap winding* the method of connection to the commutator bars is as follows: One side of a coil is connected to a commutator bar, and the other side of the coil, which is located 180 electrical degrees (the distance from the center of a north pole to the center of the adjacent south pole) away, has its end connection brought back and soldered to the next adjacent commutator segment. This method of overlapping the ends is continued all the way around the armature until all the slots have been filled and the circuit has been closed on itself. The coils must all be symmetrical. This means that if there is a forward throw of a certain num-



A typical lap winding shown in developed view. In the winding shown each inductor is connected at the rear of the armature to one five slots away. Thus #3 is connected to 8, 5 to 10, etc. After having made one complete "element"—as, for example, A-1-6-B—the winding forms a second "element," B-3-8-C, which laps over the first. This is continued around the armature until the winding closes on itself.

ber of slots on the first coil, all the other coils must have the same forward throw. In like manner all the return throws must be the same. In the *lap wound* generator there are as many paths for the current as there are poles. Hence the name *parallel* or *multiple winding*. This necessitates the use of as many sets of brushes as there are poles. An increased number of paths in parallel means increased current capacity. In the case of a motor, the greater the number of armature paths between brushes, the greater will be the speed, other conditions remaining equal.

LAW OF ELECTROMAGNETIC INDUCTION—Also known as the "*Law of Generator Action*" and as "*Faraday's Law.*" If there is relative motion between an electrical conductor and a magnetic field, such that the conductor cuts *flux*, an *electromotive force* (q.v.) will be induced in the conductor. The amount of the induced electromotive force will depend upon the strength of the magnetic field, upon the speed of cutting, upon the length of the conductor cutting the field and upon the direction of motion between the conductor and the field. Thus the stronger the magnetic field, the greater the induced electromotive force. The induced electromotive force will also increase with increased speed of cutting and with increased conductor length. When the conductor cuts the flux at right angles, the induced electromotive force is maximum. If the flux is cut in any other direction, the induced electromotive force will be less. The induced electromotive force decreases from maximum to zero as the angle of cutting decreases from 90 degrees to zero degrees. If a conductor is of such length and moves in such a direction, and at such a speed, as to cut 100,000,000 lines of force in one second, one *volt* (q.v.) will be induced in it. Expressed as an equation the induced electromotive force (in volts) will equal the flux cut (in *lines* or *maxwells*) divided by the product of the time (in seconds) times 100,000,000. This equation refers to the average value of the electromotive force induced in a single conductor. If a number of conductors are used the same electromotive force will be induced in each. If the conductors are so connected that their electromotive forces add up, the total average electromotive force can be found by multiplying the above equation by the number of conductors.

LATOUR, MARIUS—French radio expert. Born in October, 1875, he was educated at the University of Paris and the Ecole Superieure d'Eléctricité, Paris. He was for many years consulting engineer to the General Electric Company, and he specialized in the construction of high-frequency machines. Latour is the designer of the so-called S. F. R. alternator, in which there are a smaller number of stator slots than usual.

During the World War Latour was engaged in research work under General Ferrie, and he invented a system of elimination of the interference produced in telephone lines by neighboring high-tension power lines which has been installed throughout the greater part of France. Latour is the inventor of the now widely used system of high-frequency multiplex telegraphy and telephony, using the three-electrode valve for generation and reception. He is a member of many scientific societies, including the Institute of Radio Engineers, and of the American Institute of Electrical Engineers. He has written many articles on radio for scientific and technical journals, and is the inventor of a great many important radio developments covering practically the whole range of the art.

LEAD—Pronounced LEED—One alternating current quantity reaching its maximum at an earlier time than a second alternating current quantity. Thus in an alternating current circuit, the current is said to *lead* the voltage if maximum current occurs before maximum voltage. If the current reaches its maximum 90 *electrical degrees* ahead of the voltage, current and voltage are said to be in *quadrature* (q.v.) with current *leading* and voltage *lagging*. (See *Degrees, Electrical*, also *Leading Current* and *Lag.*)

LEAD SULPHATE—Formula $PbSO_4$—A white insoluble salt which is found in native form in the ground and which can be formed artificially by adding sulphuric acid to a soluble lead salt. The active elements of a lead *storage battery* (q.v.) consists of (PbO_2) *lead peroxide* on the positive plate and (Pb) *spongy lead* on the negative plate, with dilute *sulphuric acid* (H_2SO_4) as the *electrolyte* (q.v.). The final result, on discharge of such a battery is the formation of *lead sulphate* on both the positive and negative plates. This is a part of the process of producing current. After a normal discharge, the sulphate is finely crystalline and of such nature that it is easily reduced by the current flowing through the battery on charge. If charging is neglected and the battery is allowed to stand in a discharged state, the sulphate gradually ceases to be crystalline. It fills the pores of the plates and finally makes the active material hard and dense, thus lengthening the time required for a charge. A battery in this condition is said to be *sulphated*. If sulphating proceeds too far, it will result in *buckling* of *plates* (q.v.), loss of active material, greatly decreased capacity, lower efficiency and an increased internal resistance. A moderately sulphated battery can be restored by means of a prolonged charging at a moderate rate. In a badly sulphated battery, a number of successive charges and discharges may be necessary.

LEAD-IN—The wire leading from the aerial to the radio apparatus. *Lead-in* wire, as used for receiving sets, is usually rubber covered wire although bare antenna wire can be used provided it is properly insulated from the walls of the building. A poorly insulated lead-in will greatly reduce the efficiency of the finest antenna. (See *Down Lead.*)

LEAD-IN INSULATOR—Any form of insulator used for passing aerial lead-in through window, wall or roof. These insulators are usually made of porcelain, electrose or insulated copper strips. (See *Insulator, lead-in*, also *Window Lead-in.*)

LEADING CURRENT—An alternating current which reaches its maximum value at an earlier time than the voltage. When an inductance is inserted in an alternating current circuit, the self-induced *electromotive force* (q.v.) will combine with the *impressed* electromotive force and the resultant of the two will be the active electromotive force which causes the current flow. The current will always be exactly in *phase* (q.v.) with and proportional to the resultant electromotive force. The induced electromotive force is 90 degrees behind the current and therefore behind the resultant electromotive force, which is in phase with the current. The impressed electromotive force will lead the current and will be higher than the resultant electromotive force by an amount which at each instant is equal to the counter-electromotive force of the inductance. When a condenser is inserted in an alternating current circuit the current will charge the condenser. As the amount of current stored in the condenser increases, the electromotive force of the condenser increases also until the impressed and the condenser electromotive forces are equal. The condenser electromotive force, being a counter pressure, the current flow will cease when the two electromotive forces balance. The current being zero at this point and the condenser electromotive force a maximum, it follows that the condenser electromotive force is 90 degrees in advance of the current and hence of the resultant electromotive force which is in phase with the current. The impressed electromotive force lags behind the current which in this case is a *leading current* and moreover the impressed electromotive force is greater than the resultant electromotive force. It follows that if either capacity or inductance be placed in an alternating current circuit, the phase of the current with respect to the impressed electromotive force will change and the current flow will be reduced. Capacity sets up an electromotive force 90 degrees in advance of current flow, while inductance sets up an electromotive force of 90 degrees behind current flow. These two effects tend to neutralize each other when the proper amount of inductance and capacity are connected in series in a circuit and when they are just equal, no electromotive force other than the impressed is left to act on the circuit, the resultant and impressed electromotive forces are identical and there is no phase displacement. This is said to be a *resonant* (q.v.) circuit. (See *Lead, Lag*, also *Inductive Rise.*)

LEADS—Wires conveying or "leading" current from one point to another in a circuit. The conductors in any system of electrical distribution are referred to as *leads*. Sometimes the term *lead* is applied to the flexible wire or cable conveying current to or from a piece of apparatus.

LEAK—See *Grid Leak*.

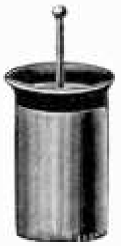
LEAKAGE LINES—Also termed *leakage flux*—That part of the total magnetic flux in a magnet, transformer, generator, etc., which fails to complete the closed magnetic circuit and hence is dissipated or wasted. (See *Keeper.*)

LEAKAGE, SURFACE—The flow of electricity across the surface of insulators. Its amount depends on the material and preparation of the surface and the humidity of the atmosphere and is recorded by measuring the surface *resistivity* (q.v.). Several methods are employed to reduce *surface leakage*. Porcelain *insulators* for outdoor use are often of the *petticoat* type so that a portion of the surface of the insulator remains dry during a rain or snowstorm. Another method very generally used in radio work to reduce surface leakage, is the use of corrugated surfaces on insulators. This method increases the length and hence the resistance of the surface across which leakage is likely to take place.

LENGTH OF AERIAL—The distance from the aerial binding post at the instrument to the farthest point of the antenna system, measured to any of its extremities. Only one component wire of a system is taken into consideration even if two, three or four are used. In a *T aerial* only half of the horizontal span must be added to the length of the down lead. In the *umbrella* type, the length of one radial lead is added to the down lead.

LENZ'S LAW—An induced current always tends to stop the motion which produces it. Stated in another way, whenever current flows in a conductor, due to electromagnetic induction, the action between the magnetic field which is being cut and the field around the conductor is always such as to tend to oppose further motion of the conductor. The following is still another way of stating *Lenz's Law*: The field due to the induced current always acts to prevent a change of the original field.

LEYDEN JAR—A condenser consisting of a glass jar with an outer and an inner coating of tinfoil covering the bottom and the sides nearly to the neck.



A small leyden jar.

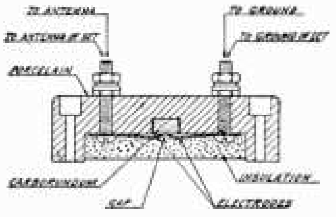
A brass rod terminating in an external knob passes through a wooden stopper and is connected to the inner coating by a loose chain. This condenser received its name from Leyden, the city in Holland in which it was invented.

L. F. C.—Abbreviation for *Low Frequency Current*. (See *Frequency, Low*, also *Frequency*.)

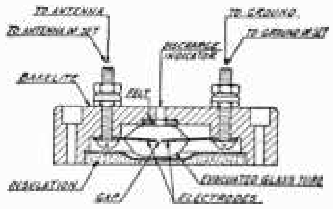
LIGHT—Radiant energy or visible *radiation* which affects the eye so that objects become visible. Light consists of *ether* vibrations varying between 400 billions per second producing waves 271 ten-millionths of an inch in length and giving red light, up to 750 billions per second producing waves of 165 ten-millionths in length, giving violet light. Faster or slower vibrations produce waves not visible to the human eye. Shorter waves are called *ultraviolet rays*, while those immediately above the red rays are known as *infra-red rays*. The speed of light waves is identical with that of other electromagnetic waves and electricity, and is 186,000 miles or 300,000,000 meters per second.

LIGHT LINE AERIAL—A device which acts as an aerial for a radio receiving set and which utilizes the electric lighting system by means of a plug to which a condenser is attached. The plug is inserted in any lighting socket and the aerial connection of the receiving set it attached by means of a flexible lead to one terminal of the condenser. (See *Adapter, Aerial*.)

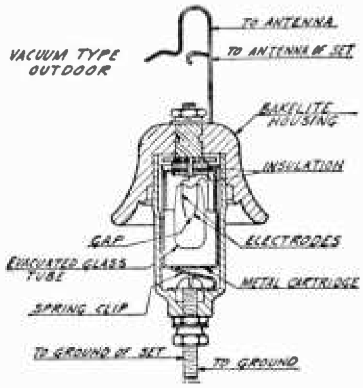
LIGHTNING ARRESTER—(Also called *lightning protector*.) A device for protecting radio or other electrical apparatus from lightning or from atmospheric discharges. Radio *lightning arresters* are provided with two terminals, one being connected with the aerial and the other directly to a ground. Between these terminals is a medium which offers practically no resistance (or technically speaking, which offers low *impedance* (q.v.)) to the flow of very high frequency currents such as lightning discharges. However, this medium acts as an insulator to the normal operating currents. Hence, during the ordinary reception of radio signals, the currents flow past the *arrester* to the receiving instrument but they are unable to pass through the insulating medium of the *ligtning arrester* to the ground. When there is a lightning discharge, the arrester offers the shortest and most direct path to the ground and hence the dangerous current never reaches the apparatus but proceeds directly to the ground through the *lightning arrester*. The more popular designs of lightning arresters are of three types: vacuum, non-air-gap and air-gap. The vacuum type is the more sensitive of the three, due to its having a low functioning voltage. In a usual form, it consists of two terminals in a sealed glass chamber from which air has been partially exhausted. This type of arrester can be discharged repeatedly without impairing its efficiency. The non-air-gap type of arrester involves the use of a carborundum stone, with a special clay binder. This type of arrester has a rectifying action similar to that used in a carborundum detector. The air-gap type of *lightning arrester* depends for its efficiency on a closely spaced air-gap which offers a low break-down voltage. The Underwriters requirements call for the use of an approved lightning protective device on all radio receiving sets where outside aerials are used. Further requirements are that such arresters shall operate on 500 volts or less. (See *Arrester*.)



A carborundum type lightning arrester consisting of a block of carborundum held between two pieces of high resistance carbon.



Vacuum type of lightning arrester for indoor work.

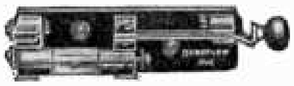


Sectional view of vacuum type lightning arrester used for outdoor work.

Outdoor vacuum type lightning arrester shown above in sectional view.

LIGHTNING GAP—This refers to the *air gap* or *vacuum gap* in a *lightning arrester* (q.v.). This gap is connected across the aerial and ground leads to the receiving set. When the potential in the aerial rises above a certain value (usually 500 volts or less) a spark jumps the gap, discharging the excessive energy to the ground without damage to the radio apparatus. (See *Gap Arrester*.)

LIGHTNING SWITCH—A single pole, double throw knife *switch* (q.v.) used for grounding the antenna during a storm, or in some cases at all times when the apparatus is not in use. The upper terminal of the switch is usually connected to the aerial, the central terminal to which the switch arm is connected, leads to the radio set and the lower terminal is connected to the ground. In most installations, the *lightning switch* is mounted outside the building in which the radio apparatus is located. (See *Ground Switch*.)



Lightning switch combined with vacuum type lightning arrester.

LIKE CHARGES—Bodies which carry like *electrostatic charge* (q.v.) exert a repulsion against each other.

LIKE POLES—Like magnetic poles repel one another. This is one of the *laws of magnetism*. (See *Magnetism, Laws of*.)

LIMITING VOLTAGE OF BRUSH DISCHARGE—The potential at which a brush discharge passes into an arc or spark. Brush discharges and arcs may be reduced in radio transmitting apparatus by eliminating sharp points or edges on conductors and by coating the edges of metal plates with paraffin. (See *Brush Discharge*, also *Corona*.)

LIMITING VOLTAGE OF GLOW DISCHARGE—The potential at which the glow gives place to the *brush discharge* (q.v.) in a high tension line or in a radio transmitting aerial (q.v.). (See *Corona*.)

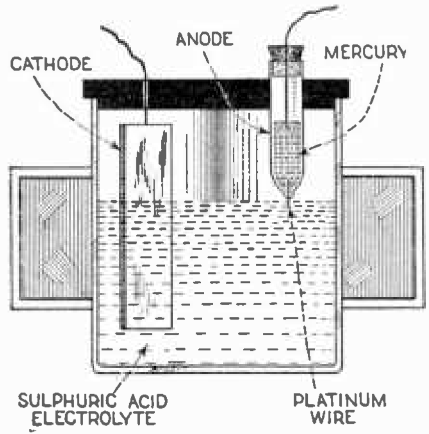
LIMITS OF AUDIBILITY—The limiting *frequencies* (q.v.) at which audible sounds are produced. These range from 500 to 1000 cycles per second up to as high as 10,000 cycles per second. *Audio frequencies* (q.v.) are sometimes defined as those conveniently heard in the telephone. (See *Frequency, High*, also *Frequency, Low*.)

LINE—A conducting wire between terminals in a system of electric communication or distribution. The positive wire is sometimes specifically referred to as the *line* and the return wire as *earth*. In many cases the earth or ground is used in the place of a return wire.

LINE OF FORCE—A theoretical conception used to map out a magnetic field and to show the direction along which the magnetism acts. *Lines of force* are conceived as forming closed loops and the path they traverse is called the *magnetic circuit* (q.v.) The positive direction of the *lines of force* is arbitrarily taken as that in which the north-seeking end of a compass moves. *Lines of force* are represented in diagrams by curves so drawn that the direction of the tangent at any point is the direction of the *magnetic force* (q.v.) at that point. The closeness of the lines is used to indicate the intensity of the force. The *line of force* is also used to indicate and map out an *electrostatic* (q.v) field in the same way as it is used for the magnetic field. The *line of force* is also called the *line of flux* or the *line of induction*. This latter term is used especially where the line of force is being considered in respect to its electrical effect. In some cases it is simply referred to as a *line*. Thus a line (*of force*, or *of flux*, or *of induction*) is an electromagnetic unit of magnetic flux and is equal to 10^{-8} *webers* (q.v.). In the practical system of measurements, the *maxwell* (q.v.) equal to one *line*, is the unit of *magnetic flux* (q.v.). When 100,000,000 *maxwells* are cut by a single conductor, in one second, one *volt* (q.v.) will be induced. (See *Law of Electromagnetic Induction*, also *Electromagnetic field.*)

LINEAR OSCILLATOR—See *Oscillator, Linear*.

LINE RADIO—Also known as *Wired Wireless*—A system of communciation devised by Major General George O. Squier which permits the transmission of electromagnetic waves along a wire or conductor. Instead of the waves spreading out in all directions, as in ordinary broadcasting, the waves travel along a predetermined path, viz: the conductor. It is possible to transmit either code or speech by *wired wireless*. Vacuum tubes are used as oscillators at the transmitting end and a specially designed vacuum tube set is used as the receiver. When code transmission is desired, a telegraph key is inserted in the circuit to intermittently stop and start the oscillating waves. This produces dots and dashes and in this way it is possible to send code using undamped radio frequency waves. When it is desired to telephone, the key is omitted and the radio frequency or *carrier waves* (q.v.) are produced continuously except when they are varied or modulated in amplitude corresponding to the voice of the speaker at the transmitting end. The wave which passes from the transmitting end of the wire to the receiving end is of radio frequency and is called the *carrier wave*. In a way, this wave is analogous to the wire which carries the voice current in wire telephony. *Line radio* can be transmitted over ordinary telephone or telegraph lines at the same time as these lines are being used for their ordinary purposes and without any interference whatsoever. High-tension lines are also used for transmission of *wired wireless*.



A liquid barreter.

LIQUID BARRETER—An electrolytic detector which utilizes a very fine platinum wire dipped to a small depth in nitric or sulphuric acid. These detectors were formerly used to some extent in receiving wireless code messages. The electrolytic detector of the *barreter* type was invented and named by *Fessenden* (q.v.). The illustration shows a liquid barreter. In the glass jar is a platinum glass-anode, lead cathode and sulphuric acid electrolyte.

LITZENDRAHT—abbreviated Litz—A German word, meaning braided wire. A high frequency conductor built up of a number of very fine conducting strands. The individual strands are enameled and the conductor is usually so constructed that each strand comes to the surface or very near the surface at regular intervals. In the most effective form of conductor the strands are braided so as to form a woven tube. The strands are usually covered by a single braided silk wrapper. The use of *litz* tends to reduce *skin effect* (q.v.). This type of wire has been found to be especially effective when used in the construction of *loop antennas* (q.v.).

LOADSTONE—also spelled *Lode-stone*—Iron ore which shows magnetic properties. The name loadstone is derived from a word meaning leading stone and refers to the property of a compass of pointing to the north magnetic pole. The loadstone is also referred to as a *natural magnet*. (See *Magnetite*, also *Magnet.*)

LOADING—Adding capacity or inductance to a circuit. *Inductance coils* (q.v.) called *loading coils* are used to increase the inductance and condensers are used to increase the capacity. A loading coil may be used to increase the *wave length* (q.v.) of an antenna by placing it in series between the *lead-in* (q.v.) and the receiving set. In the case of a transmitting antenna, the loading coil may be used to tune the aerial for *resonance* (q.v.) at a desired frequency. An example of the use of loading, is that of the addition of a loading coil to a receiving set for the purpose of enabling the set to receive higher wave lengths.

LOADING INDUCTANCE—An inductance coil used to increase the wave length of a circuit. This term usually refers to an inductance coil used in connection with a radio receiving set for increasing its receptive wave length range. Sometimes the term *loading coil* is applied to a unit consisting of an inductance coil, mounted beneath a panel in a small cabinet. On the outside of the panel is a contact arm and a number of studs. These latter lead to taps taken from the inductance coil. By moving the contact arm from one stud to another it is possible to vary the loading of the circuit as desired. A loading coil connected in series with the aerial will increase the natural wave length of the aerial. (See *Loading*, also *Inductance, Antenna.*)

LOCAL ACTION—Electrochemical action within a cell, usually at the positive plate, which does not add to the useful output. In primary cells, zinc is the material usually employed for the positive plate. This zinc practically always contains impurities such as carbon, iron, etc. When the zinc is immersed in the electrolyte, there is a difference of potential between the zinc and the impurities and small local currents flow from the zinc through the electrolyte to the impurities and back to the zinc again. These currents serve no useful purpose and moreover use up the zinc and the electrolyte. *Local action* can be practically eliminated by coating the surface of the zinc with mercury. This is called *amalgamation*. In secondary cells or *accumulators* (q.v.) local action is due to the action which takes place between the lead of the positive and the coating of lead sulphate.

LOCAL OSCILLATIONS—Oscillations set up in the vicinity of a receiving set for test purposes or within the set, as in the *super-heterodyne*, to produce oscillations differing in frequency from the incoming oscillations so as to establish a beat frequency. *Local oscillations* may be produced by means of a buzzer. This is a method frequently used in testing. The use of such oscillations enables a manufacturer of radio receiving sets to test these sets for selectivity, etc., without waiting for actual broadcasting. In the *super-heterodyne* (q.v.) local oscillations are produced by a suitably arranged vacuum tube. (See *Driver.*)

LOCUS—The path of a movement graphically represented by a curve. In mathematical language, the *locus* of an equation is the curve that contains all the points whose co-ordinates satisfy the equation. The circle is defined as the *locus* of all points in a plane equidistant from a fixed point in the plane called the center.

LODGE, SIR OLIVER—British Physicist and radio pioneer. Born at Penkhull, near Stoke-upon-Trent, June 12th, 1851, Oliver Lodge went to the Newport Grammar School at the age of eight, but at fourteen was taken into business to help his father. He worked in the evenings for the intermediate examination in science at the University of London, and eventually took first-class honors in physics. In 1872 he went to University College, London, and in 1877 took his D.Sc. in electricity and became demonstrator, and afterwards assistant professor in physics at University College.

Sir Oliver Lodge.

In 1881 he was appointed first professor of physics at Liverpool, and in 1887 he was made a Fellow at the Royal Society. In 1888 he received the honorary L.L.D. of the University of St. Andrews, the first of a long series of such distinctions. In 1900 he was appointed the first principal of the University of Birmingham, a post from which he retired in 1920. In 1902 he was knighted. Sir Oliver Lodge is one of the foremost physicists of his time, and his brilliant series of researches into electrical phenomena, which he has made his special study have had a profound effect in all branches of that subject. To him, indeed radio owes as much as to any man, for he dealt with fundamentals when the whole subject of electromagnetic radiation was in its infancy. He was led to study the surging and oscillating character of an electrical discharge along wires as a result of his investigations as to the best means of protection against lightning.

One very remarkable experiment of his is now well known under the name of Lodge's resonating jar, now used as a measurer of wave length. In these experiments Lodge was really dealing with the electromagnetic waves discovered by Hertz in 1888. Lodge early recognized the vast importance of the discovery by Hertz, which so brilliantly confirmed the theories of Clerk-Maxwell, and he threw himself into work of investigating these ways with an energy which made him the foremost British physicist on the subject at the time. All this was pioneer work before Marconi and others came along and built upon the solid foundations which Lodge had prepared.

It was during this early period that Lodge discovered his coherer, and with this detector devised the first practical wireless telegraph, sending signals over a distance of several hundred yeards. In May, 1897, Lodge took out his fundamental patent for tuning—a patent that was successfully upheld in the law courts, and extended for seven years by Lord Parker. The patent was acquired by the Marconi Company in 1911. Sir Oliver Lodge has been a pioneer in many other directions. His theories and experiments in connection with the ether, of which he is the leading exponent, are well known, and he has carried out a number of interesting researches on the passage of electricity through liquids. Sir Oliver was the first to devise a simple and direct experiment to show the speed and direction of travel of the constituents of a salt in solution when broken up by a current of electricity. For his researches on electric waves and the passage of light through a moving medium, Sir Oliver Lodge received in 1898 the Rumford Medal of the Royal Society, one of the highest honors the society bestows.

Sir Oliver Lodge has won a well-deserved reputation for the clearness and simplicity with which he is able to explain many of the difficult and fundamental truths of physics, and this clarity of expression is well shown in the many articles he has written.

LODGE DISC DETECTOR—An imperfect contact detector consisting of a steel disc rotating with its sharp knife edge just touching some mercury having a film of oil on it. When an oscillation passes through the circuit, momentary cohesion sets in between the disc and the mercury, but this is immediately broken by the revolving motion of the disc. In this way, oil re-insulates the disc at the completion of each passage of oscillations. Using this type of detector, code signals can be recorded with great precision on a *Morse* tape using a syphon recorder. The *disc detector* is in reality a specialized form of *coherer* (q.v.).

LOG—A list of dial readings of a radio receiving set with corresponding call letters of the broadcasting stations received at these readings. A radio set is said to *log* when the same stations always come in at exactly the same dial readings. Thus on a three dial set, if WEAF comes in at 61, 60 and 60 and always comes in at these identical readings using the same aerial, the set *logs*. All present day sets are constructed so that stations can be accurately logged. Sometimes the term log is used to refer to a graph or chart on which dial settings are plotted against wave lengths of stations recorded. A graph is a diagrammatic representation by means of lines, of the relation between several quantities. Figure 1, gives a simple illustration of this. Suppose it is desired to obtain a general idea of how the radio business varies from year to year or from season to season. On a piece of paper, ruled both vertically and horizontally, as in Figure 1, the months and years are marked at the bottom horizontally. The vertical lines then represent the months and the bottom horizontal line is called the *axis of time*. These vertical lines are known technically as *ordinates*. The vertical line to the extreme left is called the axis of ordinates and after it has been marked as shown in Figure 1, to represent dollars, it may be referred to as the *axis of dollars*. The horizontal lines are known as *abscissas*, the bottom horizontal line being the *axis of abscissas*. Assume that a certain radio concern did $10,000 worth of business in the month of January, 1924. Looking upward along the vertical line representing this month, until the horizontal line representing $10,000 is reached, a point is put at the intersection of these two lines. Suppose that in the following month, February, 1924, the firm does $12,000 worth of business. The point is found as before by following the line February, 1924, up to the line indicating $12,000. Each horizontal line in the figure represents $1,000, so that this point should be found two lines higher than the one marked for $10,000. This can then be continued indefinitely, plotting the amount of business for each month. Assume that in the summer there is a lull in business. The decline starts, say, in the month of May. The business done amounted to $8,000. By glancing at the chart it is possible to ascertain a number of facts which stand out much clearer than where columns of figures are given. Thus the seasonal character of the business is apparent at a glance. It can also be seen readily that the business was better in 1925 than in 1924, etc. Radio logs are plotted in exactly the same way. Each point must be obtained individually in order for the curve to be absolutely accurate, although in many cases a few well chosen points are sufficiently satisfactory. In Figure 2, the dial setting is marked along the bottom of the chart. The scale is here chosen at one division on the chart equal to 5 divisions of the dial. If preferred the scale could be chosen so that one division on the chart would equal one division on the dial as shown on chart on the following page, which is a typical log of an actual set. Proceeding, it is first necessary to find out the limits of the chart. The limits of the horizontal scale are already known, i.e., zero to 100 on the dial. Looking over the list of broadcasting stations, it is found that they all have wave lengths which fall, roughly between 200 and 600 meters. Therefore it is not necessary to make the vertical scale include wave lengths outside of this range. Consequently the vertical scale is started at 200. Counting upward, two divisions on the chart are taken, for convenience, as equal to 50 meters. Having done this, actual readings are next taken on the radio set. Suppose that the first station tuned in is WEAF and that this is tuned in at 85 on the dial. This station has a wave length of 492 meters. Looking along the bottom of the chart for 85, the vertical line is then followed until the position of 492 meters is reached. This is slightly below the 500 line on the chart, Figure 2, and is indicated by the letter A. Next suppose that WOO, having a wave length of 509 meters is tuned in at 90 on the dial. This, then gives the point marked B. Then another station is tuned in, indicated by the point C,

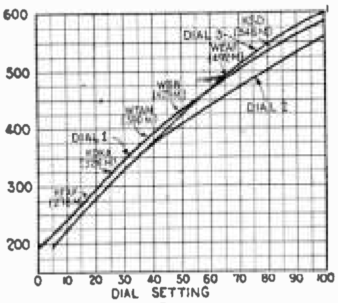

FIG.3

A three-dial radio log using only one chart.

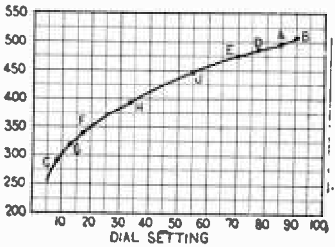

FIG.2.

A radio log.

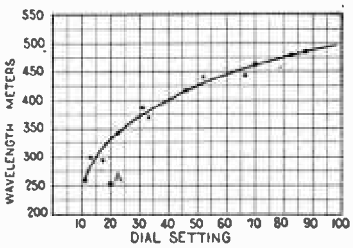

FIG.4

Radio log showing curve drawn so as to touch as many points as possible.

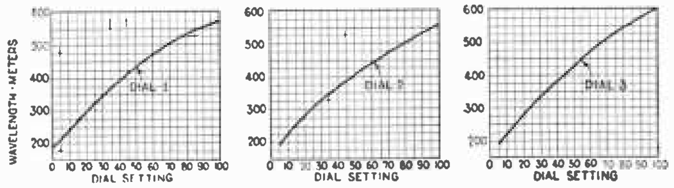

Fig. 5—A three-dial radio log using three separate charts.

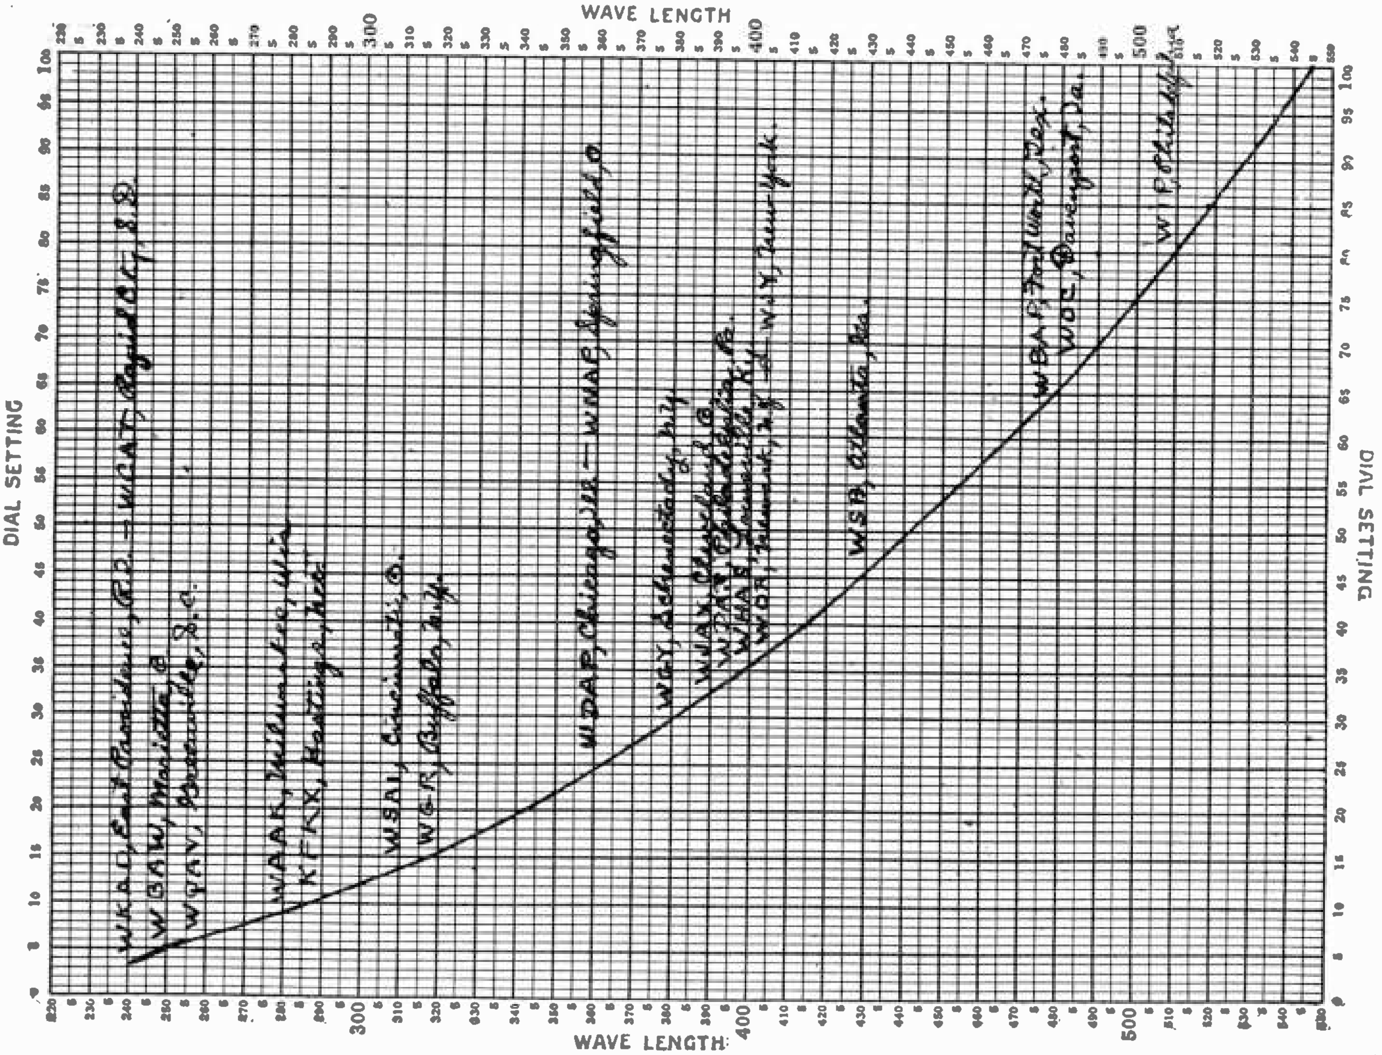
Various stations are thus located by points on the chart until enough points are obtained to draw the curve. If the points do not give a smooth curve, it is necessary to approximate a curve, that is to draw it so as to pass through as many of the points as possible. This has been done in Figure 4.

Sometimes points are obtained that do not seem to have any meaning, such as the point A in Fig. 4. This point may have been subject to inaccuracies in reading the dial, or perhaps the operator did not read the wave length correctly from the list of stations. There is always the possibility, also, that he did not plot the point properly. He has plotted the point A as 251 meters at a setting of 20 when it might have been 335 meters at 20 on the dial, in which case it would have fallen directly upon the curve. If none of these difficulties can be found with the point A it can be discarded, however, because it is an absurd point, as the 12 other points, which determine the curve, will testify. Generally it is not good practise to discard points, but the experimenter must learn to use his good judgment.



An example of a station log chart.

In single-control sets, where only one dial is employed it is only necessary to have one of these radio log curves. In receivers, such as the Neutrodyne or any two-stage radio frequency amplifier, where three dials are employed, it is generally necessary to log each dial separately. The reason for this is, that although these sets are supposed to tune to stations with identical dial settings, many of them do not do so, a difference as great as 10 divisions on the dial often being found. A three dial log is shown in Fig. 5. Separate charts may be used for each dial, or, for convenience, as has been done in Fig. 3, the three charts may be combined into one. If the difference between the dial settings is very small, say only a division or two, one curve will be sufficient.

Many things can be learned from studying the curves obtained. Take for instance, Fig. 2. This is practically a straight line at the higher wave lengths, changing from about 500 meters to about 400 in 55 divisions of the dial. In the remaining 35 divisions of the dial the wave length changes from 400 to 250. In the first case there was a range of 100 meters for 55 divisions and in the latter case a range of 150 meters in 35 divisions. This is because the curve bends downward. At the low dial settings a small change in the dial reading means a relatively large change in wave length, while at the upper end of the dial the same change in dial reading will mean a relatively small change in wave length. The reason why the stations are so crowded at present, at the small end of the dial, is then very apparent, i.e.:

To illustrate, a station operating on a 200 meter wave corresponds to a frequency of 1500 kilocycles (1 kilocycle equals 1000 cycles), and a station on 200 meters corresponds to a frequency of 1,363.5 kilocycles. In other words the difference in wave length is only 20 meters whereas the difference in kilocycles in 136.5. These two wave bands are at the low end of the present broadcast wave band. Now at the high end of the band we find a wave length of 600 meters corresponds to 500 kilocycles, and a wave of 580 meters corresponds to 517.2 kilocycles, or a difference of but 17.2 kilocycles for the 20 meter difference in wave length. At the lower end of the broadcast band between 200 and 220 meters we found a difference of 20 meters equalled 136.5 kilocycles. This indicates that as the wave length becomes lower the difference in frequency becomes very high.

To bring this most strongly to the mind, go down to the extremely low wave of 5 meters. Here the frequency is found to be 60,000 kilocycles. Going up to 25 meters, this corresponds to 12,000 kilocycles, so that for this difference of 20 meters there is the tremendous difference of 48,000 kilocycles.

The accompanying illustration, Fig. 6 will explain the matter very clearly. In changing the dial setting from 100 to, let us say, 90, the wave length is changed roughly from 600 to 580 meters. This is a change from 500 to 517 kilocycles. On the other end of the dial from zero to about 10 we have a change of wave length of roughly 200 to 220 meters, an approx-mate change of from 1500 to 1363 kilocycles. In the first case on the upper part of the dial we have only made a change of 17 kilocycles in the frequency. On the lower end of the dial we have made a change of 137 kilocycles.

17 / 10 KILOCYCLES = 2 WAVE CHANNELS (APPROX.)

Fig. 6—This illustration shows clearly why stations are crowded on the dial at the lower wave lengths.

According to the frequency allocation as made by the Government, which places broadcast frequencies 10 kilocycles apart, on the upper 10 divisions of the dial there is room for approximately 2 frequency channels whereas on the lower 10 divisions of the dial there is room for roughly 14 frequency channels. This shows very clearly that we would have to be able to separate 14 stations on the lower 10 divisions whereas we have only 2 to separate on the upper 10 divisions of the dial.

So it will be understood why turning the dials but a degree or two at the low setting causes a relatively large change in frequency, tuning in perhaps several stations within one degree of the dial, while at the higher settings, due to the small difference in frequency, as stated, on the higher waves, it may be necessary to turn the dials two or three degrees on either side of the peak of the broadcast wave before it is tuned out. (See *Dial.*)

LOGARITHM—abbreviation LOG—The power to which a number (defined as a base) must be raised in order to equal a given number. As an example, given the number 100, assume that it is desired to determine the *logarithm* of this number to the base 10. (When 10 is used as a base, the *logarithms* obtained are said to belong to the *common* or *Briggs system.*) Then the exponent or power which will raise 10 to the value of 100 is known as the *logarithm* of 100. Obviously, 10^2 equals 100, therefore 2 is the logarithm of 100. *Logarithms* are used in the processes of multiplication, division, raising to powers and taking roots. The whole number, or integer part of a logarithm is called its *characteristic* and the fractional part, is referred to as its *mantissa*. The characteristic of a number greater than unity is positive and is one less than the number of figures to the left of the decimal. The characteristic of a number less than unity is negative and is one greater than the number of ciphers between the decimal and the first significant figure. A *table of logarithms* gives the mantissas only, the characteristic being determined as indicated above.

Logarithms are also used which have as their base the number 2.718 +. These are called *natural* or *Naperian logs*. The base number is usually represented by the symbol ε (epsilon). The natural logarithm of any number may be found from a table of common logarithms by dividing the common log by the logarithm of 2.718 or simply by multiplying the common log by 2.30259. The symbol l_n is often used for the natural logarithm and the abbreviation *log* without a subscript is usually used for the logarithm to the base 10. (See *Naperian Log*, also *Mantissa*, and *Log Table.*)

LOGARITHMIC CURVE—A curve which has no definite minimum in a decreasing curve, or no definite maximum in an increasing curve. A *logarithmic curve* may be further defined as a curve whose ordinates increase arithmetically while its abscissas increase geometrically. A series of damped electrical oscillations diminish according to a logarithmic law and hence a curve drawn tangent to the successive maximum displacements will be a *logarithmic curve.*

LOGARITHMIC DAMPING—See *Damping.*

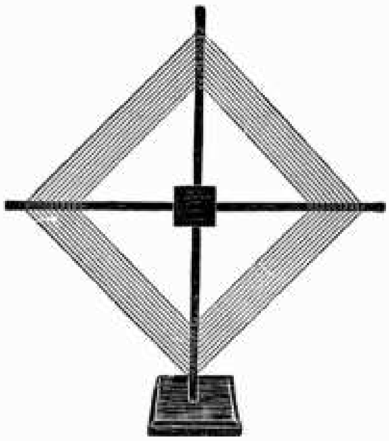
LOGARITHMIC DECREMENT—The *Naperian logarithm* (q.v.) of the ratio of any maximum to the next following maximum, with the current in the same direction in a decaying wave train. In other words the logarithm of the ratio of two maxima, one cycle apart. The rapidity with which the oscillations decay depends not only on the resistance of the circuit, but on the inductance as well. The greater the resistance and the smaller the inductance, the more rapid is the damping and the rate at which the oscillations increase. If the resistance, inductance and capacity of the circuit have fixed values, each successive maximum of current is the same fraction of the preceding maximum as the latter is of the maximum immediately preceding it. Thus, if the second maximum is 75 percent of the first maximum, the third will be 75 percent of the second, etc. The numerical value of the rate of decrease in this case is .75 and the natural logarithm of .75 is the *logarithmic decrement* or simply the *decrement.* (See *Decrement*, also *Damped Waves.*)

LOG TABLE—A tabulated arrangement of logarithms which gives the *mantissas* (q.v.) only. The numbers whose logarithms are to be looked up are arranged for convenience in consecutive order. (See *Logarithm.*)

LOMBARDI, DR. LUIGI—Italian radio authority. Dr. Lombardi was born at Dronero, August 21, 1876. He graduated from the Royal Engineering School at Turin, Italy. He was Professor of Electricity at the Zurich Polytechnical School, Zurich, Switzerland, and also at the Royal Polytechnic School, Naples, Italy. Dr. Lombardi published many scientific papers including a study of condensers for transmission and he also invented a special high-tension electrical condenser.

LONGITUDE—The distance east or west of a meridian passing through Greenwich, England, measured in degrees, minutes and seconds.

LOOP ANTENNA—*Loop Aerial*—Also called *Coil Aerial* or simply *Loop*—A receiving or transmitting *aerial* (q.v.) consisting essentially of one or more turns of wire connected to the radio set so as to form a closed circuit. The *loop* acts as a simple inductance coil. The ordinary radio aerial acts as a huge condenser with the aerial system as one plate of the condenser and the *ground* or *counterpoise* (q.v.) as the other. Electromagnetic waves reaching the aerial set up an alternating electromotive force between the wires forming the upper plate of the condenser and the ground or lower plate of the condenser. This action takes place through *electrostatic induction* (q.v.). In the *loop aerial, electromagnetic induction* (q.v.) sets up an induced electromotive force thus causing alternating current to flow to the detecting apparatus. While coil antennas may be used for transmitting, their use in this connection is rather limited. On the other hand, the use of the loop for radio receiving is widespread. The greater the area enclosed



A typical loop antenna.

by a loop the greater the amount of energy it will receive. Loops more than two feet in diameter are usually constructed so as to be collapsible. A common type of loop shown in the illustration is 36 inches high and 28 inches wide. It consists of twelve turns of wire wound in the same vertical plane and held in place by polished hard rubber strips. It has a heavy cast base permitting rotation of the loop as desired. This loop folds up so as to fit into a four inch tube. In another type of loop, sometimes called the *box type*, the wires are wound so as to lie in the same horizontal plane instead of the vertical plane. The use of *Litzendraht* (q.v.) for winding loops has been found to add to their efficiency. Loops are commonly used on *super-heterodyne* (q.v.) sets, *reflex* (q.v.) sets and in some *tuned radio frequency* (q.v.) sets. These latter generally require an extra stage of amplification, although tuned radio frequency sets having only five tubes (detector, two stages of radio frequency and two stages of audio frequency) will operate on a loop and give especially good results when used with the new power tube. As a general rule, it may be stated that any set which will give good results with a loop, will give better results, insofar as distance is concerned, with an outside aerial. For this reason loop operating sets are quite generally constructed with extra binding posts for connecting aerial and ground. The loop is connected directly into the grid circuit, while the aerial and ground are connected to the circuit through an inductance such as an *oscillo-coupler* or antenna coupler. Loops may be used with satisfactory results inside of buildings. Where a compact, portable and selective aerial is desired, the loop is especially useful. The use of the loop, results in a marked directional effect and also has a tendency to reduce *static* (q.v.) and other forms of *interference* (q.v.). Loops are employed in wireless direction finders or *radio compasses* (q.v.) and are also used as aerials in submarine and aeroplane work. Where the loop is used as an aeroplane antenna it may be wound on the wings of the plane or it may be wound on a small frame and placed in the rear of the plane. (See *Coil Antenna*, also *Frame Aerial.*)

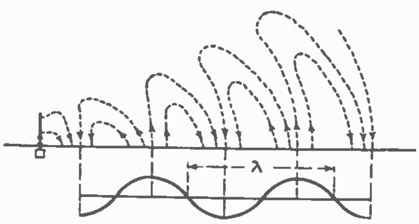
A box-type loop.

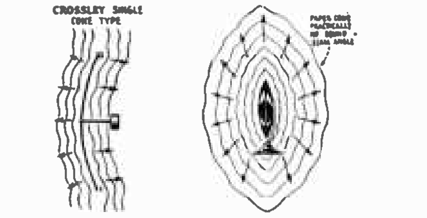
LOOPS—The points of greatest amplitude in a wave train. Sometimes called *antinodes*. The term *loop* is also used in describing the electrostatic field spreading out from a charged aerial. Each time an aerial is charged (for example by an induction coil) and discharged across a spark gap a group of gradually decaying oscillations is produced in the aerial called a *train* of oscillations. The interval of time which elapses between a flow of the electricity in the aerial in one direction, and a succeeding similar movement is called the *periodic time* and the reciprocal of this is called the frequency. For example, if the periodic time is one-millionth of a second, the frequency is one million. The diagram shows the manner in which *semi-loops* of electric force represented by the dotted lines move away from the aerial which is represented by the short black line.



Semi-loops of electric force represented by the dotted lines moving away from the aerial represented by the short black line.

LORENZ COIL—A form of low loss inductance coil, having an air core and of cylindrical shape, being wound in a single layer, with turns slightly kinked to make the coil self-supporting. (See *Coil, Inductance Coils*, also *Low Loss Coils.*)

LOUD SPEAKER—A sound producing device for converting audio frequency currents into sounds loud enough to be heard by an assemblage of people. Nearly all *loud speakers* utilize an electromagnet in order to directly or indirectly cause a diaphragm to vibrate.



At the left is shown a cone-type speaker having a single diaphragm; at the right one with a double diaphragm.

The audio frequency currents flow through the windings of the electromagnet and the vibrations of the diaphragm correspond to the minute changes and fluctuations of the current thus accurately reproducing sounds. In loud speakers which utilize a metallic diaphragm, the electromagnet directly actuates the diaphragm. In other types, the diaphragm may be of mica, as in the Baldwin unit type, or of parchment or wood as in the cone type speakers. In these speakers, the electromagnet actuates an armature which in turn actuates the diaphragm through a lever action. In certain loud speakers, the electromagnet is of very powerful type and has a very small coil of fine wire attached to a diaphragm but not touching the poles of the magnet. The small coil is connected to the radio set or amplifier and the fluctuating audio frequency currents pass through it. These currents force the coil out of the strong magnetic field in the air gap. In moving, it moves the diaphragm to which it is attached. Speakers of this nature are sometimes called electrodynamic speakers. They are also referred to as power speakers. Such speakers give plenty of volume and in certain makes are reasonably good in tonal quality but they have the disadvantage that the electromagnet must be energized from a source of current such as the storage battery. A loud speaker has been developed in England called the Crystavox for use with crystal sets. This consists essentially of an electromagnetically operated speaker connected with a microphonic relay. The relay is actuated by a storage battery. Its function is to magnify the incoming signals from the crystal set, passing them along with increased strength to the electromagnet of the loud speaker. Still another type of speaker which has been used to a limited extent abroad, dispenses entirely with the electromagnet as the actuating source of diaphragm vibration. In this type, electrostatic principles are involved. An agate cylindrical drum, over which a band of copper or similar metal is wound, is revolved at a uniform rate by a small motor or by clockwork. To one end of the band a diaphragm is fastened mechanically. The other end of the band is secured by a fairly stiff spring. Current from the receiving set is led to the cylinder by means of a brush contact and as the current fluctuates the attraction of the band to the cylinder fluctuates with it and the drag on the diaphragm due to the rotation is increased and decreased. The use of the motor constitutes the most serious disadvantage in this type of loud speaker.

Having discussed the various *types* of loud speakers, from the standpoint of principles of operation, the more important of these will now be considered from the constructional standpoint. The early forms of directly actuated metallic diaphragm, electromagnetic loud speakers consisted essentially of a watch-case telephone receiver, or a pair of receivers attached to a horn. The purpose of the horn was to concentrate and redistribute the sounds caused by the vibration of the diaphragm. One of the first improvements was to modify the shape of the horn so as to make it conform more nearly with correct acoustical principles. Another improvement was to introduce an adjustment by means of which the air gap could be varied. In some cases this was accomplished by moving the magnet closer to the diaphragm and in others by moving the diaphragm itself. This adjustment provided a means of getting greater sensitivity on distant stations (by drawing diaphragm closer to the magnet) and of preventing sticking of diaphragm or rattling, on local stations. The ordinary metallic diaphragm has *one* frequency to which it will respond most strongly. This is called its *resonant* frequency. Special speakers

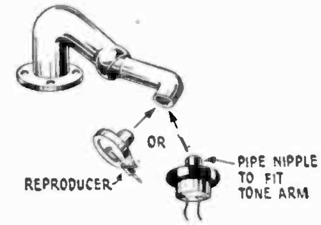
A loud speaker of the horn type having curved cast metal neck and spun brass bell.

called *tuned receivers* have been designed in England which permit the resonant frequency to be varied. In one type, the variations of the magnetic field operate a vibrating reed attached to a non-magnetic diaphragm. The resonant frequency can be varied by adjusting the position of the vibrating reed with a set screw. Another method of getting rid of resonant points in diaphragms has been to use corrugated instead of flat diaphragms. In some of these diaphragms the center is left flat, the remainder of the diaphragm being corrugated with concentric circles either evenly spaced or spaced in section at radii bearing a ratio to each other corresponding to prime numbers. In some cases conical diaphragms with corrugated edges are used. The material as well as the shape of the horn have been found to materially affect the sound reproduction. Horns are constructed of metal, fibre, composition, hard rubber, wood, etc. In general the horn should be of a material which will not give out metallic sounds. The tone arm which carries the speaker unit at one end and the horn at the other is usually constructed of cast metal such as a lead alloy or aluminum. The requirement here is that it must be of an acoustically "dead" material. In some cases the speaker unit and sound chamber are concealed in an artistically designed cabinet thus forming a *cabinet speaker*. Loud speaker units are also made especially for use in conjunction with the sound chamber of a phonograph. These are referred to as *phonograph attachments*. They are ordinarily attached to the phonograph tone arm being put in place of the phonograph reproducer. Some phonographs are now made with provision for attachment of the speaker unit without removal of the reproducer. There is also an attachment on the market for use in connection with a phonograph which has provision for conveniently changing over from the reproducer to the speaker unit or vice versa. Cone speakers may be of the single cone variety or of the double cone style. In these speakers a metal rod extends from the magnet armature and is rigidly fastened to the center of the cone. The most common type of cone speaker has a parchment diaphragm. This seems to give excellent reproduction especially for tones in the lower register. Its points of disadvantage are that it is affected to some extent by moisture and temperature change and furthermore seems to bring out static interference more clearly than some other types. Another type of cone speaker uses a teak wood diaphragm. Some of these speakers have a small fastening screw at the point of attachment between the rod and the diaphragm. This is provided so that tension can be removed from the diaphragm during shipment and also if the speaker is to remain in a room where change in temperature may take place. A cylindrical parchment speaker which utilizes the same principle as the cone speaker, has recently been placed on the market. Its chief point of difference is that the parchment is not under tension as in the case of the cone speaker. Large volume loud speakers are provided with power amplifiers which are often an integral part of the speaker itself. One of the most recent loud speakers is contained in a large cabinet and contains apparatus for utilizing ordinary lighting circuits for operating the set and speaker. The power amplifier unit is also contained within the speaker cabinet and the design of the speaker is such that it can handle any volume without distortion. The rectifier is arranged to supply not only the necessary voltages for the power amplifier but also plate voltage for practically any type of receiving set. (See *Horn, Loudspeaker,* also *Distortion.*)



A loud speaker unit used as a phonograph attachment.

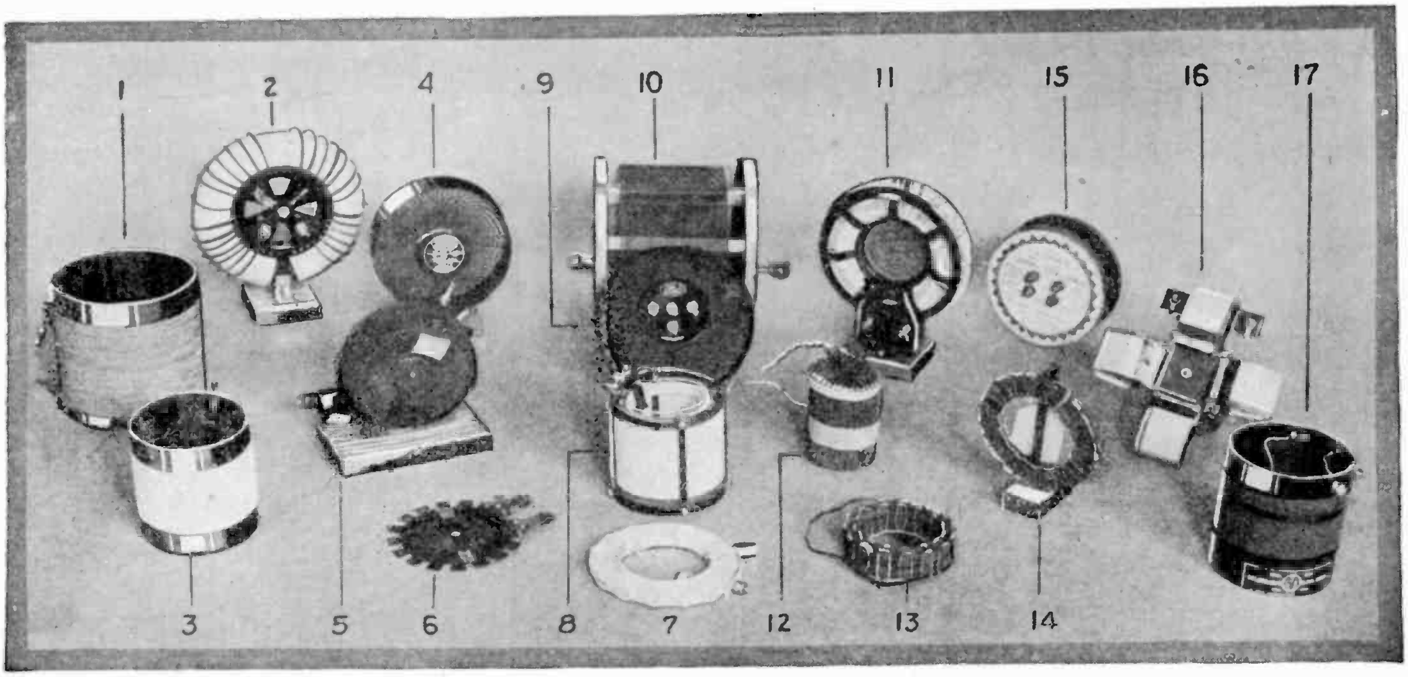
LOUDSPEAKER UNIT—The sound reproducing unit attached to the tone arm of the horn type speaker or to the diaphragm of the cone type speaker. Various types of units are described under the heading *Loudspeakers.*

LOW FREQUENCY—See *Low Frequency Current.*

LOW FREQUENCY CURRENT—An alternating current of less than 10,000 cycles. In radio work the alternating currents used are often classified as *low* frequency currents and *high* frequency currents. While there is no fixed value separating high and low frequencies, 10,000 cycles is generally taken as the dividing line. Thus audio frequency currents are considered as low frequencies and radio frequency currents are high frequencies. The term *low frequency* current as applied to power and lighting circuits refers to circuits having frequencies of 25, 60, etc., cycles per second. (See *Current, High Frequency.*)

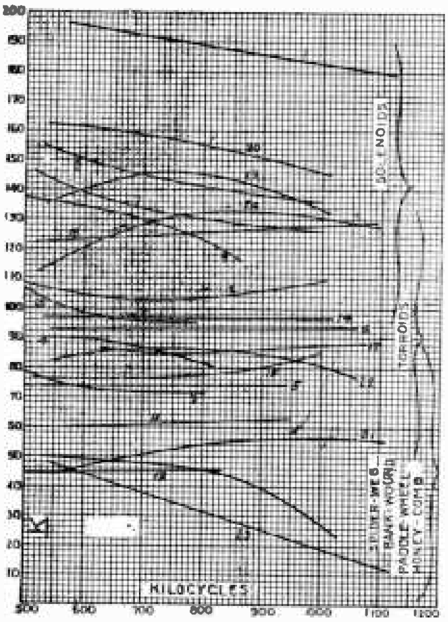
LOW FREQUENCY IRON CORE INDUCTANCE—A variable inductance having an open-ended iron wire core. This inductance is used with spark transmitters to place the primary transformer circuit in resonance with the alternating current frequency.

LOW LOSS COILS—*Inductance coils* (q.v.) having low resistance and specially wound so as to reduce to a minimum condenser effect and hence dielectric losses. The term low loss has been used rather loosely but for practical purposes coil losses should be taken as referring to self-capacity, often called *distributed capacity* (q.v.) ohmic resistance, *skin effect* (q.v.) in the wire due to the effects of frequency and leakage and absorption in or through the insulating materials upon which the coil is built or with which the wire is covered. While it is impossible to obtain a coil having pure inductance only, it is feasable to design the coil so that the various losses will be reduced to a minimum. Often, it has been found that a design which will greatly reduce one type of loss will result in an increase of another. The illustrations show various types of low loss coils together with curves showing comparative efficiency tests. Figure 1 shows the results of an investigation regarding the distributed



Various types of low loss coils including: 1, Bell wire coil; 2, Naxon; 3, Marco; 4, All-American; 5, Orbit; 6, Turney; 7, Sickles; 8, Aerocoil; 9, Erla; 10, Wavemeter coil; 11, Thorola; 12, Pathe; 13, Freshman; 14, Coast Coil; 15, Summitt; 16, Quadroformer; 17, Bruno.

capacity of various coils. This was obtained by making measurements of the inductance of the coils. If the self-capacity of the coil is very small, the self-inductance will not change perceptibly as the frequency changes. On the other hand, if the self-capacity amounts to anything, the curve showing the relation between inductance and frequency will bend upward as the frequency increases, and the greater the capacity of the coil, the more sharply will the curve bend. The curves shown in Figure 1 do not give any idea of what value the self-capacity may have, but simply show whether the inductance varies or not, which is one method of determining how harmful is the effect of the distributed capacity. The more sharply the curve bends upward the less desirable is the coil. In general, the smaller the size of the wire (for sizes smaller than about No. 16 B & S) the higher the resistance. The larger the wire and the thinner the insulation, the greater is the skin effect. The greatest inductance is obtained for a given amount of wire when the coil has a true cylindrical shape. The skin-effect in multi-layer coils is much greater than in single-layer coils. The effect of coil capacity and absorption or leakage in insulation is small compared with the skin-effect except in multi-layer coils, where the distributed capacity may become very great. To keep the physical size of toroidal coils within practical limits the diameter of the turns must be relatively small, so that many more turns are required to obtain a given inductance.



The efficiency of a coil is indicated by the height of its curves on this graph.

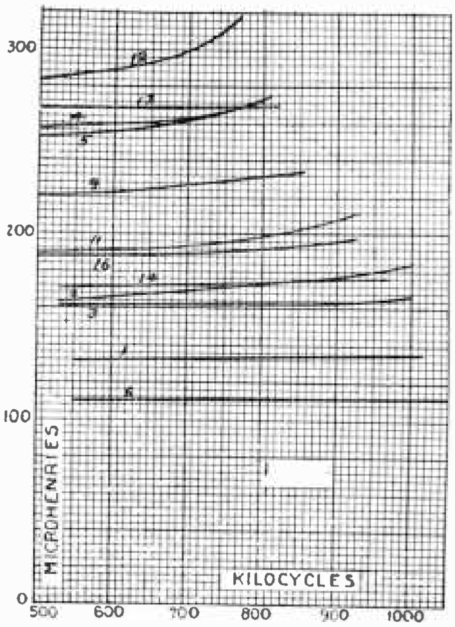


Fig. 1.—The curvature of the graphs indicate the presence of distributed capacity in the coils.

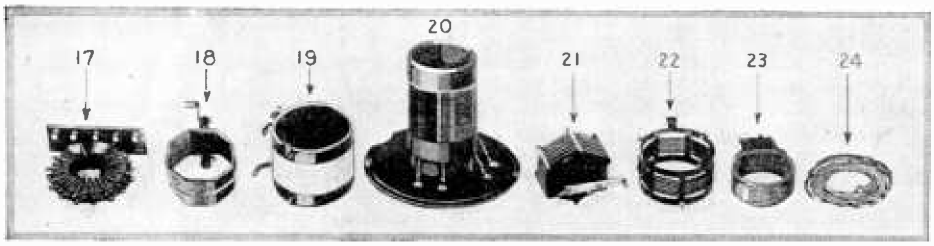


Additional examples of low loss coils: 17, Marwol; 18, Eastern Coil; 19, Workrite; 20, Walbert; 21, Andrews; 22, Bremer Tully; 23, Cotocoil; 24, Kresge Lorenz coil.

LOW TENSION — abbreviation L. T. — A comparatively low voltage. A circuit supplied by a low voltage battery such as the filament circuit of a vacuum tube is called a low tension circuit. In electrical engineering work, any circuit of 600 volts or under is considered to be a low tension circuit.

LUGS—Metal projections used for permanently connecting conductors with electrical apparatus. In one type of lug, the metal is bent over at one end to form a tube into which the conductor can be soldered, while the other end is flat and has a hole drilled to receive any desired terminal.

Typical lugs.

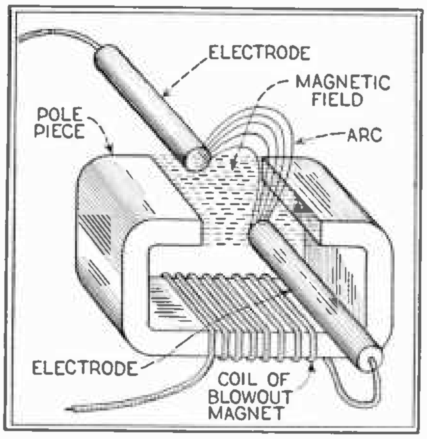
M

MAGNET—A piece of iron or steel having the power to attract other pieces of iron and to attract or repel other magnets. Natural magnets are known as *Loadstones* (q.v.). (See *Electromagnet*, also *Permanent Magnet* and *Temporary Magnets*.)

MAGNET WIRE — Insulated wire for the construction of magnet coils. In radio extremely fine wire is used to wind the coils of the electromagnets used in headsets and loud speaker units. The most common insulation used in radio work for magnet wire is enamel. Other types of magnet wire utilize a single cotton covering, a double cotton covering or a silk covering. (See *Enameled Wire*.)

MAGNETIC ATTRACTION AND REPULSION—The mechanical force tending to draw together two magnetic poles of unlike polarity, or to force apart two magnetic poles of like polarity.

MAGNETIC BLOWOUT—An electromagnet with its pole pieces placed so that the direction of the magnetic field will be at right angles to the movement of the ions in an electric arc. The coil of this magnet is energized in some cases in series with the line and acts to expel or blow out the arc. In the series arrangement, the blow-out action is stronger, the larger the current to be interrupted. For small shunted arcs, permanent magnets are often used. The operating principle of the blowout coil depends upon the fact that in a magnetic field, an electric current tends to move across the lines of force or in other words to cut them. In the illustration, the pole pieces are shown so placed that the general direction of the lines of force is at a right angle to the flow of the ions in the arc. The electromagnetic action causes the arc to move outside the field. This increases the length of the arc, thus rapidly breaking it. Magnetic arcs are used in connection with *keys* (q.v.) used for interrupting a large current, in certain types of *lightning arresters* (q.v.) and also in motor controllers..



A magnetic blowout.

MAGNETIC CIRCUIT — The path traversed by magnetic lines of force. A magnetic circuit may be entirely through iron, as in the case of a closed core transformer or partly through iron and partly through air as in the case of a motor or generator. (See *Line of Force*.)

MAGNETIC COUPLING—See *Coupling*.

MAGNETIC COUPLING TRANSFORMERS—See *Coupling Transformer*, also *Jigger*.

MAGNETIC FIELD — The whole space over which a magnet exerts influence. The space traversed by the magnetic flux. Wherever magnetism is present the space in the immediate vicinity is called a magnetic field. (See *Electromagnetic Induction.*)

MAGNETIC FLOW—The passage of magnetic lines through a magnetic circuit. This term is sometimes used in the place of magnetic flux. (See *Flux Magnetism.*)

MAGNETIC FLUX—Symbol ϕ—The total magnetism present at any cross-section perpendicular to the lines of force. Magnetic flux is analagous to current flow. That is to say, it is convenient to consider a flow of magnetism in the same way as electricity is considered to flow. The unit of magnetic flux in the c.g.s. (centimeter gram second system) electromagnetic system is the *maxwell* (q.v.) or simply the *line.* The unit of magnetic flux in the practical system is also the *maxwell.* (See *Line of Force, Alternator,* also *Flux, Magnetism.*)

MAGNETIC FLUX DENSITY—The number of lines of force per unit cross-sectional area of a magnetic path. The *gauss* (q.v.) is the unit of magnetic flux density. It is equal to one *line* (q.v.) per square centimeter.

MAGNETIC FORCE—The force with which a magnet attracts or repels any piece of iron or steel. The intensity of a magnetic field at any point as measured by the force which it would exert upon a unit magnetic pole if placed at that point.

MAGNETIC FORCE DUE TO CURRENT—A magnetizing force due to current flow which can be determined mathematically for any point in the surrounding medium. Consider any closed stream line of electric current surrounded by a medium having uniform magnetic properties. It can be demonstrated that each elementary length of the current stream line, dl, contributes to the magnetizing force H, at any point T an amount dH =

$$\frac{(\mathrm{I}\sin\Theta)\,dl}{r^2}$$

where I is the current flowing along this stream line, r is the distance from T to dl, and Θ (theta) is the angle between r and dl. The direction of dH is perpendicular to the plane of r and dl. The total magnetizing force at T is the vector sum of dH for all the elementary lengths into which the current stream line is divided.

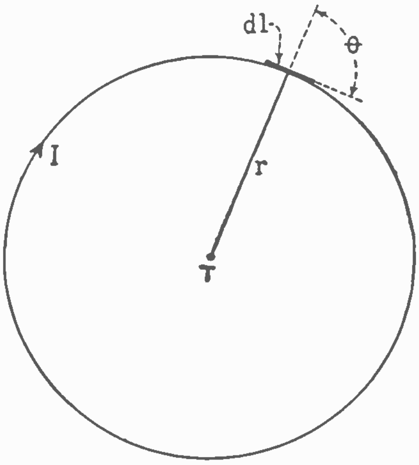


Diagram illustrating method of determining magnetic force due to current.

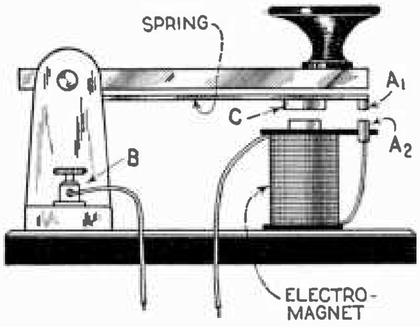
MAGNETIC HYSTERESIS—The opposition which minute particles of a magnetic material offer to being magnetized or to having their magnetization changed. It is sometimes referred to as molecular friction or as *magnetic lag.* (See *Hysteresis.*)

MAGNETIC INDUCTION—See *Induction,* also *Diamagnetic Material.*

MAGNETIC INDUCTIVE CAPACITY—symbol μ (mu)—Also termed Magnetic Inductivity—Names sometimes used instead of *Permeability* (q.v.). The ratio between the number of lines of force per unit area passing through a magnetizable substance and the magnetizing force which produces them. Stated another way, it is the ratio of flux density to magnetizing force. It can be considered as a measure of the ease with which magnetism passes through any substance. The magnetic inductive capacity of air is taken as unity. The term magnetic inductive capacity is analogous to *specific inductive capacity* (q.v.) which is the ratio of the dielectric constant of a material to that of a vacuum.

MAGNETIC INTERRUPTER—A device energized by an electromagnet for interrupting a circuit. (See *Interrupter.*)

MAGNETIC KEY—An electromagnetic adjunct to a wireless transmitting key for reducing or eliminating sparking due to the self-induction of the heavy currents which are interrupted. A form of magnetic key is shown in the illustration. Underneath the lever arm of the key is placed a spring to which an iron armature C and a platinum contact A_1 are attached. If the key and hence the spring are pressed down contact A_1 touches contact A_2 and the path of the current is completed. The current passes not only through the key, but also through the winding of the electromagnet. If the key is released so as to move upward, the contact A_1 still remains touching A_2, as the magnetic action due to the current continues to hold down the armature C and hence the spring with the contact A_1. Not until the alternating current reaches a zero value is the armature released. This releases A_1 from A_2, at an instant of zero current and hence there is no spark.



A magnetic key.

MAGNETIC LEAKAGE—Magnetic flux which serves no useful purpose. There are no substances which will prevent the passage of magnetic flux. This fact introduces a certain amount of difficulty into practical magnetic circuit calculations, since it is impossible to confine all the flux into a predetermined magnetic path. Since there is no magnetic insulator there will always be a certain amount of *leakage flux.* However this can be reduced to a minimum by proper design of the magnetic circuit. Magnetic Leakage is also referred to as *Stray Flux.*

MAGNETIC LINES OF FORCE—See *Line of Force,* also *Electromagnet.*

MAGNETIC MOMENT—The product of the strength of pole of a magnet and its virtual length. The torque exerted by a magnetic field upon a magnet depends upon the magnetic moment.

MAGNETIC NEEDLE—A light, thin steel magnet mounted on a pivot or suspended so as to be free to move. It takes a position pointing to the magnetic north.

MAGNETIC POLES—Points on a magnet where the lines of force leaving or entering the iron are concentrated. In a magnetic needle, that end which tends to point north is called a north or positive pole; that end which tends to point south is called a south or negative pole. A unit magnetic pole is defined as one which, when placed at a distance of one centimeter from a like pole of equal strength, will repel it with the force of one dyne. The north magnetic pole of the earth is situated in latitude 70 North and longitude 97 West. The south pole is located at latitude 70 South and longitude 102 East. It should be noted that the magnetic poles do not coincide with the geographical poles. (See *Induction, Magnetic.*)

MAGNETIC PROPERTIES—Materials are classified according to whether or not they offer a good path for the magnetic lines of force. Substances of comparatively low *reluctance* (q.v.) are termed *magnetic.* They are also often referred to as *ferro-magnetic.* They include iron, steel, nickel, cobalt, manganese, chromium, magnetite, certain alloys of copper, manganese and aluminum (called Heusler Alloys), and certain other oxides. The magnetic laws governing these substances can best be set forth by means of magnetization curves. Substances having high reluctance are termed *non-magnetic.* For commercial purposes, air is the most important non-magnetic substance. However, practically all substances, with the exception of the ferro-magnetic ones, follow the same magnetic laws as air. While the reluctance of a non-magnetic substance is constant, the reluctance of magnetic substances varies, as the amount of *flux* (q.v.) in the substance changes. Although air and all other substances, with the exception of the ferro-magnetic ones are classed as non-magnetic substances, and are poor conductors of magnetic flux, when compared to iron, etc., nevertheless they are by no means magnetic insulators. There are no substances which will absolutely prevent the passage of magnetic flux. (See *Ferro-Magnetic Substances.*)

MAGNETIC PYRITES—See *Pyrites.*

MAGNETIC STORM—Sudden and irregular variations of the earths magnetic field. Magnetic storms are sometimes coincident with the appearance of sun spots. These storms often disrupt telegraph service and also cause much interference with radio communication.

MAGNETISM—A phenomena exhibited by certain materials which is characterized by the attraction or repulsion of soft iron or of conductors carrying electricity. Magnetism is one of the manifestations of electricity, since a current flow is always associated or linked with a *magnetic field* (q.v.). (See *Free Magnetism, Magnet,* also *Magnetic Properties.*)

MAGNETISM, LAWS OF—Like magnetic poles repel one another; unlike magnetic poles attract one another. The force exerted between two magnetic poles is proportional to the product of their strengths and is inversely proportional to the square of the distance between them. (See *Like Poles.*)

MAGNETITE — symbol Fe_3O_4 — A mineral composed mainly of magnetic oxide of iron. When found in magnetized condition it is known as a *loadstone* (q.v.) or a natural magnet. It is a black brittle substance having a specific gravity of 5.2.

MAGNETIZATION—(also spelled *Magnetisation*)—The process of communicating magnetism. The act of rendering iron, steel, etc., magnetic. According to Ewing's theory, a substance which is magnetized has its molecules rearranged so that they assume symmetrical positions, each molecule lying in line with or parallel with its neighbor. In this rearranged position each molecule adds its separate magnetic force to every other one and the cumulative effect of this is that the substance exhibits the property of a magnet. (See *Demagnetization.*)

MAGNETO GENERATOR—A small generator consisting essentially of an armature rotating between permanent magnets, usually of the horse-shoe type. Magnetos are mainly used for motor ignition, medical coils, bell ringing and for firing high explosives. (See *Intermittent Current.*)

MAGNETOMOTIVE FORCE OR DIFFERENCE OF MAGNETIC POTENTIAL—abbreviation m.m.f.—The force causing magnetic flow. *Magnetomotive force* is the magnetic cause, while *flux* (q.v.) is the magnetic effect, just as in electrical terms, *electromotive force* (q.v.) is the cause and current is the effect. The c.g.s. (centimeter gram second) unit of magnetomotive force is the gilbert (q.v.). The unit ordinarily employed in practical calculations of the magnetic circuit is the *ampere-turn* (q.v.). (One ampere-turn is equal to 1.2566 gilberts.) An ampere-turn consists of a current of one ampere flowing through one complete turn of a conductor. The expression "turn" means that the conductor is wound in a solenoid. That is to say, it is wrapped around a core which may consist of air or of any other substance. The same magnetic field will result from ten ampere-turns consisting of ten amperes flowing through one turn, as from ten ampere-turns consisting of one ampere flowing through ten turns. (See *Force, Magnetomotive.*)

MAGNIFIER, OR RELAY—An apparatus for intensifying the variations of a current. The term *magnifier* has been incorrectly used for *amplifier* (q.v.). One type of *magnifier* used in radio is the microphonic relay (see loud speaker) by means of which the minute currents in a crystal set can be magnified so as to actuate a loud speaker. In the ordinary telephone repeater, a microphone is acted upon by the receiver of the first line circuit so as to introduce a local circuit which acts inductiveley on the second line wire. Relays are also used in wire telegraphy to boost weak line currents by means of strong local batteries. (See *Relay.*)

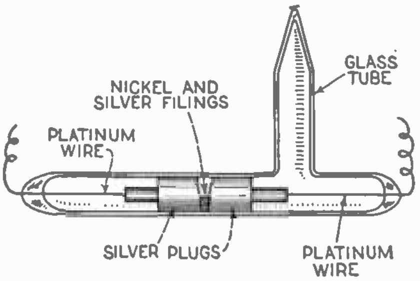
MANTISSA — The decimal part of a *logarithm* as differentiated from the integral part or characteristic. For example in the logarithm 1.23578, 1 is the characteristic and the decimal .23578 is the mantissa. (See *Logarithms.*)

MARBLE—The name given to any limestone sufficiently compact to permit being polished. Pure marble is white, the presence of oxides giving the different colors. Marble is used extensively for switchboard work and when so used must be free from metallic veins. Where circuits carrying 1000 volts or more are used, the switchboard should be saturated with an insulating varnish and baked. Inasmuch as the marble shows oil spots, it is sometimes stained black and given a finish called a *marine finish*.

MARCHANT, EDGAR WALFORD. British radio expert. Born in 1876, he was educated at University School, Hastings, and Central Technical College and London University. In 1897 he was appointed superintendent of the laboratory and workshops of Lord Blythswood at Renfrew, where he carried out many experiments in wireless telegraphy. He became chief assistant at Finsbury Technical College, 1900, under Professor Silvanus P. Thompson, and the following year was appointed lecturer in electro-technic at University College, Liverpool. In 1903 he was appointed the first professor of electrical engineering at the university.

Marchant was for some time closely associated with W. Duddell in developing the oscillograph, and the two read a joint paper on the study of the electric arc by the aid of oscillographs to the Institution of Electrical Engineers, of which institution Marchant became vice-president. He is also a vice-president of the Radio Society of Great Britain. He has written many papers on radio, and contributed an article to the proceedings of the Royal Society on the magnetic behaviour of iron under oscillatory discharge of a condenser.

MARCONI FILINGS COHERER—Also called Marconi Coherer—A detector of electric waves consisting of fine nickel and silver filings contained in a suitable glass tube between two electrodes consisting of two silver plugs. These two plugs are connected to platinum wires brought out through the sealed ends of the tube, which is carefully exhausted of its air. The metallic filings in a loose condition have feeble conductivity for the current from a single dry cell. If a very weak electric oscillation is passed through the coherer, the filings cling together or cohere and hence conduct electricity better and they will then pass sufficient current from a single dry cell to operate a telegraphic relay. To bring these filings back to a non-conductive condition, the tube is tapped by an electromagnetic tapper, similar to an electric bell with the gong removed. The Marconi coherer is now obsolete. (See *Coherer.*)



The Marconi filings coherer.

MARCONI, GUGLIELMO—Italian-Irish radio pioneer. Guglielmo Marconi was born at Bologna, Italy, April 25, 1874, and was educated at the Leghorn Technical School, under Professor Rosa. From his earliest years he was keenly interested in communication by means of Hertzian waves, and began his brilliantly successful series of experiments in June, 1895. These first experiments were carried out on his father's estate near Bologna. Marconi soon found that the Hertzian form of resonator gave only feeble signals at a distance, and he substituted a vertical wire, with the result that in 1895 he was able to transmit signals to a distance of one and a half miles. About the same time he improved the Branly coherer, which he was using as a detector, and invented an electric tapping device to decohere the filings.

This early apparatus of Marconi, from which has sprung the far-flung wireless chain of to-day, consisted of a coherer, a relay, a decoherer, and a Morse printing instrument, all working from storage batteries. Between the coherer and the relay Marconi interposed choke coils, and this had a very marked effect on the receptivity of his set. By close attention to the details of his system he was able to carry on his signals at greater ranges than had up to this time been accomplished by other experimenters.

The transmitting apparatus used by Marconi in these early efforts consisted of a large spark gap to which the aerial and earth wires were connected. The high-tension current for the spark was provided through an induction coil from batteries. The spark gap consisted of a ball discharger comprising four brass balls. The two middle balls were separated by a small space filled with vaseline oil, the actual spark jumping from the two end balls to the middle ones and through the vaseline, producing a high-frequency spark.

Marconi came to England in 1896, where he took out the first patent ever granted for a practical system of wireless telegraphy. He made a number of experiments at Westbourne Park, and demonstrated his system before Sir William Preece and other high officials at the Post Office. In the following year he increased the range of his set to nine miles using a 29 in. spark coil and kites to raise the vertical aerials. In July, 1897, in demonstrating before the Italian Government, he covered 12 miles between warships, and he began to instal a number of his sets for lighthouses, and the success of his experiments led to stations being erected for the corporation of Trinity House.

Guglielmo Marconi.

In 1899, the first proof of the advantages of wireless over other forms of communications came with the saving of the lives on board the ship R. F. Matthews, which ran into the East

Goodwin lightship. The latter was equipped with one of Marconi's transmitting sets and was able to communicate with the South Foreland lighthouse and summon assistance.

The genius of Marconi lies not so much in his inventions, as in his far-sightedness in being the first man to realize the immense commercial possibilities of radio, and to make the best use of all the scientific effort of his time to further the object he had in view.

Marconi has received innumerable honors from all countries. He holds the honorary degrees of universities all over the world, and the freedom of a large number of cities. In 1909 with Professor Braun, he was awarded the Nobel Prize for Physics, and in 1914 he was given the Honorary Knighthood of the Grand Cross of the Victorian Order. He has been awarded the Albert Medal of the Royal Society of Arts, the Gold Medal of the Institute of Radio Engineers of New York, the John Fritz Gold Medal for the invention of wireless telegraphy, and the Franklin Gold Medal of the Franklin Institute. He was the Italian delegate to the Peace Conference, and signed on behalf of Italy. He is chairman of the board of directors of the Marconi Company.

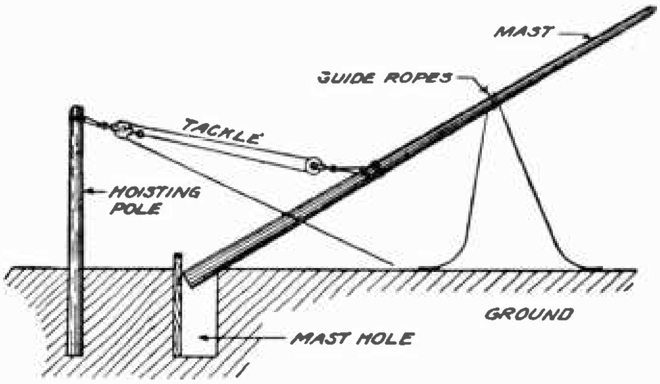
MARINE TYPE CHARGING PANEL—A switchboard equipped with resistance coils, carbon filament pilot lights, voltmeter and necessary switches. Manipulation of the switches allows the battery to be placed on charge or on the line. By throwing a switch on this board, it is also possible to work the wireless transmitter either from the ship's generator or from the storage battery.

MASS—The quantity of matter which a body contains. Physical quantities such as force, velocity, etc., are expressed in terms of length, *mass*, and time. The unit of length is the centimeter; of mass, the gram; and of time, the second. Hence this system of measurement is known as the C.G.S. (centimeter gram second) system. The gram is equal to 15.432 grains and represents the mass or quantity of a cubic centimeter of water at 4 degrees centigrade.

MASTER-OSCILLATOR SYSTEM—A radio telephone transmitting circuit in which a small extra *audion* (q.v.) is used to supply the power to excite the grid circuit. This extra oscillator or exciter is referred to as the master-oscillator. The master-oscillator system has several advantages over the self-excited system. Changes in antenna constants, such as might be caused by a swaying aerial or *lead-in* (q.v.) do not affect the transmission where the former system is used. In addition the master-oscillator system is more convenient to work with and the adjustment for maximum output for different wave lengths and antenna resistances is more easily made.

MASTER-OSCILLATOR SYSTEM AMPLIFIER—In the master-oscillator system, the power tube acts as an amplifier of the power supplied by the small extra exciting, or master-oscillator. The exciter must develop sufficient power to supply the losses in its own oscillating circuit and those of the grid circuit of the power tube.

MASTS, ERECTION OF—High powered stations generally use latticed steel masts. In some cases tubular metal masts in telescoping sections are used. Wooden masts have been used to quite an extent. For portable outfits, these are made in sections which can be fitted together like a fishing rod. Guy ropes or wires are necessary in practically every instance. In erecting a mast, it is usual not to make the installation too rigid, but rather to allow some freedom of movement so that the mast may sway slightly in the wind. Where a one-wire aerial is being erected this may be fastened to any support available. In marine construction, the ship's masts are used to support the aerial, the wires being stretched between the two booms or spreaders. from which halyards run to the masts. (See *Aerial.*)



A method of erecting a tall mast using tackle and hoisting pole.

MATCHED IMPEDANCES—Circuits balanced or matched so that the total impedance of one circuit will equal the impedance of another circuit with which it is coupled. (See *Impedances, Matched.*)

MAXWELL—symbol φ—The unit of *magnetic flux* (q.v.). It is also known as the *line* (q.v.). One maxwell is equal to one line of force. (See *Flux Density*, also *Kiloline.*)

MAXWELL'S CORKSCREW RULE—If the direction of travel of a right-handed corkscrew represents the direction of current in a straight conductor, the direction of rotation of the corkscrew will represent the direction of the magnetic lines of force.

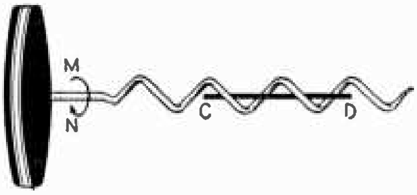


Illustration of Maxwell's corkscrew rule. When current flows from C to D, magnetic lines encircle the wire in the direction of the curved arrow MN.

MAXWELL'S LAWS—The magnetic fields surrounding parallel currents in the same direction will react upon each other in such a way that the conductors will tend to move together. In the case of parallel currents in opposite directions, the fields between the two conductors will be in the same direction and will merge together, thus tending to push the conductors apart. The magnetic fields around two conductors at an angle will react upon each other in such a way as to tend to bring the conductors parallel, and with the currents flowing in the same direction.

MAXWELL'S LAW OF MOTOR ACTION—A conductor carrying a current whose direction of flow is at right angles to a magnetic field, will tend to move out of this field.

MAXWELL'S RULE—Every portion of a circuit is acted upon by a force urging it in such a direction as to make it enclose the greatest possible number of lines of force.

MAXWELL TURNS—The deflection value in a ballistic galvanometer or *fluxmeter* (q.v.). This depends upon the number of turns in the exploring coil and the instantaneous value of the flux in maxwells linked with this coil. (See *Grassot Fluxmeter.*)

McLACHLAN, NORMAN W.—British radio authority. Born at Longtown, Cumberland in 1888, and educated at Carlisle Grammar School and the George Watson and the Heriot Watt Colleges, Edinburgh, and Liverpool University. He was appointed lecturer in Engineering and Mathematics at Newcastle-on-Tyne in 1909. In 1913 McLachlan was appointed supervisor of classes in engineering subjects in the Liverpool Technical Institutes, and after the Great War, during which he was engaged in aeronautical research and the study of anti-submarine devices, he made a special study of magnetos at the National Physical Laboratory, Teddington. Appointed research engineer to the Marconi Company, he is the author of many papers on wireless and electrical subjects in the journal of the Institution of Electrical Engineers and other scientific journals, including those on Characteristic Curves of a Poulsen Arc., the Magnetic Behaviour of Iron at very High Frequencies; and Theory of Iron-cored High Frequency Transformers. He has taken out a number of radio patents.

MEASUREMENT OF INDUCTANCE—Some methods of measuring inductance (also applicable to the measurement of *capacity*) are various bridge methods; by measuring the voltage, current, power, and frequency; and by the wave meter method. Connections in one bridge method for measuring inductance are similar to those in the ordinary *Wheatstone Bridge* (q.v.). A coil having a known inductance is balanced against the inductance to be measured. A device called a *Secohmmeter* is in use to increase the sensibility of bridge measurement of inductance. The Secohmmeter serves the purpose of making an alternating current to use in measurements of self-induction and of commutating such portion of this current as flows in the galvanometer circuit to a direct current. When a source of alternating current of known frequency is available the following method is convenient. Place the inductance across the alternating current mains, measure the power absorbed, the current flowing, the voltage across the unknown inductance and the frequency of the circuit. Then the inductance L is equal to the reactance, x, divided by

2 π times the frequency. Expressed as a formula

$$L = \frac{x}{2\pi f} = \frac{\sqrt{\left(\frac{E}{I}\right)^2 - \left(\frac{\text{Power}}{I}\right)^2}}{2\pi f}$$

The inductance L should be expressed in henries. This method gives results of fair accuracy but is not adapted to measurements of low values of inductance. Small inductances are more usually measured by bridge methods. In the wave meter method, a condenser is discharged through a spark gap in a circuit containing a known capacity and by means of a wave meter measuring the wave length. The expression for the number of oscillations in a closed circuit containing both inductance and capacity is given by the formula

$$n = \frac{1}{2\pi\sqrt{CL}}$$

and the wave length is equal to the velocity of propogation divided by the number of waves and calling λ the wave length we have

$$\lambda = V \text{ times } 2\pi\sqrt{CL}$$

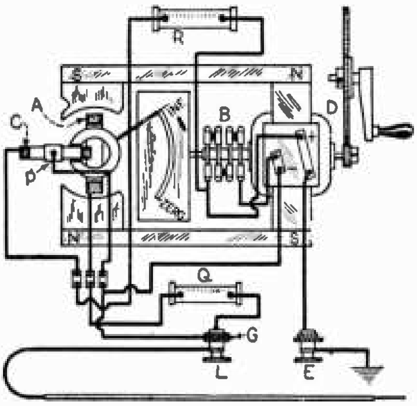
In this last equation everything is known but the inductance which can be calculated. (See *Inductance*, Measurement of.)

MEASUREMENT OF WAVE LENGTH—The usual method of measuring an unknown wave length is by means of a wavemeter. Other apparatus required in this connection is a hot wire ammeter indicator in a coupled circuit, or crystal detector and telephones. Also an antenna excited oscillating circuit supplied by electron tube. A wavemeter placed in inductive coupling with a coil or antenna carrying radio current will show decided increase of current in its own coil and condenser when it is tuned to resonance with the source. The wave length is read directly from the wavemeter setting for resonance or from a calibration curve. A receiving set can be used to measure the wave lengths of received waves if it is first standardized in terms of wave lengths. The operator listens in through the head set attached to the receiving set. As the wavemeter condenser knob is turned the loudest sound is heard when the wavemeter circuit is tuned to the same wave length as that for which the receiving set is adjusted. The wave length is then read from the wavemeter scale or calibration curve. Continuing in this manner, the receiving circuit can be calibrated as a wavemeter by setting it at many different adjustments and reading the wave lengths at resonance each time. The wave length of the waves emitted by an antenna, when no added inductance or capacity is inserted in the antenna circuit, is known as its fundamental wave length. For a single vertical wire grounded antenna the fundamental wave length is slightly greater than four times the length of the wire. The approximate constant often used is 4 2 and this applies also to "L" or "T" type aerials with vertical lead in wire, the total length being measured from the transmitting apparatus up the lead-in wire and over to the end of the flat top. It is of course, more accurate to measure the wave length radiated from an antenna directly by use of a wavemeter. The wavemeter coil needs merely to be brought near the antenna or lead-in wire and the condenser of the wavemeter adjusted to give maximum current in the wavemeter indicator. The wave length corresponding to the wavemeter setting is then the length of the waves radiated by the antenna. The fundamental wave length of the antenna may be determined by gradually decreasing the number of turns in the *loading inductance* (q.v.), measuring the wave length for each setting of the loading coil and plotting a curve showing the wave length corresponding to the various numbers of turns of the loading coil. The fundamental, then, is the wave length corresponding to zero turns and is found at the point where the extension of the curve cuts the wave length axis. (See *Measurement of Inductance*, also *Formula*.)

MECHANICAL MIXTURE—A mixture of two or more elements which leaves them essentially the same. This is sometimes incorrectly called a mechanical compound. Sugar and sand mixed together give an example of a mechanical mixture. A *chemical compound* is formed when two or more substances combine chemically to form another substance having different characteristics. Thus iron filings and sulphur can be combined to form a third substance unlike either of the original two.

MEG OR MEGA—symbol M—The prefix placed before the name of a unit to denote one million times (10^6) that unit, as for example *megohm* (q.v.) *mega-volt*, *megerg*, etc.

MEGGER—An instrument for measuring insulation resistance or in general any resistance by the direct deflection of a pointer on a scale. The "Evershed" type is made in two forms (1) the *megger* insulation testing set and (2) the bridge-megger testing set which combines the functions of type (1) with those of a *Wheatstone Bridge* (q.v.). Both types consist of an ohmmeter of the moving coil type combined in one box with a hand driven generator for providing the necessary testing voltage and current. When the handle of the generator is not being turned, the pointer is entirely free and will rest anywhere on the scale. The general principles underlying the construction and operation of the megger are shown in the illustration. As can be seen, the megger is a combination of a *magneto generator* (q.v.) shown at the right, with an ohmmeter shown at the left, in a magnetic circuit common to both and consisting of two pairs of field poles braced by strong bar magnets, NS, NS, and forming two bi-polar field magnets in series. In the right hand one, and rotated by a folding handle and spur gearing D, is the armature of the generator, with its brush gear B, and terminal bars marked + and —. In the left hand field is the current coil A, pressure coil P, and compensating coil C of the ohmmeter, connected to resistances Q and R, a *guard plate* G, and the only two external terminals L and E (marked Line and Earth on the actual instrument). The bridge-megger testing set is available for use both as an insulation testing set and as a specialized Wheatstone Bridge. It differs from the ordinary megger in outward appearance only by the addition of two pairs of terminals and of two switches, one of which is the *ratio* switch of the Wheatstone Bridge and the other one is a two-way change over-switch. This latter when set to "Megger" prepares the instrument for measuring insulation resistance or high metallic resistance by coupling the two windings of the constant voltage generator in series and making the two front terminals, marked Line and Earth, the only two available for connection. When the change-over switch is set to "Bridge" the instrument is ready for Wheatstone Bridge work, the two windings of the generator now being connected in parallel in order to increase the current obtainable from it. In this case the ohmmeter part is changed into a galvanometer for the bridge and the arms of the bridge are switched into their appropriate places in the circuit and connected to the terminals marked R and X at the end.



A diagrammatic illustration of a megger.

MEGOHM—One million ohms. This unit is usually employed in the measurement of insulation resistance. It is also used in measuring *grid leaks* (q.v.), etc. See *Ohm*, also *Begohm.*)

MEGOHMITE, also spelled Megohmit—An insulating material similar to micanite, obtainable in several forms, one of which is known as *hard megohmite* and is made of thin sheets of mica built up of shellac. *Flexible megohmite* consists of sheets of mica stuck together by vegetable adhesives. Flexible megohmite covered with Japanese paper is called mica paper while flexible megohmite covered with linen, is called *mica linen.*

MEISSNER, ALEXANDER.—Austrian radio expert. Born at Vienna, 1883, he was educated at the Technical High School and University of Vienna. He joined the Telefunken Company in Berlin, 1907, and is one of the leading authorities in Germany on radio. To him is due a large number of wireless inventions, including the Telefunken compass, musical quenched sparks, interference preventers, the direct current cathode valve relay for the reception of Morse Code, etc. In 1913 he invented the generation of oscillations by means of the three-electrode valve. He holds many patents, including spark gap for impulse excitation, quenched-spark signalling in conjunction with G. Von Arco, etc., and he is the author of many papers for scientific journals and societies on the subject.

MERCURY ARC RECTIFIER (MERCURY VAPOR CONVERTER)—A device for changing alternating current to direct current, which depends for its action upon the unidirectional conductivity of the mercury arc in an exhausted vessel. An idea of the principle of operation of the mercury arc rectifier may be obtained from the illustration. Assume an instant when the terminal H of the supply transformer is positive, the anode A is then positive and the arc is free to flow between A and B, B being the mercury cathode. Following the direction of the arrows still further, the current passes through the lead J, through the reactance coil E and back to the negative terminal G on the transformer. A little later when the impressed electromotive force falls below a value sufficient to maintain the arc against the counter electromotive force of the arc and the lead. the reactance E which heretofore has been charging, now discharges, the discharge current being in the same direction as formerly. This serves to maintain the arc in the rectifier until the electromotive force of the supply has passed through zero, reverses and builds up to such a value as to cause A′ to have a sufficiently positive value to start an arc between it and the mercury cathode B. The discharge circuit of the reactance coil E is now through the arc A′B, instead of through its former circuit. Consequently the arc A′B is now supplied with current, partly from the transformer and partly from the reactance coil E. The new circuit from the transformer is indicated by the arrows enclosed in circles. The amount of reactance inserted in the circuit reduces the pulsations of the direct current sufficiently for all ordinary commercial purposes. The mercury rectifier is used in small sizes for charging storage batteries from alternating current circuits and in the larger sizes for operating direct current arc lamps from alternating circuits and also in electric traction work in the place of rotary converters in the substations or even on the train itself.

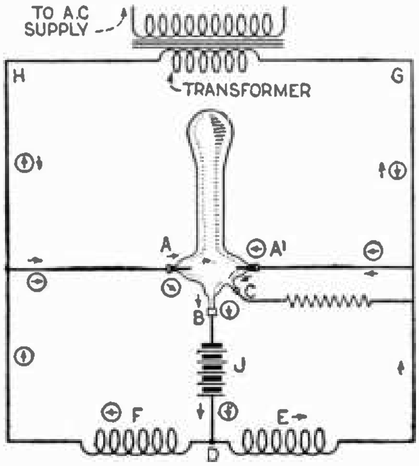


Illustration showing action of mercury arc rectifier.

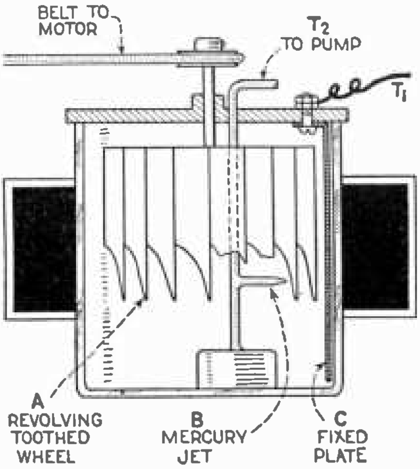
MERCURY INTERRUPTER (MERCURY JET INTERRUPTER)—A contact breaker in which contact is made between moving metallic contacts and a jet of mercury provided by a small centrifugal pump driven by the same motor as the contacts. When the primary winding of an induction coil is supplied with a continuous current it is necessary to interrupt the current in order that a secondary voltage shall be induced in the secondary winding. The mercury interrupter offers a satisfactory method of accomplishing this. In one type of mercury interrupter a stream of mercury is forced from a jet against a metal plate. The stream of mercury is interrupted by a toothed wheel of insulating material so that the electrical circuit is periodically made and broken between the mercury and the metal plate. In some forms of mercury interrupters, the jet itself revolves, the mercury impinging against a fixed metal plate. The mercury interrupter is used in operating X-ray bulbs from an induction coil where the source is direct current. A form of mercury interrupter is shown in the illustration. A is a tooth-shaped wheel made of insulating material. This wheel is driven by a small motor and the number of revolutions can be varied within wide limits. A small centrifugal pump forces the mercury upon the jet B, while the revolving wheel A interrupts the contact of the mercury with the plate C. The wheel A can be raised or lowered, thereby enabling the duration of contact of the mercury with the plate to be varied without altering the number of interruptions in a given time.



A type of mercury interrupter.

MESH GROUPING—A method of connecting coils in a polyphase circuit whereby they form a closed circuit and have the line wires attached to the points of junction between the coils. The term mesh is used interchangeably with delta. (See *Delta Connection.*)

METER—An instrument used to make measurements. (See *ammeter* or *amperemeter, double range meters, integrating wattmeter, voltmeter, wavemeter, wattmeter.)*

METER (*Measure*)—A unit of length in the *metric system* (q.v.). One meter is equal to 100 centimeters or 39.37 inches. It is equal to the length of a standard platinum bar, kept in Paris, and representing approximately a ten-millionth part of a quadrant of the earth's meridian measured from the equator to the pole through Paris. Wireless waves are measured in meters. The length of a wave is the distance, usually measured in meters between two points in the successive waves where the disturbance is at a maximum or at a minimum or between any two points of equal disturbance. There is a fixed relationship between the length of a single wave, the frequency of oscillation and the velocity of the wave. Thus if 3,000,000 waves pass a given point in one second, each wave must be 100 meters long, since the velocity of radio waves is equal to 300,000,000 meters per second.

METER-AMPERES—The product of the antenna current in amperes at the point of maximum current and the antenna effective height in meters, for any radio transmitting station. It constitutes a factor for indicating the radiating strength of radio transmitting stations.

METRIC SYSTEM—A system of measurement in which the meter is the fundamental unit of length and in which all the units both fundamental and derived are divided decimally and higher units are formed in multiples of ten. (See *Centimeter Gram Second.*)

MFD—Abbreviation for *Microfarad* (q.v.)

MICA—An anhydrous silicate of aluminum and potash or sodium. Mica has very high insulating qualities and can withstand high temperatures. Mica obtained in the natural state is separated into laminations which are sorted and graded. These are then cemented together to form plate or flexible mica of any desired thickness or purity. Mica is used in radio work as the dielectric of small fixed condensers. It is also used as the sound producing diaphragm in certain types of head sets and *loud speakers* (q.v.).

MICABOND CLOTH—India sheet mica faced on one side with muslin and on the other side with Japanese insulating paper bonded together with a special binder. It is used for insulating field coils and transformer coils.

MICABOND PAPER—India sheet mica faced on one side with Japanese insulating paper of one grade and on the other side with paper of a different grade.

MICABOND PLATE—Mica sheets bonded together with orange shellac. Various grades of plate are made some of which are used for magnet spools, others for insulating of commutator segments, while still others are used in electric irons.

MICANITE—A form of reconstructed mica. Canadian amber mica and white India mica are used.

MICRO—A prefix placed before the name of a unit to denote one-millionth part of that unit, as for example *microfarad* (q.v.).

MICRO-AMPERE—One-millionth of an ampere. A unit used in measuring extremely small currents. (See *Ampere.)*

MICROFARAD—abbreviation Mfd.—A unit of electrical capacity equal to one-millionth of a farad. Since the farad is too large for most practical measurements, the microfarad is generally used. (See *Farad,* also *Jar.)*

MICROHM—A unit of resistance equal to one-millionth of an *ohm* (q.v.).

MICROMETER—An instrument for making minute measurements. Usually controlled by an accurate screw of fine pitch.

MICROMETER SPARK GAP—A minute adjustable spark gap of about four-hundredths of an inch placed in the aerial circuit of a multiple tuner to allow heavy charges to pass readily to earth by sparking across its points.

Courtesy of Western Electric Co.
An example of the microphone used in modern broadcasting.

MICROPHONE—A sound magnifier. The ordinary form of microphone consists essentially of a diaphragm set in vibration by the sound waves and causing by its motion variation in the resistance of a mass of loosely packed carbon granules. This variation in resistance causes corresponding variations in the current through the instrument so that at every instant the form of the current corresponds to the variations in sound. This type of microphone is often referred to as a *Carbon Microphone*. The telephone transmitter is a form of microphone, and the microphone (nicknamed *Mike*) used in radio broadcasting is merely a larger and more sensitive variation of the same instrument. (See *Electro-magnetic Microphone.*)

MICROPHONE, CARBON—See *Microphone*, also *Granular Carbon*.

MICROPHONE TRANSMITTER—See *Microphone*.

MICROPHONIC JOINT—A loose contact between two solid conductors, so mobile that feeble vibrations vary its resistance.

MICROPHONIC RELAY—An instrument for magnifying the variations of a given current by passing it through an electromagnet that acts on the diaphragm or reed of a microphone. The resistance variations are repeated in the current produced by a constant voltage in a circuit in series with the *microphone* (q.v.). In general a microphonic relay can be described as a microphone combined with a telephone so that a message transmitted over the telephone is repeated by the microphone over another line.

MIL—A unit of length equal to one-thousandth part of an inch.

MIL-FOOT—A wire one foot long having a diameter of one mil. Unit resistance may be measured in *ohms* (q.v.) per mil-foot. This refers to a conductor having a cross-sectional area of a *circular mil* (q.v.) and a length of one foot.

MILLI—The prefix placed before the name of a unit to indicate one-thousandth part of that unit, as for example *milli-ampere* (q.v.).

MILLI-AMPERE—One-thousandth of an *ampere* (q.v.). Sometimes abbreviated to *milli-amp*.

MILLI-MICRO—A prefix denoting one thousand millions. (10^{-9}). The term *Billi* is an alternate prefix.

MILLI-VOLT—One-thousandth of a volt.

MILS, CIRCULAR—See *Circular Mils*.

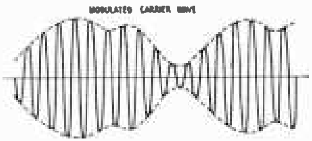
MIRROR GALVANOMETER—A galvanometer for measuring very small currents which utilizes a reflected beam of light for a pointer. In one type of mirror galvanometer a fixed nearly circular magnet is used and a coil of wire is suspended in its field. When the current flows through the coil it tends to turn the coil so as to set its axis in the direction of the magnetic force. This movement can be observed by means of a beam of light reflected from a mirror fixed to the coil. (See *Galvanometer.*)

MINERALLAC—An insulating compound made in several different grades all of which are impervious to water and show no alkali or acid reactions.

M.M.F.—Abbreviation for *Magnetomotive force* (q.v.).

MODULATED CURRENTS—Currents which have their amplitude periodically varied as in the case of the carrier current used in radio telephony which is varied or modulated in accordance with the vibrations of a microphone. If a sound wave actuates a microphone, its inward and outward displacement, varying the resistance in the aerial circuit, results in a high frequency current in the aerial of variable amplitude, called a modulated high frequency current. The illustration shows an extremely simplified diagram of the apparatus in a broadcasting station. The initial impulse that starts a radio signal towards the receiving set is furnished by the voice of the speaker or singer or by some other sound originating in the studio. This sound strikes the microphone, the operating element of which is a thin metal disk or diaphragm. The sound waves cause this diaphragm to vibrate. In doing so, the disk causes changes to take place in the electrical circuit. Pulsations of current are set up, the pulsations corresponding in strength to the variations of the spoken word, music or other sound as the case may be. These fluctuations are quite weak when they first come from the microphone and therefore they must be strengthened. They go through what is known as a voice amplifier which utilizes vacuum tubes to make the current stronger. The next piece of apparatus to consider is the *oscillator* (q.v.). This consists of one or more vacuum tubes, connected in a circuit of such a type that the tubes, when lighted and properly furnished with a high voltage direct current, will generate another current, alternating in character, which is said to be oscillating at radio frequency. Upon this current so generated, the voice current is impressed or super-imposed. This process is called *modulation* (q.v.). The current from the oscillator is known as the *carrier wave* (q.v.) current and when voice currents are impressed upon it, it is known as modulated radio frequency current. This current flows in the aerial and there sets up radio waves.

MODULATION—Variation of current or wave form to conform to sound waves or to other predetermined forms. Various forms of modulation are dot and dash modulation, chopper modulation, buzzer modulation and *speech modulation* (q.v.). (See *Distortion, Double Modulation*, also *Modulation Frequency Ratio.*)



Graph of a modulated carrier wave.

MODULATION, DOUBLE—See *Double Modulation*.

MODULATION FREQUENCY RATIO—The ratio of modulation frequency to wave frequency. An alternating current is said to be *modulated* when the amplitude of its oscillations is varied periodically. The frequency at which the variations occur, that is to say the *modulation frequency* is necessarily less than the frequency of the alternating current which is being modulated. The nature of the variations may assume practically any form. As examples, there are dot and dash modulation, chopper modulation, buzzer modulation and *speech modulation* (q.v.).

MOLECULE—The smallest group of *atoms* of an element or compound which can exist by themselves. A familiar analegy states that if a drop of water could be magnified to the size of the earth, its component molecules would be the size of base-balls.

MOLYBDENITE—symbol MoS_2—A lead gray sulphide of Molybdenum. It is used as a rectifier detector in contact with copper.

MOLYBDENUM—Symbol Mo—A silver white metal found in nature as *molybdenite* (q.v.), a sulphide of molybdenum. When pure this metal is ductile and can be forged. It is used chiefly as an alloy to produce extremely hard steel. Molybdenite is used as a *crystal* (q.v.) in the detection of radio waves.

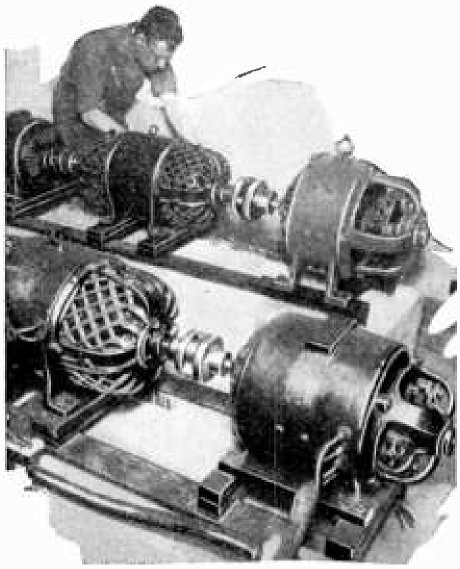
MORSE LIGHT—A search light used to signal code messages by means of intermittent flashes. (See *Code.*)

MORSE INKER—An instrument for recording Morse code signals in the form of dots and dashes on a moving paper band. In one form of Morse recorder, the attraction of the armature raises an inked wheel against the paper ribbon and thereby prints upon it the dots and dashes of the message.

MOSCICKI CONDENSER—A condenser in which the dielectric thickens out at the edges. It is essentially a form of *Leyden Jar* (q.v.) composed of a glass tube, especially thickened at the neck where the dielectric stress is greatest, coated inside and out with metal foil. The design of this condenser is such as to minimize *brush discharge* (q.v.) or *corona* (q.v.) effect at its edges.

MOTOR—A device for transforming electrical energy into mechanical energy. Motors may be designed for operation on direct current, on alternating current or on either direct or alternating current. These latter are known as *universal* motors. Direct current motors are classified as shunt, series and compound. This classification is arrived at according to the manner in which the field windings are connected. In the shunt motor the field winding is connected in parallel with the brushes (that is with the armature winding). In the series motor the field winding is connected in series with the armature and the line. Compound motors have a shunt winding in parallel with the brushes and a series winding in series with the armature and the line. Compound motors may be further classified as differentially compounded and cumulatively compounded. A differentially compounded motor is one in which the series field winding is so connected as to oppose the shunt field. A cumulatively compounded motor is one in which the series field aids the shunt field. The speed of the shunt motor is nearly constant, falling slightly as the load increases. The speed of the series motor decreases as the load increases. The differential motor may be constructed so that an absolutely constant speed will be maintained at all loads. The speed of the cumulative motor decreases rapidly as the load is increased. Alternating current motors are of the series type, the induction type, commutator type, synchronous type and repulsion type. There are a number of special classifications of alternating current motors such as single phase induction, polyphase induction, repulsion induction, etc. An ordinary direct current series motor used on alternating current will operate but at a low power factor, with a large eddy current loss and with violent sparking at the commutator. In order to adapt the series motor for universal use, it must be specially designed, the field structure being *laminated* (q.v.) in order to avoid *eddy currents* (q.v.) and the field coils having only a few turns to avoid too great *self-inductance* (q.v.) and consequently low *power factor* (q.v.). Sparking at the brushes can be avoided to a certain extent by designing the motor for a small field flux and with but a few turns in series in each armature coil.

MOTOR-ALTERNATOR—A *motor generator* (q.v.) set consisting of an *alternator* (q.v.) driven by a direct or alternating current motor. Such a set may be used for converting from direct to alternating current, or for frequency changing.



Motor Alternator set installed at Station WRNY.

MOTOR-GENERATOR—A generator or generators driven by an electric motor. Motor generators are used for converting alternating current to direct current or vice versa, for changing from one voltage or from one frequency to another or to obtain a variable from a fixed voltage.

MOVABLE COIL—Inductance coils which can be moved or rotated so as to vary the inductance. Examples of movable coils used in radio are vario couplers, loose couplers, etc. (See *Coupler, Loose; Coupler, Vario,* also *Fixed Coils.*)

MULLARD, S. R.—British radio authority. Born in 1884, he was educated as an electrical engineer and was ultimately appointed head of the research laboratory of Edison & Swan, Ltd., where he developed the Pointolite arc lamp. During the World War, he served in the Royal Air Force and became head of the wireless section laboratory at the Imperial College of Science for the Air Ministry. He carried out a series of researches on vacuum tubes and in 1920 founded the Mullard Radio Valve Company.

MULTIPLE—As applied to an electric circuit, a divided circuit. Two conductors are said to be connected in multiple or *parallel* (q.v.) when their two ends are joined together.

MULTIPLE SERIES—See *Series Parallel.*

MULTIPLIER—A resistance placed in series with a voltmeter for limiting and controlling the amount of current flowing through the voltmeter windings. This resistance may be either internal (enclosed by the voltmeter case) or external.

MULTI-POLAR—Having more than two poles. Usually a generator or motor whose field magnet has more than two poles. Small machines may be made with two poles, *bi-polar* (q.v.), but all others have a number of poles, that is to say they are *multi-polar.* The use of multi-poles results in a lighter machine and incidentally there is a saving of field copper and a reduction in sparking. If there are too many poles, however, there will be excessive *leakage flux* between the poles. (*See Homo-polar.*)

MUSICAL SPARK—A spark giving a regular distinct musical note. This may be produced by a high speed rotary discharger, a *quenched gap* (q.v.) or an arc.

MUSICAL SPARK SIGNALS—Signals in which the sparks occur at regular intervals of time and fast enough to give a musical note. Usually the spark rate is between 100 to 1200 discharges per second.

MUTE ANTENNA—A local circuit or resistor used in testing transmitting apparatus. The mute antenna in this case is substituted in the place of the actual antenna. It is also referred to as a *dummy aerial, phantom antenna, mock antenna,* or *artificial antenna.*

MUTUAL CAPACITY—The capacity effect of one conductor upon another one in the same electrostatic field. The mutual capacity is not the same as the capacity of the two wires regarded as the two plates of a condenser, one positively charged while the other is charged negatively. It really represents a decrease in the capacity of one of the wires with respect to earth caused by the presence of the electrostatic field of the other. The total capacity of the two wires is diminished by the overlapping of the two individual fields. (See *Capacity Measurement of Antenna.*)

MUTUAL INDUCTANCE—Symbol M—The magnetic flux that is common or mutual to two inductively coupled circuits. The mutual inductance of two circuits is the change in the interlinkage of flux that takes place in one circuit for a change of unit current in the other. This is also called the *coefficient of mutual induction* or the *mutual induction coefficient.* The units of mutual inductance are the same as those of *self-inductance.* (See *Inductance, Mutual; Self-Inductance, Induction, Coupling, Induced E.M.F., Induction, Mutual; Coefficient,* and *Mutual Induction Coefficient.*)

MUTUAL INDUCTION—The interaction between two current-carrying coils, not having direct metallic connection. The reactance of a coil such as shown in the illustration at A_1 is reduced by the proximity of another coil, A_2 if the circuit of the latter contains no external source of electromotive force, such as an alternator. The reason for this lessening in the primary reactance is that the flux excited by the first coil induces a current in the secondary coil and this current opposes the action of the primary current. As a result the total *magnetomotive force* (q.v.) the *flux* (q.v.) and consequently the *counter-electromotive force* (q.v) induced in the first coil are reduced. The effect of the secondary coil depends upon its distance from the primary coil and upon the amounts of the resistance R_2 and reactance X_2. If both coils are mounted on the same iron core, the action is greatly increased. In some instances mutual induction is desirable, as in the case of coupled radio circuits, or even in the ordinary transformer. In other cases, mutual inductance may be undesired as in the case where a radio antenna parallels a power line. (See *Induction, Mutual; Mutual Inductance,* also *Mutual Induction Coefficient.*)

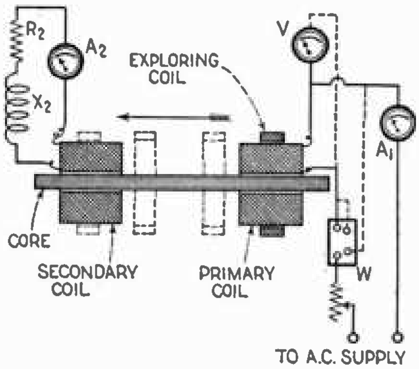


Diagram illustrating mutual inductance. The reactance of the coil A_1 is reduced by the proximity of coil A_2, since the circuit of A_2 contains no source of electromotive force. The effect of the secondary coil depends not only upon its distance from the primary coil but also upon R_2 and X_2. The presence of the iron core greatly increases the action.

MUTUAL INDUCTION COEFFICIENT—Another name for *mutual induction* (q.v.) That coefficient by which the rate of change of the current in a circuit must be multiplied to give the electromotive force induced in an adjacent circuit. From the principle of conservation of energy, it can be shown that the mutual inductance of a circuit A with respect to a second circuit B equals the mutual inductance of B with respect to A. (See *Mutual Inductance, Inductance, Mutual; Self-Inductance, Induction, Coefficient,* also *Coupling.*)

N

NAGYAGITE—A mineral containing lead, gold, antimony, sulphur, and tellurium. It receives its name from the location of its discovery near Nagyag in Transylvania. It is also known as black or leaf tellurium, and has been used as a crystal rectifier in conjunction with zincite.

NALLY, Edward Julian—American radio pioneer. Born April 11th, 1859, in Philadelphia, he joined the Western Union Telegraph Company in St. Louis and worked his way up in the telegraph service until in 1913, he was appointed vice-president and general manager of the Marconi Wireless Telegraph Company of America. Nally was one of the first to see the possibilities of wireless, and under his control the first commercial wireless communication was established between the United States and Japan, in 1914, and in 1920, he founded the first commercial wireless service between the United States and Great Britain, and afterwards to other countries. He was appointed the first president of the

Radio Corporation of America, and is a member of many scientific and other societies.

Edward Julian Nally.

NAME PLATE—A metal plate affixed to a radio set or other apparatus, giving the maker's name, trade name of apparatus, serial number or other details concerning the machine.

NAPERIAN BASE—The base of the so-called natural system of *logarithms* (q.v.). It is usually represented by the symbol ϵ (epsilon) and is numerically equal to 2.718 appx. (See *Damped Waves.*)

NAPERIAN LOG—See *Naperian Logarithms.*

NAPERIAN LOGARITHMS—Also called *Natural Logarithms.* Logarithms to the base ϵ. Logarithms constitute a tabular system of numbers, by which the operation of multiplication can be performed by addition, division by subtraction, involution by a single multiplication, and evolution by a single division. John Napier, Laird of Merchiston, Scotland, is generally regarded as the inventor of logarithms. The logarithms set forth by Napier were those of trigonometric functions. Later on Napier's logarithms were adapted to positive integers, using as a base the number 2.718 appx. and these logarithms are now called natural or Naperian logarithms. (See *Decrement,* also *Logarithms.*)

NATIONAL ELECTRIC CODE—A uniform code of rules, based upon the requirements of fire underwriters, for the electric wiring and electric installations in buildings. Unless these rules are compiled with fire insurance will not be issued or if issued previously will be voided. The National Electric Code contains a section covering special requirements for radio installations. The code is revised annually to meet new conditions and requirements. Copies of the code can be obtained from local insurance agents or from the National Board of Fire Underwriters at New York or Chicago.

NATURAL ELECTRIC WAVES—Wireless waves due to natural causes such as lightning discharges. When received in the radio apparatus, they are called *strays* (q.v.), *static* (q.v.), atmospherics, *X's* (q.v.), and various other names. There are many different causes for these stray waves. Some produce a grinding noise in the loud speaker, others a hissing noise often associated with snow or rain. Nearby lightning produces a sharp snap. Another type of strays cause loud crashes in the speaker.

NATURAL MAGNET—A substance which possesses in a natural state the properties of a magnet. Such a substance is the *lodestone,* a magnetic oxide of iron also called *magnetite* (q.v.). (See *Loadstone.*)

NATURAL FREQUENCY—The frequency at which free oscillations occur in a circuit. If L, C, and R are respectively the inductance, capacity and resistance of a circuit, then free oscillations in the circuit will have the frequency

$$f = \frac{1}{2\pi}\sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}}$$

This is the natural or *fundamental frequency* of the circuit. The natural frequency of an aerial is the frequency corresponding to the natural wave length. (See *Natural Wave Length,* also *Measurement of Wave Length.*)

NATURAL RECTIFIER—A mineral which possesses the property of conducting an electric current in one direction only. (See *Crystal,* also *Crystal Detector.*)

NATURAL WAVE-LENGTH—Length of the wave emitted by an aerial when no added inductance or capacity is inserted in the aerial circuit. This is also known as the *fundamental wave length* (q.v.). By putting *inductance coils* (q.v.) (*loading inductance*) (q.v.) in the aerial circuit, longer waves may be radiated, while condensers put in series with the antenna enable it to produce shorter waves than the aerial would ordinarily radiate. The use of a series condenser is avoided wherever possible since it has the effect of decreasing the total capacity of the aerial circuit and thereby decreasing the amount of power which can be given to the antenna. The addition of some inductance has a beneficial effect, since the decrement of the aerial is thereby lessened and a sharper wave results. (See *Measurement of Wave Length; Wave Length.*)

NAUTICAL MILE—abbreviation *Naut*—A marine unit of distance. Equivalent to one minute of longitude at the equator. This unit is also sometimes referred to as a *Telegraph Naut.* It is equal to 1.1528 statute miles (the statute mile being equal to 5,280 feet). The term *nautical mile* is used especially in submarine cable work. and also in matters pertaining to navigation. The term *naut* is differentiated from *knot* in that the former refers to a distance whereas the latter refers to a rate or unit of speed.

NEGATIVE CARRIER*—An electron combined with neutral gas molecules. When the velocity of the electrons in a vacuum tube is less than the value necessary to cause ionization by collision, the electrons attract the neutral gas molecules and so form heavy negative carriers. The ease with which this formation of negative carriers takes place depends on the nature of the gas. Such gases as argon and mercury vapor do not readily form negative carriers, while hydrogen and oxygen combine with electrons more easily. The effect of this negative carrier formation is to counteract the reduction of the negative space charge occasioned by the heavy positive ions formed by collision ionization. The positive ions are ions of the gas from which one or more electrons have been removed. The ions therefore have very nearly the same weight as the gas atoms. The negative carriers, on the other hand, may consist of an atom or molecule to which has been attached an electron. It is also possible that the attraction between an electron and the neutral gas molecules can result in the formation of clusters consisting of more than one molecule held together by the electron. These negative carriers, therefore, move as slowly as, and often more slowly than, the positive ions and consequently have a relatively great effect in counteracting the tendency of the positive ions to reduce the negative space charge of the electrons. (See *Electron Theory,* also *Ion.*)

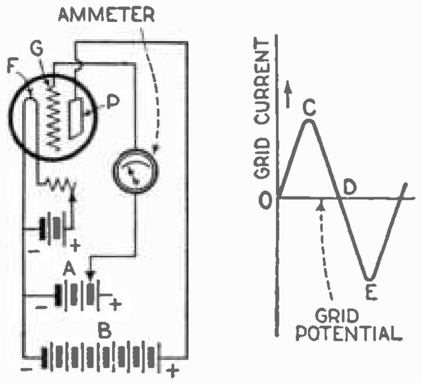
NEGATIVE CORPUSCLE—The natural unit of negative electricity. The *electron* (q.v.). It is more usual to refer to the negative corpuscle simply as the *corpuscle.* This was the name given by Sir J. J. Thomson to the carriers of electricity shot off from the cathodes in vacuum tubes. The corpuscle was found to have a charge equal to the electron and a mass which is $\frac{1}{1845}$ of that of the hydrogen atom.

NEGATIVE ELECTRODE—In a *primary cell* (q.v.) the *cathode* (q.v.) which is the carbon, copper, etc., electrode, is the *negative electrode,* while the *pole* of this electrode is the positive pole, since it is positive in relation to the external circuit. In a *secondary* or *storage cell,* the spongy lead plate, which is the anode during discharge, is called the *negative electrode* and its pole the *negative pole.*

NEGATIVE ION—An atom, which is the smallest particle of an element capable of existing, plus an *electron* (q.v.) (See *Anion, Cathion, Electron Theory,* also *Ion.*)

NEGATIVE POLE—The south-seeking end of a magnet. In a generator, the terminal into which the current returns from the external circuit. In a storage cell, the terminal of the negative plate. In a primary cell, the pole of the positive plate.

NEGATIVE RESISTANCE—A current path within a vacuum tube or an arc in which current decreases as voltage increases. The emission of electrons from cold electrodes under the impact of electrons (known as *secondary electron emission* (q.v.) or *delta rays*) results in a negative resistance or *falling characteristic.* The presence of secondary electrons can be shown by referring to the illustration. The plate P is kept at a constant positive potential with respect to the filament F by means of the battery B. When there is no difference of potential between the filament and the grid G, the cur-

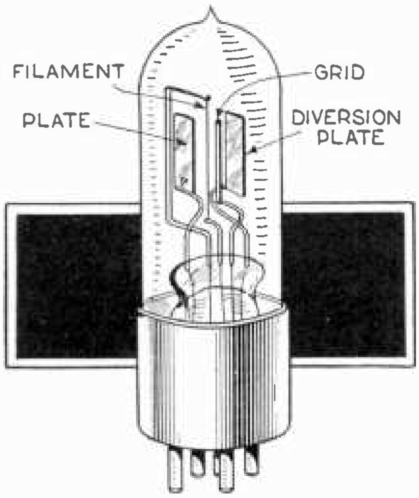


At the left is a hook-up for demonstrating negative resistance. The curve at the right shows the decrease of grid current although grid potential is increased.

(*Van der Bijl—The Thermionic Vacuum Tube.)

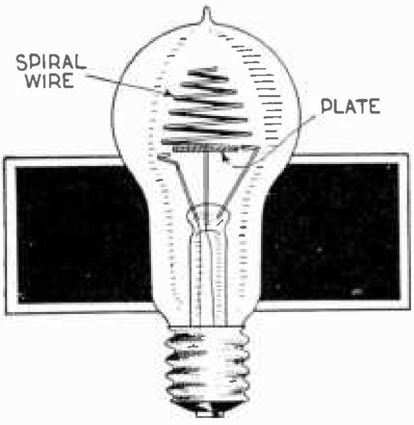
rent in the circuit FGA is very small, since practically all the electrons emitted from the filament are drawn through the openings of the grid and thrown on to the plate. If the potential of the grid (positive with respect to the filament) is increased, the current to the grid at first increases, as shown by the part OC in the accompanying curve. When the grid potential reaches a certain value, the current as indicated by the ammeter begins to decrease, drops down to zero at D and then reverses its direction of flow. The reason for this is that while the difference of potential between the filament and the grid is small, the electrons that strike the grid enter it, but as the positive grid potential is increased the electrons on striking the grid emit *secondary electrons* from it and these are drawn to the plate which is maintained by the battery B at a positive potential, with respect to the grid. The net current as shown by the ammeter is the sum of the electrons entering the grid and those leaving it. When the velocity with which the electrons strike the grid increases beyond a certain value, one primary electron can knock out more than one secondary electron from the grid and the current in the filament-grid circuit reverses. When the positive grid potential is increased to such an extent that the grid becomes positive with respect to the plate, the secondary electrons are no longer drawn away to the plate, but are driven back to the grid so that the reversed current in the grid circuit again decreases as shown at E on the curve, and finally assumes the original direction. Hence, considering the current as indicated by the ammeter and the voltage between filament and grid, it can be seen that over the portion of the curve CDE, the current decreases as the voltage increases. Therefore CDE represents a *negative resistance* characteristic. It has been found that a device which possesses a negative resistance can function as an amplifier and also as a generator of continuous oscillations.

NEGATRON—An English vacuum tube containing a filament, a grid and two plates. This tube was devised by J. Scott-Taggart, who used it for obtaining *negative resistance* (q.v.) characteristics. The two plates are fixed one on each side of the filament. The accompanying illustration shows a typical negatron. The bulb is tubular in shape and the four electrodes are plainly shown. The grid, in this tube, is a metal rod.



A negatron tube, showing the two plate construction.

NEON LAMP—An incandescent lamp in which a reddish light is produced by the incandescence of neon gas at low pressure. This lamp has very low current consumption and has been applied to pilot lights, signs, etc.



Neon Lamp

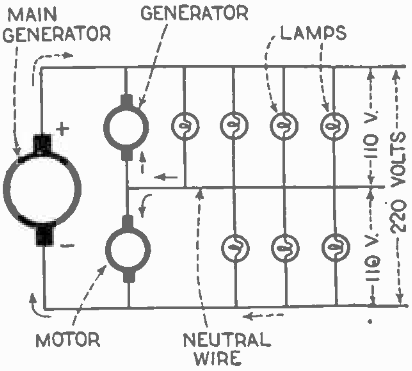
NEON TUBE—A vacuum tube containing the gas neon at low pressure used in the Fleming *Cynometer* (q.v.) etc. In this instrument, which is used to measure the frequency of electric waves, wave lengths, etc., a capacity formed by one brass tube sliding over another can be varied simultaneously with an inductance consisting of an air core solenoid and arranged so that the point at which resonance takes place is indicated by the glowing of the *neon tube* and can be read from a calibrated scale.

NERNST LAMP—An incandescent lamp in which the incandescent body consists of a strip of material composed of a mixture of oxides of metal such as zirconium, magnesium and other refractory oxides. The incandescent portion of the lamp is called the *glower* and is conductive only at a high temperature. Consequently it has to be heated by an auxiliary heating coil. The heating coil is automatically cut out of the circuit when the current starts to flow through the glower.

NEUTRAL BODY—A body void of electrification. A charged body which loses its electrification is said to be *discharged* or *neutralized.* All matter is capable of electrification.

NEUTRAL LINE OF MAGNET—The middle portion between the two magnetic poles of a bar magnet, where there is no manifestation of magnetism.

NEUTRAL WIRE—A middle wire, in a *three wire system* (q.v.) of power distribution, which is kept at a potential mid-way between the positive and the negative mains. In the three-phase system of alternating current distribution, the conductor connected to the neutral point of a "star" or "Y" connected alternator is also known as the neutral wire. The neutral wire is here also known as the *common return.*



A three wire system with unbalanced load, showing neutral wire.

NEUTRODYNE—See *Neutrodyne Circuit,* also *Hazeltine Neutrodyne Receiver.*

NEUTRODYNE CIRCUIT—A circuit used in radio reception in which radio frequency amplification is used for neutralizing the effects of capacity of the tube and its socket. Figure 1 shows a portion of a receiving circuit. In this diagram the tube capacity is represented by a condenser shown in dotted lines. By studying this circuit, it can be seen that a closed oscillatory circuit exists, made up of the inductances and capacities in the plate and grid circuits. Just as radio frequency currents can pass through condensers in a receiving set, so they can pass through or across the vacuum tube from the plate to the grid, which forms a condenser. This condenser effect is the reason why radio frequency amplifiers oscillate. A difference of potential occurs in the plate side of the coil in the plate circuit. Instead of this being handed on to the next tube for additional amplification, a portion of this potential leaks through the capacity of the tube and its socket and affects the grid in such a way that trouble is experienced with self-oscillation. In the neutrodyne circuit, the

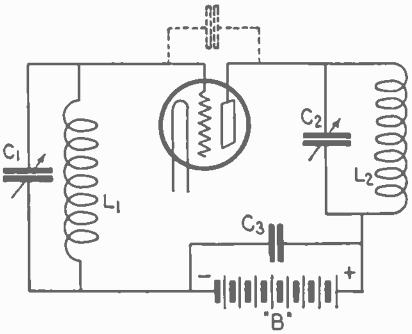


Fig. 1. A portion of a receiving circuit. Dotted line shows tube capacity represented by an equivalent condenser.

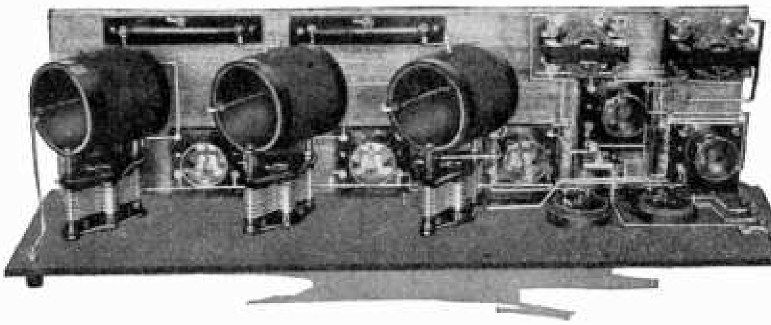

Fig. 2. A typical neutrodyne set.

inter-element capacity of the amplifier vacuum tubes is neutralized by means of special condensers called *neutrodons*. The capacity of these is very low, being approximately equal to the internal capacity of a vacuum tube. By reason of this equality, any tendency of a large amount of radio frequency current to pass back through the tube through the grid is defeated and instead is neutralized by the combination of the neutralizing capacities, the inter-element capacity of the vacuum tubes and the secondary windings of the tuned radio frequency transformers. This effect is in reality a bucking one, since the current is made to take two paths. Each neutralizing condenser must be adjusted so that its capacity will equal that of the vacuum tube it is connected with. Since it is impossible for a neutrodyne circuit to oscillate, there is no radiation of energy from the set, with consequent disturbance of other receiving sets in the vicinity.

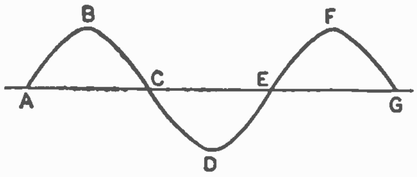
The neutrodyne circuit was invented by Professor L. A. Hazeltine. The typical neutrodyne receiving set uses five tubes, employing two stages of tuned and neutralized radio frequency amplification, with detector and two audio frequency stages. (See *Hazeltine Neutrodyne Receiver.*)

NICHROME WIRE—A nickel-chromium-steel alloy wire, which is able to withstand a bright red heat in the atmosphere without oxidizing. Nichrome is practically non-corrosive. It has a very high melting point, about 1550 degrees Centigrade and is used extensively in electrical heating appliances and resistance elements.

NIGHT EFFECT—Changes in the strength of radio signals noticeable especially at night. This effect is also known as *fading* (q.v.). Fading does not generally occur in the immediate vicinity of the transmitting station. It seems to happen more often on wave lengths below 400 meters. A certain station is being received with normal intensity, when suddenly the sounds become very faint and in a few minutes they may again become normal or may even become stronger than usual. In some cases the variations from strong signals to weak take place every few minutes while in other cases there may be an interval of several hours. It has been observed that fading takes place over land more often than in radio transmission at sea.

NOBLE, Sir William—British engineer. Born in 1861 and educated at Gordon's College, Aberdeen, he thereafter entered the Aberdeen telegraph office. In 1893 he was appointed engineer for the northeast area of Scotland, rising rapidly in the service until he became chief engineer in 1919. He retired from the Post Office in 1922, and became a director of the General Electric Company and of the British Broadcasting Company. Sir William Noble has written many articles on telegraphy and telephony and is considered to be an authority on these subjects.

NODES—In a wave form, such as shown in the illustration which represents an alternating current sine wave, the zero points. Thus in the alternating current sine wave, the points of zero current or potential, at A, C, E, and G, are nodes, and the points B, D, and F are the anti-nodes or *loops* (q.v.).



Sine wave illustrating nodes and anti-nodes.

NODEN VALVE—An *electrolytic rectifier* (q.v.) which allows only current in one direction to pass through it. This rectifier utilizes an aluminum rod or cylinder as a cathode and the anode may be of iron, lead or of carbon. Ammonium phosphate is used as the electrolyte. The principal of operation of this rectifier depends upon the fact that the current in the positive direction is stopped at the aluminum plate through the formation of an insulating crust of aluminum phosphate and aluminum oxide. These two substances present an extremely high resistance to the passage of the current in the positive direction, but the compounds dissolve again upon reversal of the current. By suitably combining two or more cells, both the half waves of an alternating current can be rectified. In Fig. 1 is shown the principle upon which the Noden Valve acts, and Fig. 2 shows a hook-up for connecting four cells to obtain full wave rectification. (See *Electrolytic Rectifier Full Wave*, also *Rectifier.*)

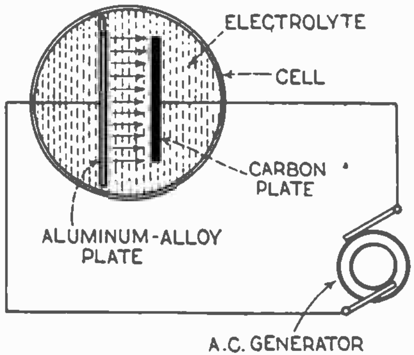


Fig. 1. Diagrammatic illustration of the principle of the Noden valve.

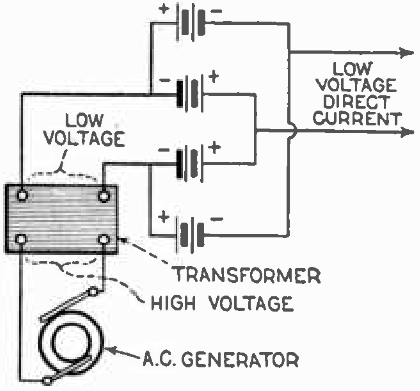

Fig. 2. A hook-up for connecting four Noden cells to obtain full wave rectification.

NON-CONDUCTOR—See *Insulator.*

NON-INDUCTIVE COIL—A coil having negligible inductance. Such a coil may be wound by doubling the wire upon itself and then winding the two parallel halves side by side.

NON-OSCILLATORY—Free from oscillations or vibrations. Without periodicity, that is to say, *aperiodic* (q.v.). A current which is uniform in direction and flow and free from oscillations is said to be a non-oscillatory current. A non-oscillatory circuit is one in which an impressed potential will produce current that gradually diminishes in amplitude without reversing its direction of flow. This is also called an *aperiodic circuit* (q.v.). Such a circuit can have no natural period of oscillation.

NON-PERIODIC—See *Aperiodic*, also *non-oscillatory.*

NON-RADIATIVE ANTENNA—A combination of capacity and inductance equivalent to that of an aerial, used to test transmitting apparatus without radiating waves. (See *Mute Antenna.*)

NORTH MAGNETIC POLE—A point on the earth at a latitude 70 degrees North, longitude 97 West. The north magnetic pole does not coincide with the north (geographic) pole. (See *Magnetic Poles.*)

NORTH POLE—See *Magnetic Poles*, also *North Magnetic Pole.*

NO-VOLT RELEASE—An electro-magnetically controlled device, inserted in the field circuit of a motor so that it holds the handle of the motor starter in place on the last stud, but if the supply current fails, the magnet becomes de-magnetized and allows the spring attached to the starter handle to pull the handle back to the "off" position. This prevents damage to the windings of the motor, in case the current comes on again, since it is then necessary to start up the motor in the usual way, using the starter and gradually increasing the voltage by cutting out the limiting resistances provided in the starter. (See *Overload Release.*)

NULL METHOD—An electrical method of testing in which adjustments are made so that zero deflection is obtained in a galvanometer, as for example when using a *Wheatstone Bridge* (q.v.). This is sometimes referred to as the *zero method.* (Null is also a German word meaning zero.)

O

OCTAHEDRITE—Chemical Symbol TiO_2—Titanium dioxide, an eight sided crystal which has been used as a crystal detector for detecting and rectifying radio currents. (See *Crystal.*)

OERSTED—The unit of *reluctance* (q.v.). The reluctance or in other words, the magnetic resistance offered by a cubic centimeter of vacuum. Unit *magneto-motive-force* (q.v.) will generate a unit of *magnetic flux* (q.v.) through unit reluctance. The oersted was named after the Danish physicist, H. C. Oersted.

OHM—Symbol Ω (Omega)—The unit of electrical resistance. It is the ratio of unit *electromotive force* (q.v.) to unit current. The ohm is the basis of the entire electrical system of units and the volt and the ampere are defined in relation to it. Very elaborate apparatus is required in order to determine the ohm absolutely. However, resistances can be compared easily and once the standard is determined it is a simple matter to make duplicates. In accordance with an act of Congress, the ohm was adopted as a legal unit and defined as follows: The unit of resistance shall be what is known as the international ohm, which is substantially equal to one thousand million units of resistance of the centimeter-second-gram system of electromagnetic units and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice, 14.4521 grams in mass, of a constant cross-sectional area and of the length of 106.3 centimeters. Stated in English units, the ohm is specified as the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice (32 degrees Fahrenheit), 0.5050 of an ounce in mass (approximately 3/100ths of a pound), of a constant cross-sectional area and of a length of 3.487 feet.

OHMMETER—An instrument used to measure resistance directly in ohms. It is particularly adapted for measuring high resistances, although certain types of ohmmeters are made for measuring lower resistances. In one form of ohmmeter, the moving system is deflected by forces due to currents in two coils at right angles to one another. These carry currents in one case proportional to the current through the conductor under test, and in the other case proportional to the potential drop across it. This is in effect, a special form of *galvanometer* (q.v.) and when combined with a hand driven generator gives the conventional *megger* (q.v.) The bridge type ohmmeter depends on the *Wheatstone Bridge* (q.v.) principle. In this instrument, however, the rheostat resistance remains constant and the bridge arms are formed by a wire, called a *slide wire*, resistances being varied by means of a moving contact as shown in the illustration. This type of instrument is often referred to as a *slide wire ohmmeter*. While a straight slide wire is used in some types, in others the wire is wound on an insulating cylinder. In the Weston direct-reading ohmmeter, there is a permanent magnet and a moving coil having two windings and an adjustable magnetic shunt. Provisions are made for connecting an unknown resistance and an auxiliary battery in the circuit of the instrument. A checking plug is provided for checking the accuracy of the instrument before use. When the key is closed, the battery current is divided between two windings. The magnetic force exerted on the one winding, which is in series with a fixed resistance, tends to deflect the pointer up the scale, while the force exerted on the other winding tends to return it to zero. With the correct battery voltage the magnetic shunt may be adjusted to bring the pointer to full scale position. When the plug is shifted to the low range position, a resistance equal to that of the low range is removed from the circuit whose magnetic force tends to deflect the pointer towards the zero position. By connecting a resistance equal to that of the low range across the "unknown" binding posts, the previous condition is restored and the pointer will go back to the full scale position. For values of resistance lower than this the opposing force will be greater and hence the coil will be brought back to a lower position on the scale. At zero resistance across the "unknown" binding posts, the magnetic forces of the two windings will balance each other, thus causing the coil to stand at zero on the scale. The Vawter indicating ohmmeter is of the galvanometer type and utilizes two coils carried by a shaft and moving in the field of a permanent magnet. A specially shaped core is used to give the desired scale characteristics. By making connections to the coils through spirals of negligible torque, the position of the pointer does not depend upon the value of the current nor on the strength of the permanent magnet.

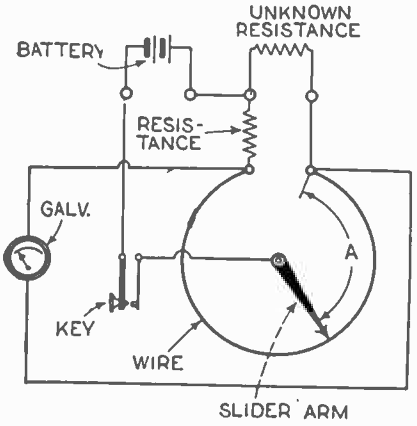

Diagram of connections of a slide wire ohmmeter.

OHMIC COUPLING—See *Resistance Coupling.*

OHMIC DROP—The fall in potential which occurs when an electric current flows through a resistance. (See *IR Drop.*)

OHMIC LOSS—Power or energy loss due to the resistance which an electrical circuit offers to the flow of current. (See *I^2R Loss.*)

OHM'S LAW—Current flowing in a conductor will increase directly with increase of voltage and will decrease directly with increase of resistance. In other words, voltage is the cause, while current is the effect. The effect is directly dependent upon the cause and inversely dependent upon the opposition offered to the cause. Ohm's law is the fundamental law of electrical engineering. Ohm's law can be stated as an equation as follows:

$$\text{Current (in amperes)} = \frac{\text{Voltage (in volts)}}{\text{Resistance (in ohms)}}$$

or

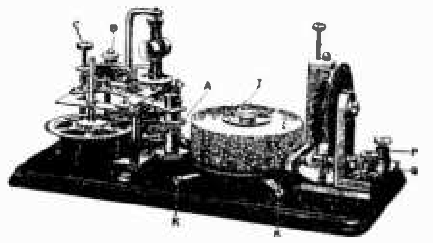
$$\text{Voltage} = \text{Current} \times \text{Resistance}$$

$$\text{Resistance} = \frac{\text{Voltage}}{\text{Current}}$$

The above three equations all mean the same thing and serve to express in various forms, the idea set forth above. Ohm's law can be applied to every conductor, provided that the conductor stays at a constant temperature, that there is no internal electromotive force in the conductor and that the distribution of the stream lines in the conductor remains unchanged. Ohm's law is easy to understand and easy to apply. Thus in a particular circuit, a certain voltage causes a certain current to flow. Double the voltage will cause double the current to flow, if the resistance is the same. If the resistance is doubled, however, the same voltage will result in only half the current flow. Double voltage and double resistance results in unchanged current flow. Ohm's law applies to a portion of an electrical circuit as well as to the entire circuit. Care must be taken when applying the law to only part of the circuit, to consider only the resistance, current and voltage of that part.

OMNIBUS BAR—A conducting bar of copper, mounted in back of a switchboard, or panel and serving as a common connector for two or more pieces of apparatus. This term is more usually shortened to *bus bar* (q.v.)

OMNIGRAPH—An intrument which sends code (dots and dashes) mechanically. It is usually operated by clockwork and is connected with a buzzer. It employs metal disc records each of which has a series of notches which correspond to the dots and dashes of the telegraph code. The omnigraph is used by beginners in learning the code and is also used to test the speed of reception of applicants for radio operators' licenses.



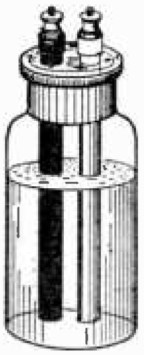
The omnigraph—an instrument which sends code mechanically.

ONDOGRAPH—An instrument for autographically recording the wave forms of varying currents, especially currents which are alternating rapidly. This form of curve tracer was invented by Hospitalier.

ONDOMETER—Another name for a *wave meter* (q.v.)

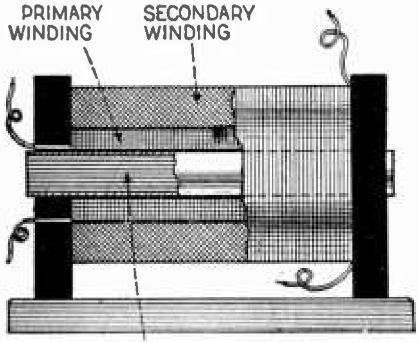
OPEN ANTENNA—According to the report of the Institute of Radio Engineers standardization committee, this is a condenser antenna, that is to say an antenna consisting of two capacity areas. Antennas may be subdivided into two general classes, those which act principally as condensers, usually simply called antennas, and those which act principally as inductances. These latter are *loop antennas* (q.v.), *coil antennas* (q.v.), etc. When electric waves reach a condenser antenna, they set up an alternating electromotive force between the wires forming the upper plate of the condenser and the ground or the other lower plate of the condenser. As a result of this alternating electromotive force, alternating current will flow in the antenna system. (See *Aerial.*)

OPEN CIRCUIT—An electrical circuit which does not offer a complete path for the flow of electricity. There may be one or more breaks in the path. An open circuit is often referred to as a *broken circuit*. Open circuits often cause trouble in radio apparatus. They may be due to the burning out of a winding, to a connection coming off a terminal, to a soldered connection breaking loose or to similar causes. The method of testing for an open circuit is to connect a battery and a headset in series with the circuit in question. If there is no click in the headset, there is evidently a break in the circuit.



An open circuit primary cell.

OPEN CIRCUIT PRIMARY CELL—A *primary cell* (q.v.) designed for intermittent use and normally kept on open circuit. Such cells usually have a *depolarizer* (q.v.) which acts slowly. In certain cases, no depolarizer whatsoever is employed. Open circuit cells are designed for use during short intervals of time only and must stand for long periods on open circuit, during which the hydrogen is gradually taken away from the negative plate. The operation of the open circuit cell will not be satisfactory if the rest periods are not long enough or are not at frequent intervals.



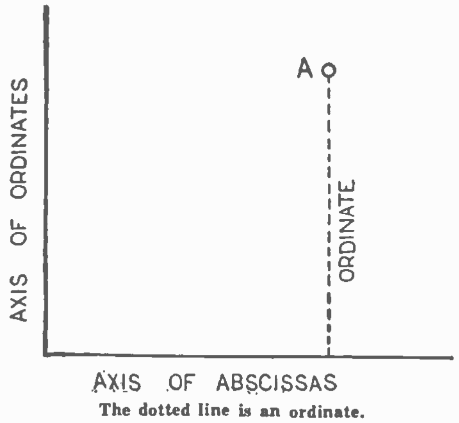
An open-core transformer.

OPEN-CORE TRANSFORMER—A transformer in which the (useful) magnetic circuit is partly through iron and partly through air, instead of entirely through iron as in the *closed-core transformer* (q.v.). It is sometimes referred to as a *polar* transformer. In one type of open-core transformer the arrangement is similar to that of an *induction coil* (q.v.), a hollow iron core, filled with soft iron wires being employed to concentrate the magnetic field.

OPPOSING ELECTROMOTIVE-FORCE—See *Back Electromotive-force.*

OPTOPHONE—An instrument utilizing a telephone receiver controlled by the variations of resistance of a *selenium cell* (q.v.) by means of which the blind are enabled to read ordinary type, through the sense of hearing.

ORDINATE—A mathematical term used in radio in making *logs* (q.v.) or other curves. Defined in mathematical language, the ordinate is that one of the coordinates of a point which is drawn parallel to a line (called the axis of ordinates) to the point from the other axis (called the axis of abscissas) or from the plane of the other axis of coordinates, assumed as a basis of reference. This definition will be clearer if reference is made to the accompanying illustration. The dotted line drawn from the point A to the axis of abscissas is the ordinate of the point A.



The dotted line is an ordinate.

OSCILLATING CURRENT—An alternating current of high frequency, consisting of a succession of waves of constant length. In some cases, the term oscillating current refers particularly to a current where the amplitude is decreasing in constant proportion due to damping. (See *Oscillation, Oscillation Frequency,* also *Logarithmic Decrement.*)

OSCILLATING IMPULSE—*An oscillating current* set up for the purpose of producing electric waves.

OSCILLATING PERIOD—The time of one complete *oscillation* (q.v.).

OSCILLATION—Periodical surging first in one direction and then in the other. Electrical oscillations are the surgings backward and forward of current periodically, as, for example, in the case of a condenser being discharged in an oscillating circuit. The oscillating action in a discharging condenser is as follows: In the case of a condenser, positively charged, upon being discharged through an inductance, the charge rushes out of the condenser, the current increasing in strength until it reaches a maximum. Then, due to self-induction the current prolongs itself, and it continues until its energy is changed back into an electric charge of an opposite sign, current flowing into the condenser which is then charged negatively. The condenser again discharges giving a maximum current in the opposite direction. the current thereafter flowing back into the condenser with the same direction charge as at first. This action constitutes one complete swing or oscillation and the current continues to oscillate, each time becoming weaker and weaker as the energy is dissipated into heat and also partially into electric waves. It is important to note that the propagation of electric waves could not be accomplished without electrical oscillations. Thus at the transmitting station, the electrical oscillations are converted into electric waves and at the receiving station, the waves are re-converted back into oscillations.

OSCILLATION CONSTANT—The square root of the product of the capacity and the inductance of a circuit. The *natural period* of a circuit is determined by its inductance and capacity in the same manner as the natural period of a steel spring clamped at one end in a vise is determined by its mass and elasticity. Where a simple aerial is used it is an easy matter to calculate the length of a wave radiated from it, provided the oscillation constant has been found. The velocity of electric waves is approximately 3 x 10^{10}cm. per second, and hence the length of the wave radiated is about 60 times the oscillation constant where the wave length is measured in meters. (See *Aerial Tuning Condenser,* also *Isochronous.*)

OSCILLATION FREQUENCY—The number of complete oscillations or cycles flowing in a circuit per second. The oscillation frequency of a circuit varies inversely as the square root of the product of the inductance and capacity. The frequency is inversely proportional to the wave length, hence the addition of either *capacity* (q.v.) or *inductance* (q.v.) to the oscillatory circuit will result in an increase of *wave length* (q.v.). (See *Frequency.*)

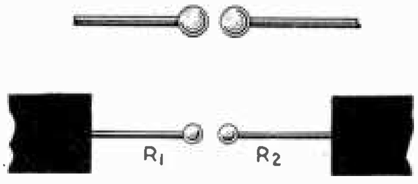
OSCILLATION POINT—That current value, known as the *critical current* (q.v.), at which the vacuum tube or tubes in a radio receiving set start to oscillate.

OSCILLATION TRANSFORMER—A high-frequency air-core transformer used for transferring electrical oscillations from one circuit to another. Either one or both the windings may be tuned to the frequency of the oscillations. The transformer used for coupling the oscillator of a transmitting set to the aerial is an example of an oscillation transformer. (See *Coupling, Inductive Coupler,* also *Transformer.*)

OSCILLATION VALVE—See *Oscillator,* also *Vacuum Tube.*

OSCILLATOR—A device or apparatus for producing electrical *oscillations.* The *vacuum tube* (q.v.) under correct conditions may be used to produce sustained oscillations of a definite amplitude and frequency. In order for a vacuum tube to act as an oscillation generator it must be capable of amplifying, part of its output energy must be returned to the input, an oscillation circuit must be combined with the tube, which possesses inductance, capacity and resistances of values such that the tube will oscillate with the desired frequency and finally the tube must have certain characteristics which when combined with the constants of the oscillatory circuit, will determine the amplitude of the oscillations. Oscillations may also be produced by means of a high frequency alternator and by a direct current generator and electric arc. (See *Alternator,* also *Alexanderson.*)

OSCILLATOR, HERTZIAN—Two insulated rods, with axes in line, with their nearer ends forming a spark gap and their outer ends bearing plates or balls to give the system the required capacity. The overall length is usually less than 6½ ft. and the whole constitutes an open oscillator. A Hertzian oscillator is sometimes called a *dipole.* When the rods are brought near each other but not in actual contact and the conductors are connected to the terminals of an *induction coil* (q.v.) a succession of sparks can be caused to jump the gap and these set up electric waves in the *ether* (q.v.).



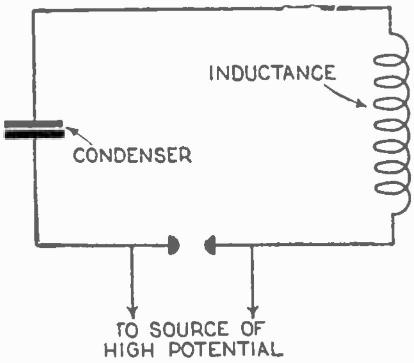
Typical Hertzian Oscillators.

OSCILLATOR, LINEAR—The straight wires connected on either side of the spark gap of an induction coil, traversed by oscillations. Linear oscillators are of the open type. As used by Hertz, they consisted of two rods, having a spark gap between their adjusted ends, while their outer ends terminated in plates or balls in order to increase the capacity of the system.

OSCILLATOR, RIGHI—In this type of oscillator, the spark gap is established between two metal spheres placed between two smaller spheres. (See *Oscillator,* also *Oscillator, Hertzian.*)

OSCILLATOR, THERMIONIC—A vacuum tube used to generate continuous oscillations. (See *Oscillator.*)

OSCILLATORY CIRCUIT—A circuit possessing *inductance* (q.v.) and *capacity* (q.v.), the electrical constants being such that an oscillatory current can be set up. The accompanying figure shows a simple oscillatory circuit, consisting of a condenser, an inductance and a spark gap. When a source of high potential is connected across the spark gap and the latter is properly adjusted, the condenser is charged and there is a spark across the gap. Provided that there is not too much resistance in this circuit, there will be set up an *oscillating current* (q.v.) of high frequency, decreasing in amplitude according to a fixed ratio. Such a current can be used to set up electric waves. Oscillatory circuits are of two general classes, closed as shown in the illustration and open, as in the case of an aerial system. An aerial which has no tuning condenser or inductance in its circuit still has distributed inductance and capacity, whereas an aerial having a tuning inductance and a condenser in its circuit, has a combination of concentrated and distributed inductance and capacity.

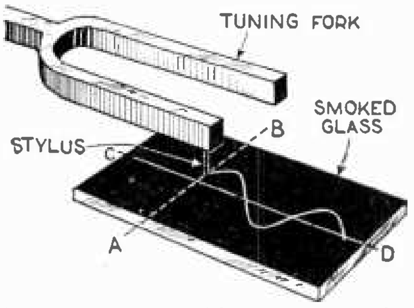


A simple oscillatory circuit.

OSCILLATORY CURRENT—See *Oscillating current.*

OSCILLION—Name which has been applied to the *vacuum tube* (q.v.) especially where used as an oscillation generator.

OSCILLOGRAM — A picture, graph or record of a wave form usually obtained by means of an *oscillograph* (q.v.).



An oscillogram obtained by means of a tuning fork.

The illustration shows an oscillogram obtained on smoked glass by means of a tuning fork. (See *Oscillagraph.)*

OSCILLOGRAPH — An instrument for recording photographically or showing visually the wave form of alternating currents or of other rapidly changing currents or voltages. The essential parts of such an instrument are a moving coil mirror galvanometer, a rotating or vibrating mirror and a moving photographic plate or film. Figure 1 illustrates the principle of the oscillograph and shows the curves it produces. The oscillograph was invented by M. A. Blondel in 1893. By means of the oscillograph the wave form of a current may be shown as a curve and its characteristics may thus be examined and studied. In order to form the curve, it is necessary to have simultaneous motion in two directions. The vibrator of the oscillograph which consists of a delicate coil of wire, with mirror attached, is made extremely light so that the moving system will have as little inertia as possible. The coil is placed in a powerful magnetic field and when an oscillating current is passed through it, it oscillates in synchronism with the current. A spot of light focused on the mirror is made to fall on a screen at the predetermined distance from the vibrator. This spot of light traces out a straight line on the screen. Substituting a photographic film for the screen and arranging the film so that it will move in a vertical path across the moving beam of light (which is assumed to be moving from right to left across the screen) a curve is traced on the film. The commercial form of oscillographs are provided with apparatus whereby the curve may be examined without the necessity of photographing it. In these the beam of light is reflected from a rotating or vibrating mirror in such a way that it receives a horizontal and an up and down motion and is focused onto a curved plate of glass. Tracing paper may be stretched over the glass so that the image of the spot of light traces a visible curve on it. The curve being repeated very rapidly appears to be standing still and hence it is possible to trace over it with a pencil or even to place a piece of photographic paper on the curved glass and make a record of the curve in this way. The motion picture camera has been applied to the oscillograph and is useful where longer records are required. It should be noted that oscillographs which utilize a moving coil, such as the Duddell or Blondin types. will work over a band of frequencies up to a maximum of about 300 cycles per second. Inasmuch as the oscillations common in radio work are of much higher frequency than 300 cycles, it has been found necessary to use an oscillograph whose moving parts are without appreciable weight. The use of electrons as moving parts has solved this problem. A Frenchman, Alexander Dufour has applied the Braun tube to the construction of an oscillograph which has no appreciable inertia and which is capable of operating at a frequency up to a million cycles per second. This device uses only minute amounts of energy in its operation and therefore does not disturb the original circuit. It is able to register both voltage and current simultaneously and is so arranged that a single impulse is sufficient for a photographic impression. The Dufour oscillograph consists essentially of two glass tubes fitted by means of a ground joint into a bronze chamber. The upper glass tube carries a cathode and an anode and the other tube has one pair of deflecting plates for electrostatic deflection of the electron stream. Two sets of coils perpendicular to each other are used for magnetic deflection and these are placed outside the tube and slightly below the deflecting plates. In order to photograph the oscillations, a drum is used which is provided with a film magazine allowing six films to be taken in succession. When visual examinations of the oscillations are to be made, a fluorescent screen is turned up into position covering the opening into the interior of the drum thus preventing the films from being exposed when using the screen. After the films are put into the drum, this is placed within the bronze chamber and locked into position. An air-tight door is used to close the opening and the film changing mechanism is operated by means of external controls. Glass windows on either side of the bronze chamber allow the fluorescent screen to be seen. The accompanying sketch shown at Figure 2, gives a diagrammatic representation of the operation of the Dufour oscillograph.

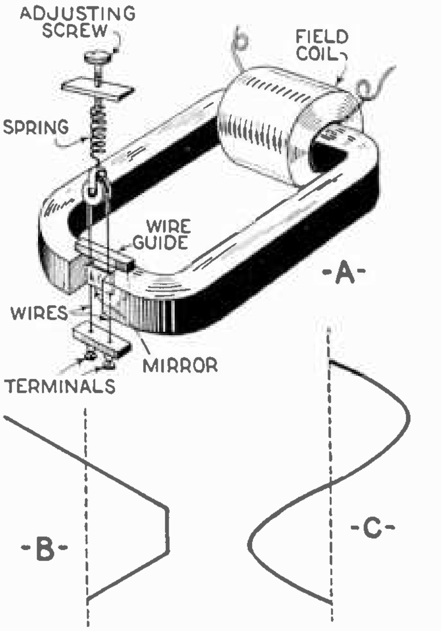


Fig. 1. The principle of operation of the oscillograph is shown at A. At B are shown diagonal and straight paths traced by the beam of light falling on a moving photographic plate. The type of curve which an oscillograph traces for alternating currents is shown at C.

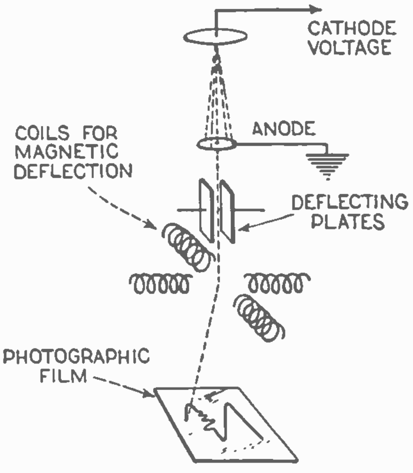

Fig. 2. A diagrammatic representation of the Dufour oscillograph.

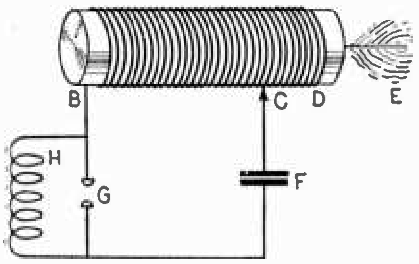
OSMOSIS, ELECTRIC—When an electric current is passed through an electrolyte having an anode on one side of a porous diaphragm and a cathode on the other side, there is a tendency for the liquid to pass through the diaphragm towards the cathode raising the level of the liquid on the cathode side. This phenomenon is known as electric osmosis.

OTOPHONE—A device for the hard of hearing, which utilizes an extremely sensitive microphone connected to a two-stage vacuum tube amplifier. The instrument uses dry cell tubes and the batteries are contained in the case with the microphone. A small telephone receiver completes the outfit.

OUDIN RESONATOR — A device used for obtaining high-frequency brush discharges. Discharges of this nature are used in the investigation of resonance effects and also in medical work. The accompanying diagram explains the principle of the Oudin resonator.

B D is an uninsulated coil of copper wire wound on an insulating core with each turn separated from the next adjacent one. At B, the helix is connected to an induction coil and it is tapped by means of a sliding contact at C. The sliding contact is connected through a condenser to the induction coil H, with a spark gap G in parallel in the circuit as shown. The circuit BGFC is a closed oscillatory circuit receiving its excitation from the induction coil H. The circuit C D E is an open circuit in contact with the oscillatory circuit. By moving the sliding contact, C, a point is reached where a brush discharge appears at E, thus indicating that electric oscillations are being set up in the open circuit. (See *Brush Discharge, Corona,* also *Oscillator.*)



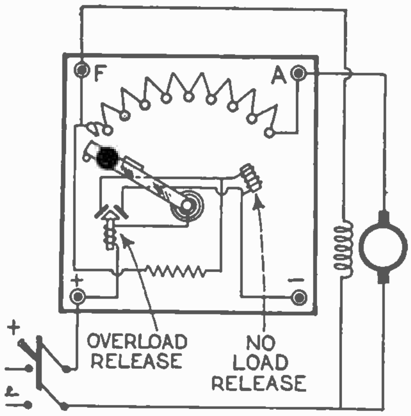
Connections of the Oudin resonator.

OUTPUT—The useful energy given out by a machine, circuit, vacuum tube or other device. (See *Input; Output, Transformer; Output Circuit of Vacuum Tube.*)

OUTPUT CIRCUIT OF VACUUM TUBE—The filament-plate circuit as differentiated from the filament-grid or input circuit. (See *Input Circuit of Vacuum Tube.*)

OUTPUT, TRANSFORMER—The product of the voltage at the secondary terminals of a transformer by the current flowing in the secondary winding. The output of any transformer is always less than the input by an amount equal to the losses. The *efficiency* of a transformer is the ratio of its useful output to the total *input.* (q.v.)

OVERLOAD RELEASE—An electromagnetic device which is used to cause a motor starter handle to return to the off position when the current exceeds a pre-determined overload value.



Overload Release.

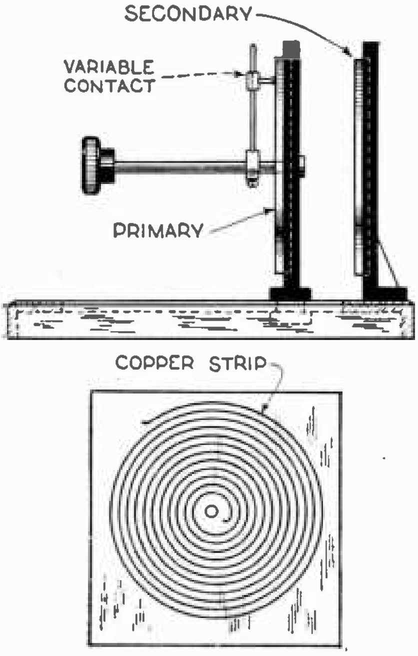
The overload magnet is usually arranged so that too strong a current will result in short-circuiting the no-volt release thus switching off the driving current. One form of overload release consists of a magnet in series with the line and the armature. This magnet is arranged to attract a pivoted iron keeper whenever excessive current flows. The pivoted arm, when attracted by the magnet, makes connection between two contacts, themselves connected so as to short circuit the holding magnet when the circuit is closed. Therefore, when more than the allowable current is drawn from the line, the overload magnet attracts its pivoted keeper which closes the circuit short-circuiting the holding magnet. The contact arm is then released by the holding magnet and the arm is pulled back to the off position, thus cutting the motor off the line. Another form of overload release utilizes an electromagnet to attract a pivoted arm, arranged so that this will break the circuit between the motor and the line. This results in operating the no-voltage release. (See *No-Volt Release.*)

OVERTONE CURRENTS—Alternating currents which have harmonic frequencies of a higher value than the fundamental or first harmonics.

OVERTONES—Higher harmonics associated with the first harmonic. This term particularly refers to sound waves. In various musical instruments, different overtones are brought out and this results in each instrument having its own tone characteristic.

P

PACKING—(referring to a *microphone*). The tendency of carbon granules in a microphone to settle or pack. In this position they are no longer sensitive and do not readily respond to the vibrations of the diaphragm. Packing may be caused by irregularity in the sizes of the carbon granules. It may be remedied by gently tapping the microphone.



Front and side view of a pancake coil.

PANCAKE COIL—A flat inductance coil. Coils of this type are used in radio receiving sets as radio frequency transformers, also as antenna couplers and oscillator couplers. They may be *basket wound* (q.v.), spider wound, etc. In wireless transmitting apparatus, aerial tuning inductances, loading inductances, and oscillation transformers (illustrated) are frequently of the pancake coil type. (See *Inductance, Antenna.*)

PANEL—A board of insulating material carrying the controlling or measuring devices of an electric circuit. The panel for controlling the charging of storage batteries is called a *charging panel.* A panel carrying generator controls is referred to as a *generator panel.* Where only a single panel is used this is usually called the *switchboard.* The usual switchboard comprises a number of panels. Switchboard panels are commonly made of marble. The usual varieties available are white Italian, pink or grey Tennessee and blue Vermont marbles. Plain slate is sometimes used for panels where the voltage is not too high. When the panels do not require a finish, soapstone is sometimes used. The front of a radio receiving set on which the dials and rheostat controls, etc., are mounted is also called a panel. These panels are usually made of Bakelite, hard rubber, composition or similar insulating substances, although a number of sets are being made with metal panels. The horizontal panel on which the sockets and transformers are usually mounted is known as the *sub-panel* (q.v.).

PANNILL, Charles Jackson—American radio pioneer. Born in Petersburg, Virginia, May 13, 1879. He entered the American Navy, 1898. In 1902 he took a post under Professor R. A. Fessenden and carried out a series of wireless experiments at Hampton Roads, later inaugurating wireless communication between New York and Philadelphia. Pannill was the first man to install wireless on the battleships of the U. S. Navy. Afterwards he carried out a series of communication experiments between various parts of the United States and erected a number of wireless stations. He joined the Marconi Wireless Telegraph Company in 1912 and became a radio adviser to the United States Government, 1914, and assistant director of Naval Communications, 1916. Pannill is a fellow of the Institute of Radio Engineers and a member of the Washington Society of Engineers.

PAPER CONDENSER—A fixed condenser, usually made of tin foil and utilizing a dielectric of paraffin-waxed paper. The 1 microfarad by-pass condenser is a typical example of a paper condenser. (See *Condenser, By-pass.*)

PARALLEL—See *Parallel Connection.*

PARALLEL CONNECTION—Two or more parts of an electrical circuit so connected that the current divides between them. This is also known as a *multiple* (q.v.) connection, *divided circuit,* or *shunt* circuit. Where a number of parts of a circuit are connected in parallel, the same potential is impressed on each part. The current flowing in each branch will depend upon the impressed voltage and the resistance of each branch. (See *Circuit, Parallel.*)

PARALLEL RESISTANCES—Resistances connected so that their terminals have the same difference of potential between them. The greater the number of resistances in parallel, the less will be the total resistance of the circuit. If there are three resistances in parallel of ½, ⅓ and ⅕ ohm, respectively, then the total resistance is equal to the reciprocal (one divided by a number) of the sum of the separate reciprocals. In this case the sum of the reciprocals is 2 plus 3 plus 5 equal to 10 and the reciprocal of this is equal to one-tenth, so that the total resistance of this parallel circuit is one-tenth of an ohm. It can be seen that the total resistance of any circuit having a number of resistances in parallel is less than the resistance of any *one* of the branches. (See *Circuits Parallel*, also *Parallel Connection.*)

PARALLEL RESONANCE—When a concentrated capacity and a concentrated inductance are connected in parallel between terminals to which an alternating electromotive force is applied, and the inductance or capacity or frequency is varied, the condition of parallel resonance exists when the current supplied by the source is a minimum. It should be noted that in series resonance, the total current supplied by the source flows through both the inductance and the capacity whereas in parallel resonance the current supplied by the source is the vectorial sum of the two currents, one flowing through the capacity and one through the inductance.

PARAMAGNETIC—Having a permeability greater than unity. Magnetic as opposed to diamagnetic. The term *paramagnetic* is used in some cases to apply to substances which have only a slightly greater permeability than air such as liquid oxygen, the rare metal erbium, etc. If used in this sense it does not include *ferro-magnetic substances* (q.v.). (See *Diamagnetic material.*)

PARTIAL—An acoustical term denoting any one of the natural vibrations of which a body is capable. An electrical *oscillator* (q.v.) possessing distributed capacity and inductance has, theoretically, an infinite number of possible frequencies, each of which is called a *partial*. The lowest frequency is called *the fundamental.* (See *Harmonics, Harmonic Current, Overtones,* also *Overtone Currents.*)

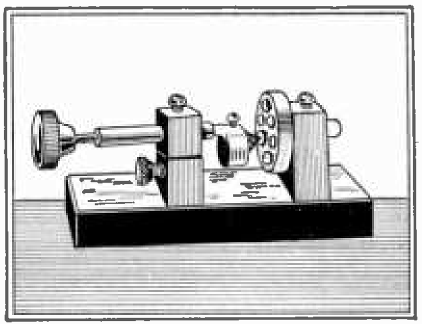
PARTITION INSULATOR—An ebonite tube having a metallic rod running through its center with wing nuts at each end. It is used for continuing a circuit through a wall or partition.

P.D.—Abbreviation for *potential difference.* (See *Potential, Difference of.*)

PELTIER EFFECT—The change in temperature, either heating or cooling, at the junction of two unlike metals, depending upon whether an electric current originating from an external electromotive force, is sent through the junction in one direction or the other. The Peltier effect is the opposite of the *thermo-electric* effect.

PERCENTAGE COUPLING—The coefficient of coupling between the primary and the secondary of an oscillation transformer in a wireless transmitting system. When the primary winding is placed close to the secondary, the coupling is said to be *close* or *tight.* When the two windings are apart the coupling is said to be *loose.* With the ordinary spark gap in the closed circuit, if the primary and the secondary windings are closely coupled a broad wave will be radiated from the aerial system. If they are loosely coupled, a *sharp* wave will be radiated.

PERIKON DETECTOR—A crystal rectifier utilizing a piece of zincite in firm contact with a piece of chalcopyrite. (See *Combination Detector,* also *Crystal Detector.*)



A Perikon detector.

PERIOD—The time required for one complete *cycle.* (q.v.) Referring to an *alternating current* (q.v.) it is the time required for the current or electromotive force to pass through the various values from zero to a positive maximum back to zero again, then to a negative maximum and finally to zero.

PERIODIC—A vibration is said to be periodic if all the phenomena are repeated regularly at equal intervals of time. This time is called *periodic time* or the *period.*

PERIODICITY—A synonym for frequency, or for angular velocity.

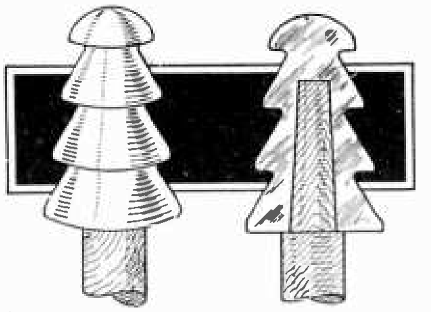
PERMANENT MAGNET—Hardened steel which when magnetized retains its magnetism after the removal of the magnetizing force. The usual method of making permanent magnets is to place the steel in a powerful electromagnetic field. They can also be made by stroking with another magnet. Permanent magnets are used in all electromagnetically operated headsets and *loud speakers.* (q.v.) (See *Magnet, Electromagnet,* also *Temporary Magnets.*)

PERMEABILITY—The *permeance* (q.v.) existing between the opposite faces of a cube of the substance each side of which is one centimeter in length. Since the permeability of air is assumed to be unity, the permeability of any substance is the ratio of the flux that passes through it to the flux that would exist in air if the magnetomotive and flux path remained unchanged.

PERMEANCE—That property of a magnetic circuit which allows the flow of magnetic flux. Its reciprocal is *reluctance* (q.v.) which is the property of a magnetic circuit by which it resists the flow of magnetic flux.

PERMITTANCE—A synonym for *capacity* (q.v.) or *capacitance* (q.v.). This property is possessed by every electrical circuit, but does not manifest itself unless there is a change in voltage. The greater the permittance of a circuit, the greater will be the opposition offered to a change in voltage.

PERMITTIVITY—See *Dielectric Coefficient and Constant, Inductive Capacity,* also *Inductivity.*

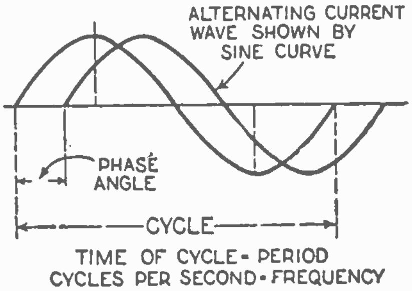


A petticoat insulator. Shown in cross-section at the right.

PETTICOAT INSULATOR—An insulator having two or more flanges or petticoats arranged one on top of the other for the purpose of reducing leakage and preventing accumulation of moisture. Petticoat insulators are usually made of porcelain. Insulators used on low tension lines are also of the petticoat type, in such cases being constructed of glass. (See *High Tension Insulator,* also *Insulator.*)

PHANTOM AERIAL—See *Mute antenna.*

PHASE—A particular state in a regularly recurring cycle of changes. In simple harmonic motion, uniform circular motion, or in periodic changes of any magnitude varying according to a simple harmonic law (as for example an alternating current) the point or stage in the period to which the rotation, oscillation or variation has advanced, considered in its relation to the position or instant of starting or to some other standard position. This relationship is usually expressed in angular measure. Defined in electrical terms, phase is the distance, usually measured as an angle, of the base of any *ordinate* (q.v.) of an alternating wave from any chosen point on the time axis. This distance represents the phase of the ordinate with respect to the point. In any sinusoidal alternating current quantity, the phase at any instant may be shown by the corresponding position of a *vector* (q.v.) revolving about a point with such an angular velocity that its projection at each instant upon a chosen reference line is proportional to the value of the quantity at that instant. As an example, consider a conductor rotating in a magnetic field. The induced electromotive force, in one complete revolution, passes through the following values. It starts at zero and rises to a maximum positive value, then falls to zero and rises to a maximum positive value in the reverse direction, finally falling to zero again. The transitions through these various values constitute a *cycle* (q.v.). The time of this transition is called a *period,* the number of cycles per second being the *frequency* (q.v.). The angle at any instant through which the conductor has rotated since the electromotive force changed its sign from negative to positive is the *phase angle.* This is ordinarily designated by the Greek letter Φ (phi). If ω (omega) is the angular velocity of the rotating conductor and f the frequency, then $\omega = 2\pi f$ (since there are 2π radians in a complete revolution). If the time in seconds which has elapsed since the conductor last passed the point of zero electromotive force be represented by t, then the phase Φ at that particular instant is equal to $\omega t = 2\pi ft$. Periodic variations are conveniently expressed by sine curves and the relative phases are indicated by the relative positions of the *nodes* (q.v.) and *loops* (q.v.).



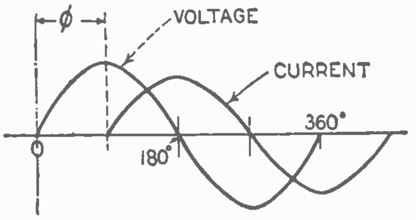
ALTERNATING CURRENT WAVE SHOWN BY SINE CURVE
PHASE ANGLE
CYCLE
TIME OF CYCLE = PERIOD
CYCLES PER SECOND = FREQUENCY

Phase displacement, cycle, etc., illustrated by means of sine curves.

Magnitudes having maximum and minimum values occurring simultaneously are said to be *in phase.* If they do not occur simultaneously, they are *out of phase.* When the corresponding maximum or minimum values of two sinusoidal alternating quantities of the same frequency occur at different instances, the two quantities are said to differ in phase by the angle between their nearest negative maxima or their nearest positive maxima or any other nearest corresponding values. The quantity whose maximum value occurs first is said to *lead* (q.v.) the other. The quantity whose maximum value occurs later is said to *lag* (q.v.). Where one quantity lags behind another by 180 degrees, the values are said to be of *opposite phase.* An alternating current may be *single phase* or *polyphase.* Another term for polyphase is *multiphase.* In a three-phase alternating current system the three separate currents differ in phase from each other by 120 degrees. In a polyphase system, if the various phases each carry or supply equal current, the system is said to be *balanced.*

PHASE ANGLE—See *Phase.*

PHASE DISPLACEMENT—The difference in phase or the phase angle between two alternating quantities, such as voltage and current, of the same frequency. Such quantities do not pass through their respective maximum positive quantities or through their zero values at the same time. The instantaneous values of any sine-shaped wave can be represented as being proportional to the sine of an angle, a complete cycle being equal to 360 degrees. When two quantities are out of phase, the respective angles corresponding to each quantity at any given instant are unequal, the difference between the two angles being called the *phase displacement* or the *phase difference.* In the accompanying illustration, the current and voltage relationship in an alternating current circuit are shown by the two sine curves. As can be seen, the current and voltage are out of phase, the phase displacement being equal to the angle Φ, in this case 90 degrees ($\frac{\pi}{2}$ radians). The current reaches its maximum value at a later time than the voltage. In this case the current *lags* behind the voltage by the angle Φ, the voltage leading the current by this angle. Since the angle of lag of the current is 90 degrees, the current and voltage are said to be in *quadrature.* In an alternating current circuit having pure inductance and no resistance (a theoretical circuit, since all electrical conductors possess resistance), the current would lag by 90 degrees as in the example given. (See *Lag, Lead, Leading Current,* also *Phase.*)



Sine curves of current and voltage, showing difference in phase.

PHENOMENA OF ELECTRIC WAVE PROPAGATION—Electric waves are created by electric *oscillations* (q.v.). They are often referred to as *radio waves.* Electric waves, light waves and radiated heat waves are included in the general term *electromagnetic waves* (q.v.). The velocity of electric waves is the same as that of light waves, 300,000,000 meters per second or 186,000 miles per second (appx.). Electric waves used for radio work have frequencies from about 10,000 to 3,000,000 cycles per second. Since the velocity of electric waves is known, it is possible to calculate the length of a wave if the frequency is known. Thus if the electric wave has a frequency of 10,000 cycles per second, the wavelength is found by dividing the velocity in meters per second by the frequency in cycles per second, which gives in this case a wavelength of 30,000 meters. Electric waves are in reality a combination of electromagnetic and electrostatic disturbances in space. The displacements are at right angles to the motion of the wave train. The electric field and the magnetic field are at right angles and travel together. They spread out or expand from the point of disturbance just as water waves spread out from a point where a stone strikes the surface of the water. Electric waves are propagated from an aerial when certain forms of alternating current flow in the aerial. Since the frequency of the propagated wave corresponds to the frequency of the current in the aerial, high frequency current must flow in the aerial to produce the high frequency electric waves used in radio. Such current may be produced by a high-frequency generator, by a direct current generator and an electric arc, or by means of vacuum tubes. The latter offer the simplest means of producing the rapidly reversing currents. Electric waves may be classified as *continuous* and *discontinuous.* Examples of the former are the waves produced by a high frequency alternator, an oscillating vacuum tube or a Poulsen arc. Examples of the latter are the waves produced by condenser discharges in a spark circuit. In these the amplitude of the waves diminishes in each wave train and the waves are referred to as *damped* waves. The high frequency current used to produce continuous waves used in radio telephony is *modulated* in accordance with the vibrations of a *microphone* (q.v.). As a result modulated waves are sent out from the aerial and these correspond in wave form to the variations of the sound waves. The sensitive apparatus at the distant receiving set picks up or intercepts the modulated electric waves, reconverts them to high frequency electric currents which are rectified into direct currents capable of actuating a 'phone and usually amplified so that they have energy enough to operate a loud speaker. (See *Oscillator, Carrier Wave,* also *Modulated Currents.*)

PHILLIPS, Raymond—British radio expert. Born October 6, 1879, he was educated at Edgebaston, Birmingham Schorne College, Buckinghamshire, and Windsor High School. For three years he was engaged on railway constructions and repairs, with special application to electric railways. In 1902 he invented a system of automatic train control and a number of appliances for electric railways which were widely adopted. In 1905 he took up the study of wireless and specialized in the control of mechanisms at a distance by electric waves. In 1910 he patented a system for controlling airships by radio and by means of a working model demonstrated how an airship could be thus controlled. During the World War he was inspector of ordnance machinery and in 1921 was appointed a member of the Inter-Allied Commission of Control in Germany. He is the author of many articles on the control of machines by electric waves.

PHONOGRAPHIC RECORDING—This refers to the amplifying of code signal currents by means of relays in tandem until the sounds produced in a telephone receiver are loud enough to cut a distinct record on the wax of a phonograph. The signals can be received at high speed and thereafter read at low speed. Instead of a phonograph a telegraphone may be used.

PHOTO-ELECTRIC EFFECT—A change in the electrical conductivity of a gaseous or solid substance when radiations of certain wavelengths come in contact with them. This refers particularly to rays of the visible spectrum and ultra-violet and infra-red rays.

PHOTOGRAPHIC RECORDER—A device for recording high-speed wireless messages by recording the deflections of a sensitive galvanometer on a moving photographic film. (See *Auto-Receiver.*)

PICKARD, Greenleaf Whittier—American radio expert. He was born at Portland, Maine, on February 14, 1877, and was educated at Westbrook Seminary, Lawrence Scientific School, Harvard and Massachusetts Institute of Technology. He made a special study of wireless telegraphy and telephony and has taken out many United States and foreign patents for radio inventions. He is noted for his pioneer work in radio telephony. Pickard began radio work in 1899 at Blue Hill observatory, Milton, Massachusetts, under a grant from the Smithsonian Institute. He was on the engineering staff of the American Telephone and Telegraph Company from 1902 to 1906. Later he was connected with the Wireless Specialty Apparatus Company as consulting engineer. He has an extensive practice as a patent expert in radio patent litigation. Pickard is a fellow of the American Institute of Electrical Engineers, a Member of the American Chemical Society and also is a Member of the Society of Chemical Industry.

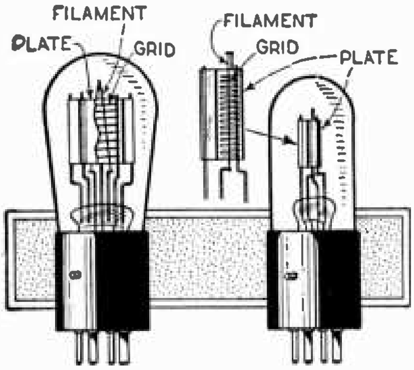
Greenleaf Whittier Pickard.

PIG-TAIL—A flexible braided or stranded copper conductor used to carry the current to the rotor of a condenser or a coupler. Pig-tails are also used on the carbon brushes of motors and generators. (See *Flexible Lead.*)

PITCH — Frequency of vibration of a sound. A shrill note is said to be of high pitch, a bass note of low pitch. The pitch of an armature winding refers to the distance from the center of a winding to the center of the next winding.

PLAIN AERIAL—An aerial having the transmitting or receiving circuit connected directly to it without the utilization of inductive coupling or any intermediate tuned circuit. An example of a plain aerial is one used to transmit code, having a spark gap in series with the aerial and the ground.

PLATE — The anode or positive electrode of a vacuum tube. The vacuum tube plate is usually made of nickel. The shape of the plate varies according to the type and construction of the tube. In some tubes the plate is tubular; in others flat. When the cathode or filament is heated, it emits electrons which pass to the grid or through the grid to the plate, depending upon the grid charge. In power tubes (transmitting) it is necessary to use some cooling device to conduct away the heat dissipated at the plate. In some cases a liquid bath or a blast of air is used or the plate may be constructed so that it can be cooled by water circulation. Other methods of preventing overheating of these tubes are increasing the area of the plate as for example increasing the diameter of a tubular plate, or blackening the surface of the plate to increase its heat emissivity.



Vacuum tubes, showing construction of plates.

PLATE BATTERY—A battery, usually referred to as the *"B" Battery* having its positive terminal connected to the plate of the three-electrode vacuum tube and its negative terminal leading to the filament. The purpose of this battery is to keep the plate voltage positive with respect to the filament so that the electrons will be attracted sufficiently to the plate. Plate batteries are usually dry cells although there are a number of storage plate or "B" batteries on the market, both of the acid and the alkaline types. It is possible to dispense with the plate battery by using a *"B" eliminator*, which is connected to the ordinary house-lighting circuit. (See *"B" Battery.*)

PLATE CIRCUIT — The circuit connected to the *plate* (q.v.) or anode of a three-electrode vacuum tube.

PLATE COMPONENT, HIGH FREQUENCY—The radio frequency current flowing in the *plate circuit* (q.v.) of a vacuum tube. (See *High Frequency Component of Plate.*)

PLATE CONSUMPTION — This refers to the current consumed in energizing the plate of a vacuum tube. Increasing the grid voltage tends to increase the plate consumption. An increasing plate voltage also increases the plate current, but tends to decrease the relatively small grid current. (See *Consumption, Current;* also *Consumption, Plate.*)

PLATE CONTROL — The vacuum tube starts oscillating at a plate voltage which will depend on the adjustments of the circuit. When the plate voltage is raised, the oscillation current becomes greater, increasing in direct proportion.

PLATE CURRENT—The current in the *plate circuit* (q.v.) of the three-electrode vacuum tube. The current passing between the plate and the heated cathode or filament.

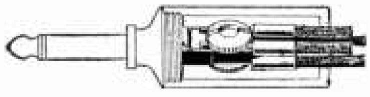
PLATE IMPEDANCE — The total resistance offered to alternating current between the filament and the plate in a vacuum tube. It is often referred to as the *tube impedance.* The impedance is independent of the alternating current input voltage.

PLATE VOLTAGE—The voltage of the plate of a vacuum tube above the filament. The potential difference between the plate and the filament. This term is usually used to refer to the voltage of the *"B" battery* (q.v.) connected to the plate, as for example, if the 22½-volt terminal of the "B" battery is connected to the plate of the detector tube, the plate voltage is said to be 22½ volts. Soft tubes, formerly used as detectors, operated best at this voltage. Most of the amplifier tubes now used as detectors operate best with 45 volts on the plate, although these tubes vary individually, some operating better with slightly increased voltage and others with a voltage less than 45. The plate voltage generally used on the amplifiers is 90 volts. The new power reception tubes use plate voltages up to 135 volts.

PLIODYNATRON — A special vacuum tube, designed by A. W. Hull, having two grids instead of one. This tube utilizes the normal amplifying property of the vacuum tube to obtain a very high voltage amplification, as high as 1,000 fold. When such high amplification is obtained, however, the operation is unstable and extremely careful adjustment is necessary.

PLIOTRON—A name given to a highly evacuated vacuum tube used for transmitting purposes. Large pliotrons are capable of developing as high as 500 watts output since they are so highly exhausted that several thousand volts may be applied to the plate and also since they can carry a plate current of nearly one-half an ampere.

PLUG — A connecting device used extensively in radio and telephone work for making connection or "plugging in" *loud speakers* (q.v.), head sets, power supply, microphone transmitters, etc. The plug has an insulating handle and the metal contact tip is designed to fit into a standard *jack* (q.v.). A flexible wire fits into terminals in the plug, the other end of the wire being connected to the apparatus such as the loud speaker, etc. The plug connection terminals may be of the conventional small binding post type or they may consist of internal spring clips.



Cross-section of plug.

PLUG-IN COIL — An interchangeable coil, often of the honey-comb type, which can be plugged into a socket, thus permitting it to be quickly and conveniently put into or taken out of a circuit. Plug-in coils are used in some cases in receiving sets designed for operation on widely varying wave bands.

PLUG-IN TRANSFORMER—*A plug-in coil* (q.v.) specifically used as a radio frequency transformer.

POLARITY — In magnets the differentiation between *North Pole* and *South Pole.* In electrical devices or circuits, the difference between *positive* and *negative poles.* It is often necessary to determine which is the positive pole or terminal of a direct current circuit, and which the negative. There are various methods of indicating polarity. A voltmeter or an ammeter will show the direction of current flow. An extremely simple method of determining polarity is to place the two terminals in a glass jar containing salt water or some other electrolyte. A much greater number of bubbles will be observed to collect around the terminal of negative polarity. A piece of used blue print paper can be utilized to indicate polarity. It is simply necessary to moisten the paper and place the terminals on it, at a distance of about ¼ of an inch apart. The paper will be whitened at the negative terminal.

POLARIZATION — In a primary cell, the current liberates hydrogen from the electrolyte in passing through it. The hydrogen is carried to the negative plate with the current and collects there. It thus increases the internal resistance of the cell. This makes it harder for the current to pass through it and as a result the electromotive force available at the terminals is materially lowered. In addition there is a slight difference of potential between the negative plate and the hydrogen and this acts in opposition to the electromotive force of the cell. This further reduces the effective voltage of the cell. The entire effect is known as polarization. Polarization may be carried to such an extent that current can no longer flow from the cell. It may be counteracted or prevented by the use of *depolarizers* (q.v.). There are three different kinds of depolarizers. Chemical depolarizers are placed in the cell near the cathode. Substances such as manganese dioxide, potassium bichromate, nitric acid or cuprous chloride are used. When the hydrogen reaches the depolarizer it combines with it to form a new compound. Electrochemical depolarizers depend for their action upon the use of a substance which will liberate a metal such as copper at the cathode instead of hydrogen. Thus with no hydrogen present there is no polarization. Of course it is necessary to use the proper electrodes and the correct electrolyte to obtain this result. Mechanical depolarizers merely blow or sweep the hydrogen away from the cathode. Being the least effective of the three methods, the latter is seldom used. (See *Local Action.*)

POLARIZATION, ELECTRIC—The state of a dielectric when subjected to electrostatic forces. Electric polarization is synonymous with electric displacement.

POLARIZED RELAY — A relay in which a magnetized swinging arm is placed between poles of two electromagnets. When current passes, one pole must change, so that the arm is attracted by one and repelled by the other. A polarized relay is much more sensitive to weak currents than the ordinary relay.

POLES—See *Magnetic Poles.*

POLYPHASE—Referring to an alternating current system in which the circuits are divided up into two or more branches having their currents displaced in phase from each other. The term *multiphase* has the same meaning as polyphase. (See *Phase.*)

POLYPHASE ALTERNATOR—An alternating current generator wound in such a way that it supplies two or more currents which differ in *phase* (q.v.) from each other by definite phase angles. The usual form of polyphase alternator is the three-phase alternator.

PORCELAIN CLEAT—See *Cleat.*

POSITIVE ELECTRODE—In a primary cell, the zinc plate or *anode* (q.v.) is the *positive electrode,* while the *pole* of this electrode is the *negative pole* (q.v.) because it is negative in relation to the external circuit. In a storage cell, the lead peroxide plate, which is the cathode during discharge, is called the *positive electrode* and its pole the *positive pole.*

POSITIVE TERMINAL POLE—The pole or terminal out of which current is considered to flow. This is more or less of a handy convention, but is contrary to the present day knowledge of electrical flow inasmuch as electrons move from negative to positive.

POTENTIAL—See *Potential, Electric.*

POTENTIAL, DIFFERENCE OF—abbreviation P.D.—Difference of electrical level. Theoretically the potential difference between two points in an electric field is measured by the work done by the electric field on a unit point charge of positive electricity moved from one point to another without disturbing the field. Potential difference is measured in volts. It may refer to any two points in a circuit, even though there is no source of electromotive force between these points. When applied to circuit between two points not possessing a source of electromotive force, the potential difference between the two points under consideration is equal to the product of the current flowing times the resistance of the circuit between the two points. In the case of an open circuit, such as the terminals of a cell, the potential difference is equal to the electromotive force. (See *Potential, Electromotive force,* also *Volt.*)

POTENTIAL DROP—The fall in voltage in a circuit due to the resistance of the conductor. (See *Potential, Electric;* also *Potential, Difference of.*)

POTENTIAL, ELECTRIC—Electrical pressure, or the degree of *electromotive force* (q.v.). Potential is electrical level. Electrical potential can be compared with the "head" of water. Thus it is customary to measure the height or head of water above sea level, which is taken as an arbitrary base. In a somewhat similar manner, the potential of the earth is taken as zero and all potential is measured from this as an arbitrary base. With this understood, it is no longer necessary to refer to the degree of electromotive force, but simply to the electromotive force or the potential. See *Potential, Difference of,* also *Volt.*)

POTENTIAL ENERGY—Energy of position. When energy is available for the production of work, it is referred to as potential energy. Energy at work is *kinetic energy* (q.v.).

POTENTIAL RECTIFIER—A *crystal* (q.v.) or other form of rectifier which requires an initial current to pass through it to become sensitive.

POTENTIOMETER (Potential Divider)—A resistance connected across a battery or other source of electromotive force and equipped with a slider so that the voltage on another circuit may be varied from zero to the full potential of the battery. Where a gas content detector vacuum tube is used, the purpose of the potentiometer is to permit a close adjustment of the *plate battery* (q.v.) potential. The potentiometer is shunted around the filament heating or "A" battery, its resistance being so high that its power consumption is practically negligible. In tuned radio frequency sets, a potentiometer is used to control the tube oscillation. The advantage of being able to make a system oscillate is obvious, as the greatest amplification is obtained when the circuits are operated just at the point before self-oscillation starts. This condition is easily found in operation, since the instant self-oscillation starts, a whistle is heard in the phone or loud speaker when tuning to any station it is desired to receive. The use of a potentiometer to control oscillations in a tuned radio frequency circuit is illustrated in the diagram shown at Fig. 1. Potentiometers used in radio apparatus are usually made either from high resistance wire or from carbon granules. In electrical engineering work, the term potentiometer means, in general, an arrangement of circuits for measuring potential difference.

Fig. 1. Tuned radio frequency circuit showing use of potentiometer to control oscillations.

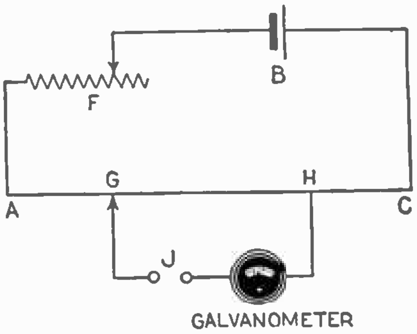

Fig. 2. A simple form of potentiometer used for electrical measurements.

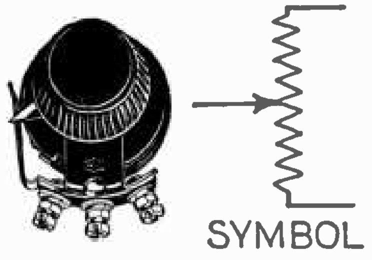

Illustration of a radio potentiometer, showing symbol at the right.

Using certain accessories, laboratory potentiometers can be used to measure voltages over all ranges, and by applying's *Ohm's law* (q.v.) the measurements obtained can be used to determine a wide range of current values.

The simplest form of potentiometer used for electrical measurements is shown in Fig. 2. AC is a resistance in which a constant current from the battery B is flowing. F is a regulating resistance used to compensate for the variations of the electromotive force of the battery. The current in AC is checked for constancy by noting that the drop in potential between the two points selected in it is equal to the electromotive force of a standard cell. The standard cell is connected in the circuit GHJ at J and the regulating resistance is adjusted until the sensitive galvanometer shows no deflection. With the assumption that AC has a uniform resistance throughout its length, and the current in it remaining constant, it is obvious that any other voltage not greater than the drop between A and C can be measured by connecting it in the circuit at J and shifting the points G and H until the galvanometer again comes to a balance.

A direct reading scale may be placed between A and C. For ordinary potentiometer measurements, the drop between A and C is made about 1½ volts as this is approximately the electromotive force of a standard Clark cell.

POULSEN ARC—An arc usually burned in hydrogen between a rotating carbon cathode and a water-cooled copper anode in a magnetic field. This arc is connected to an oscillating circuit, and due to its instability it maintains continuous oscillations which are utilized for the production of continuous waves for radio telegraphy and telephony.

POULSEN, Valdemar—Danish radio pioneer. Born in Copenhagen, November 23, 1869; he was educated at Copenhagen University and in 1893 he joined the Copenhagen Telephone Company. In 1903 he invented his famous system of arc transmission. Poulsen is a fellow of the Danish Society of Sciences. In 1900 he was awarded the Grand Prix at Paris.

POUNDAL — A unit of force. That force which acting on a mass of one pound gives it a velocity of one foot per second. It is equal to the weight of a pound mass divided by the acceleration of gravity; equal to 13,825 dynes or approximately half an ounce.

POWER—The rate of doing work. A certain amount of work may be done in a day or in a week. In the former case, more power is expended than in the latter case. Mechanical power is measured in *horse power* (q.v.). One horse power is equivalent to 33,000 foot-pounds per minute. Since power is the rate of doing work, the expression for power must contain a time element and a work element. Work is a measure of a force exerted through a distance. Hence the foot-pound measures work. Electrical power is the product of voltage times amperage. It is measured in *watts* (q.v.). (See *Kilowatt.*)

POWER AMPLIFIER—See *Power Amplification.*

POWER AMPLIFICATION—Amplification by means of apparatus consisting of a combination of power vacuum tubes, designed to carry larger currents than the ordinary tubes and specially designed transformers. Power amplifiers provide additional audio amplification and are used in connection with radio receiving sets where great volume is required as in the case of apparatus used for public address systems and for use with power operated loud speakers. (See *Amplifier.*)

POWER AMPLIFICATION COEFFICIENT—The ratio of the plate output power to the grid input power of a vacuum tube. This value may be as high as 10,000. The output power of a vacuum tube comes from the plate battery. When the grid is operated at low or negative voltage, the input power needed to produce the changes in grid voltage may be made very small compared with the output power of the tube.

POWER, APPARENT—The product of the voltage and the current in an alternating current circuit expressed in volt-amperes. This expression does not take into account any difference in *phase* (q.v.) between the voltage and the current. Thus in an extreme case (theoretical) where an alternating current flows in a purely inductive circuit, the current will lag behind the voltage by a phase angle of 90 degrees. In such a circuit, the *true power* (q.v.) would be zero, since the cosine of the phase angle between the current and the voltage would be zero, whereas the apparent power might be quite high and a heavy current might be flowing in the circuit. Apparent power is ordinarily expressed in *kilovolt-amperes* (q.v.). (See *Power Factor.*)

POWER FACTOR — The ratio of the *true power* (watts) in an alternating current circuit to the *apparent power* (volt-amperes). Where the wave form of the alternating current is sinusoidal, the power factor is equal to the cosine of the angle between the voltage and the current. Expressed as an equation, power P is equal to the product of the current I and the component of the impressed electromotive force which is in phase with the current, $E \cos \Phi$, where Φ is the angle of phase displacement between the current and the voltage ($P = IE \cos \Phi$). Expressed in another way, the power factor is the fractional amount which, if multiplied by the effective values of the current and the voltage, will give the value of the power expended. (See *Effective Electromotive force, Power, Apparent,* also *Power, True; Kilovolt-ampere, Kilowatt.*)

POWER, TRUE — The product of the *apparent power* and the *power factor* (q.v.) in an alternating current circuit. A wattmeter will measure true power, inasmuch as it takes into account the *phase displacement* (q.v.) between the current and the voltage. A voltmeter and an ammeter cannot be used to measure power, however, since the product of the two readings only gives the apparent power.

POWER TUBE—See *Vacuum Tube, Power.*

PRACTICAL UNITS—In the practical system of electrical units, the ohm, the ampere and the volt are the fundamental units. While the practical system is based originally on the Centimeter Gram Second systems, it is in no way dependent upon these systems for practical use. When used with the fundamental units of length and time, all other electrical as well as magnetic units can be derived from the fundamental units of the practical system. At the recommendation of the Chicago International Electrical Congress in 1893, the fundamental electrical units of the practical system were adopted as legal units in the United States by an act of Congress, July 12, 1894.

P R B—International Radiotelegraphic Convention abbreviation. Followed by question mark it means, "Do you wish to communicate by means of the International Signal Code?" Without the question mark it means, "I wish to communicate by means of the International Signal Code." (See *Abbreviations, International Radio Telegraphic Conventional.*)

PRESSURE—See *Potential, Electric.*

PRESSURE, ELECTRICAL—The term is synonymous with *voltage* (q.v.) or *electromotive* force (q.v.). Electrical pressure is the cause of current flow. It is measured in *volts* (q.v.). The flow of electricity along a conductor is analogous to the flow of water through a pipe. In order to make water flow, a pump is often used to force the water or in other words to apply pressure. Similarly, electrical pressure must be applied in order for an electric current to flow.

PRIMARY CELL—A device for transforming chemical energy into electrical energy. It consists of two different conductors placed in a liquid which acts chemically on one conductor, or more on one conductor than on the other, thus keeping a difference of potential between them. While the cell is being discharged either one or both of the conductors is used up and the liquid is also consumed. In many types of primary cells these can be replaced. The liquid is called an *electrolyte* (q.v.). In some cases an acid is used while in others a salt solution is the *electrolyte.* (q.v.) (See *Cell, Cell Secondary; Cell, Theory of Primary; Electrolysis, Local Action, Polarization,* also *Storage Cells.*)

PRIMARY CIRCUIT—A circuit supplying current to another which is called the secondary circuit. The two circuits are usually coupled by means of a transformer, the primary winding being in the primary circuit and the secondary winding being in the secondary circuit.

PRIMARY CURRENT — See *Current, Primary.*

PRIMARY ELECTRONS — The main stream of electrons given off by the hot filament of a vacuum tube, as differentiated from *secondary electrons* (q.v.) which may be detached from the plate by the impact of the primary electrons. (See *Negative Resistance.*)

PRIMARY TUNING INDUCTANCE—A variable inductance in the primary circuit of a radio transmitter. It is also referred to as the *aerial tuning inductance.* The aerial inductance coil may be continuously variable utilizing a sliding contact which bears on an edgewise copper strip or it may be of the drum type, in this case being made of stranded copper cable. (See *Inductance Coils,* also *Pancake Coils.*)

PRINCE, Charles Edmond — British radio expert. Born in 1874 at Cape Town and educated at Clifton and Faraday House, he joined the Marconi Wireless Telegraph Company in 1907, where he was concerned chiefly in research work on wireless telephony. In 1909 he carried out experiments in Italy and Switzerland with the first Marconi Field Station and made a number of valuable improvements in the Bellini-Tosi direction finder. In the World war, he joined the Royal Flying Corps and in 1915 he installed the first radio telephone on aircraft.

PRINTER, MORSE—See *Morse Inker.*

PROTON—A unit of positive electricity. The smallest quantity of positive electricity capable of existing in a free state. A minute particle or quantity of positive electricity carried by the nucleus of a hydrogen atom. See *Electron Theory,* also *Free Electrons.*

PULSATING CURRENT — A periodic current, that is to say a current passing through the successive equal cycles of values, the average value of which is not zero. A pulsating current is the sum of an alternating and a direct current. A current which varies regularly in magnitude is said to be pulsating while if it remains the same in magnitude it is called continuous. (See *Continuous Direct Current,* also *Current, Pulsating Direct.*)

PULSATING DIRECT CURRENT—See *Pulsating Current.*

PUPIN, Michael — American radio authority. Born in Hungary, October 4th, 1858, he came to the United States at the age of 10, and was educated at Columbia University. He also studied at Cambridge University, England. In 1891 he was appointed professor of mathematical physics at Columbia University, where he carried out an important series of researches in radio telegraphy and telephony. He is the holder of a large number of patents relating to telephony and radio, has done valuable research work on reso-

Michael Pupin.

nance and has developed radio circuits of extreme selectivity.

PUSH-PULL AMPLIFICATION—A method of connection in a vacuum tube receiving set, for supplying more power to the loud speaker than that ordinarily obtainable from a one or two stage audio amplifier. In the push-pull amplifier two tubes are used in the final stage of the amplifier, connected in such a way that they are used alternately on the two halves of each audio frequency cycle. A push-pull amplification circuit is shown in Figure 1. The first tube at the left gives the first stage of amplification and the other two in combination give the second stage. An ordinary audio frequency amplifier transformer is connected to the grid and filament of the first tube. Special transformers are usually used for the other two transformers. These have connections brought out from the center point of one of the windings as shown. The transformer between the two stages has a split secondary while the last transformer has a split primary. In cases where a tapped wound transformer is not available, two transformers can be used instead. In this case the two primary windings are connected in series and the two secondary windings are also connected in series. Figure 2 shows the method of connecting two transformers for this purpose, a connection being made to the mid-point between the secondary windings. It is essential that the two windings in series be connected so that they are continuous in the same direction around the transformer cores. In theory, the push-pull amplifier uses one tube during one half of the cycle and the other tube during the other half of the cycle. While the terminal of the secondary transformer winding leading to the grid of the tube is at a positive potential with respect to the middle of the winding, the tube is effective. During the remaining half of the cycle when the terminal is negative with respect to the tap, the tube is not operating. The action however is such that one tube is effective at all times. Although ordinary amplifier tubes can be used in the push-pull amplifier circuit it is desirable to use special power tubes which have a high amplification coefficient.

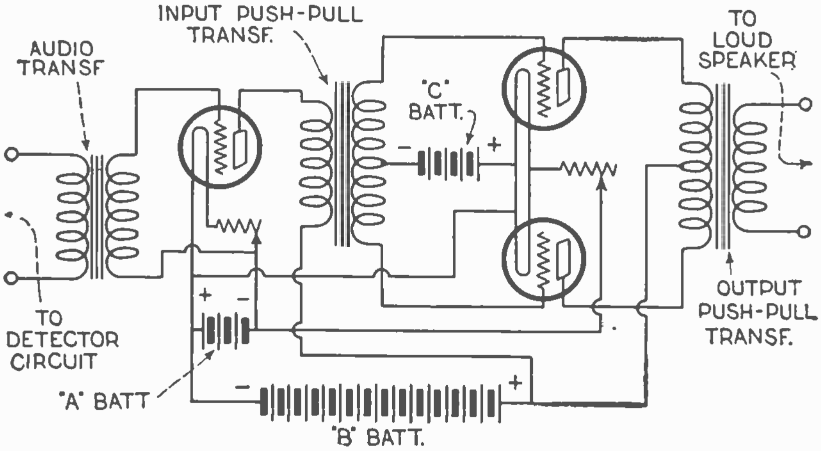

Fig. 1. Diagram of a push-pull amplification circuit.

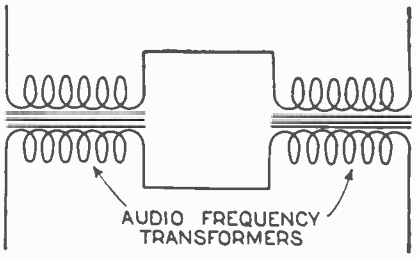

Fig. 2. Method of connecting two transformers where a tapped wound tranformer is not available.

PYRITES—Compounds of iron or copper and sulphur. Three of these are *Ferrous Sulphide* (FeS), *Bisulphide* (FeS_2), and an intermediate known as *Magnetic Pyrites* (Fe_3S_4). Pyrites crystals have been used in radio as detector crystals. (See *Crystal*, also *Crystal Detector.*)

PYRON DETECTOR—A *crystal detector* (q.v.) having an iron pyrites crystal and a copper or other metallic contact point.

Q

Q SIGNALS—International Radiotelegraphic Convention abbreviations. When the signal is followed by a question mark it asks the question. Otherwise the answer is indicated. A list of these abbreviations and their meanings follow:

Abbrev'n	*Question*	*Answer*
QRA	What ship or coast station is that?	This is . . . .
QRB	What is your distance?	My distance is . . . .
QRC	What is your true bearing?	My true bearing is . . . degrees.
QRD	Where are you bound for?	I am bound for . . .
QRF	Where are you bound from?	I am bound from . . . . .
QRG	What line do you belong to?	I belong to the . . . Line.
QRH	What is your wave length in meters?	My wave length is . . . . meters.
QRHH	What tune shall I adjust for?	Adjust to receive on tune . . . .
QRJ	How many words have you to send?	I have . . . . words to send.
QRK	How do you receive me?	I am receiving well.
QRL	Are you receiving badly? Shall I send 20 . . . — . for adjustment?	I am receiving badly. Please send 20 . . . — for adjustment.
QRLL	Request permission to test . . . minutes.	Permission to test granted.
QRM	Are you being interfered with?	I am being interfered with.
QRN	Are the atmospherics strong?	Atmospherics are very strong.
QRO	Shall I increase power?	Increase power.
QRP	Shall I decrease power?	Decrease power.
QRQ	Shall I send faster?	Send faster.
QRS	Shall I send slower?	Send slower.
QRT	Shall I stop sending?	Stop sending.
QRU		I have nothing to transmit. I have nothing for you.
QRV	Are you ready?	I am ready. All right now.
QRW	Are you busy?	I am busy (or, I am busy with . . . . Please do not interfere).
QRX	Shall I stand by?	Stand by. I will call you when required.
QRY	When will be my turn?	Your turn will be No. . . . .
QRZ	Are my signals weak?	Your signals are weak.
QSA	Are my signals strong?	Your signals are strong.
QSB	Is my tone bad? Is my spark bad?	The tone is bad. The spark is bad.
QSC	Is my spacing bad?	Your spacing is bad.
QSD	What is your time?	My time is . . . .
QSF	Is transmission to be in alternate order or in series?	Transmission will be in alternate order.
QSG		Transmission will be in a series of 5 messages.
QSH		Transmission will be in a series of 10 messages.
QSJ	What rate shall I collect for?	Collect . . . .

Abbrev'n	*Question*	*Answer*
QSK	Is the last radiogram cancelled?	The last radiogram is cancelled.
QSL	Did you get my receipt?	Please acknowledge.
QSM	What is your true course?	My true course is . . . . . degrees.
QSN	Are you in communication with land?	I am not in communication with land.
QSO	Are you in communication with any ship or station (or: with . . . .)?	I am in communication with . . . . (through . . . . .
QSP	Shall I inform . . . . that you are calling him?	Inform . . . . that I am calling him.
QSQ	Is . . . . . calling me?	You are being called by . . . .
QSR	Will you forward the radiogram?	I will forward the radiogram.
QSS	Are my signals fading?	Your signals are fading.
QST	Have you received the general call?	General call to all stations.
QSU	Please call me when you have finished (or: at . . o'clock).	Will call when I have finished.
QSV	Is public correspondence being handled?	Public correspondence is being handled. Please do not interfere.
QSW	Shall I increase my spark frequency?	Increase your spark frequency.
QSX	Shall I decrease my spark frequency?	Decrease your spark frequency.
QSY	Shall I send on a wave length of . . . . meters.	Let us change to a wave length of . . . . meters.
QSZ		Send each word twice. I have difficulty in receiving you.
QTA		Repeat the last radiogram.
QTC	Have you anything to transmit?	I have something to transmit. I have one or more radiograms for . . . . . .
QTE	What is my true bearing?	Your true bearing is . . . . degrees from . . . . . .
QTF	What is my true position?	Your true position is . . latitude . . . . . .longitude.

QUADRANT—A term formerly in use as the unit of *inductance* (q.v.), now called the *henry* (q.v.). Inductance has the same dimensions as length and this unit is equivalent to 10^9 cm., this being approximately the length of one quadrant of the earth.

QUADRANT ELECTROMETER—A sensitive *electrometer* (q.v.) which in its calibrated form is known as an *electrostatic voltmeter* (q.v.). In the usual type, the "needle" consists of a thin aluminum plate suspended on delicate knife edges, with a pointer extending from the upper part to a scale. Two pairs of quadrant plates, having opposite faces metallically connected together, are placed on either side of the movable plate and parallel to its face. Each pair is insulated from the other pair. When the pairs of quadrants are subjected to a difference of potential, the needle, if highly charged, will be attracted into one pair or repelled out of the other. (See *Kelvin's Electrostatic Voltmeter.*)

QUADRATURE—The differing in *phase* (q.v.) of two alternating current quantities by 90 degrees. For example, when the current lags behind the impressed voltage by 90 degrees, as in the case of pure inductance in a circuit, the current and the voltage are said to be in quadrature. (See *Lag, Lead,* also *Leading Current.*)

QUANTITY OF ELECTRICITY—When referring to static electricity, it is the amount of the charge. Referring to electricity in motion, or an electric current, it is the amount of current flowing in a given time. Quantity of electricity is measured in *coulombs* (q.v.). The coulomb is the quantity of electricity which has passed when a current of one ampere flows for one second. The symbol which is usually used to signify quantity of electricity is Q.

QUANTOMETER—A type of ballistic galvanometer in which the swing of the movable system is proportional to the quantity of electricity passing through the instrument. A *galvanometer* (q.v.) of this type is used for magnetic testing as in the case of the *fluxmeter* (q.v.).

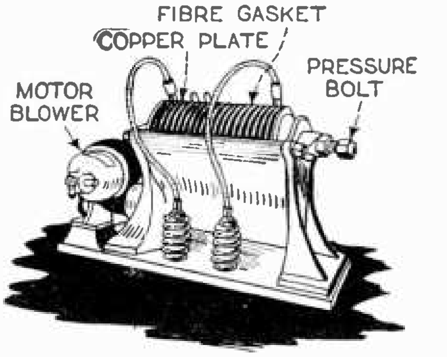
QUARTER PHASE—A two-phase alternating current system. An alternating current system having two currents differing in phase by 90 degrees or in other words by one-quarter of a cycle.

QUARTZ LAMP—A mercury vapor lamp which utilizes a tube of quartz instead of a glass container. Increased current densities can then be employed, since higher temperatures can be used with quartz than with glass.

QUARTZ OSCILLATOR—The piezo-electric quartz plate may be used as a *resonator* (q.v.) or as an *oscillator* (q.v.). When used as an oscillator it may be used either as a *master oscillator* controlling the frequency of a radio transmitting station's output or as a frequency indicator. All three of these uses are applicable to the work of maintaining station frequencies constant. The applicability of the piezo oscillator as a frequency indicator in broadcasting stations has been tested carefully by the United States Bureau of Standards, and found to be useful and satisfactory. This method gives a means of maintaining an extremely accurate check of the transmitting station frequency. (See *Master-Oscillator System,* also *Frequency Meter.*)

QUENCHED GAP—See *Quenched Spark Gap.*

QUENCHED SPARK — See *Quenched Spark Gap.*

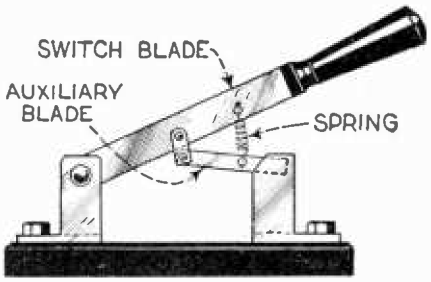


A typical quenched spark plug.

QUENCHED SPARK GAP—A spark discharger in a wireless telegraph transmitting circuit in which the spark is deionized to prevent the gap remaining conductive after the spark has passed. In this way only a few sharply defined oscillations are permitted to occur. The particular advantages of the quenched spark gap is that it enables the aerial to oscillate at its own frequency regardless of the period of the spark system. In one form of construction, a number of heavy copper plates are used, separated by micanite, fiber insulating washers or other insulating material. These are placed in an iron rack and compressed by means of a pressure bolt. The inside edge of the washer rests upon a groove which is cut in each plate. This makes it impossible for the spark to discharge over the edge of the washer. In order to make the discharge surface airtight, the washers are specially treated and as a result this helps in quenching the primary oscillations and makes the discharge noiseless. A small motor driven blower is mounted at the base of the spark discharger for the purpose of forcing air through the base of the rack against the cooling flanges of the plates. (See *Deionization, Musical Spark, Kinraidy Spark Gap,* also *Quenched Spark Transmitter.*

QUENCHED SPARK TRANSMITTER—A radio telegraph transmitter which employs a quenched spark gap. The quenched spark transmitter is not used for very high powers as it is not satisfactory for such use. In this case, a form of disc discharger is usually used. The quenched spark transmitter, however, has no moving parts and is noiseless in operation. In addition it gives large values of antenna current because closer coupling is possible. (See *Quenched Spark Gap.*)

QUICK BREAK SWITCH—A switch provided with auxiliary contacts which are released after the main contacts. The auxiliary contacts are separated rapidly, regardless of the speed with which the switch handle is pulled. This action is obtained by the tension of a spring connected between the main switch blade and the auxiliary blade, as shown in the illustration.



Quick Break Switch. Note the auxiliary spring-controlled blade.

QUIESCENT AERIAL—In a radio telephone transmitter, an aerial operated in such a manner that the carrier wave is suppressed when transmission is not actually taking place.

R

"R"—Symbol for *resistance* (q.v.)

RADIANT ENERGY—Energy transmitted through space by means of vibrations of the ether, such as electromagnetic energy, light or heat. (See *Actinic Ray.*)

RADIANT HEAT—Infra-red *radiation* (q.v.) as for example radiation from substances at temperatures insufficient to cause visible light rays.

RADIATING CIRCUIT—An electrical circuit which emits energy in the form of ether waves. In a transmitting system, the aerial circuit. Any circuit which radiates energy is a radiating circuit.

RADIATION—The transference of energy in waves through space which is not necessarily occupied by matter. Transference of energy through *ether* (q.v.). Electric or electromagnetic radiation refers to the radiation by means of electromagnetic induction. The radiation field is transmitted by wave motion. Various types of electromagnetic waves may be sent out by a radiating system. In one system the waves are known as *damped waves* (q.v.), in another *undamped waves* (q.v.) are used.

RADIATION EFFICIENCY—The radiation efficiency of an antenna at a given wave length is the ratio of the power radiated to the total power delivered to the antenna (resistance).

RADIATION FROM ANTENNA—In the case of a simple vertical antenna, electromagnetic waves are radiated in semi-loops since the lower end of the aerial is grounded. Fig. 1 gives an idea of the way in which the intertwined electric and magnetic fields radiate from the antenna. It should be noted that the electric and the magnetic fields are in planes which are at right angles to each other. The electric lines are shown in elevation while the magnetic lines appear in plan, with the wave form common to both being shown between. At any single point in space, the lines separate and come together like a bellows. After the wave has travelled a certain distance, the lines can be regarded as sections of planes and the electric lines can be represented by the diagram shown in Fig. 2. The magnetic lines can be shown by the same figure, provided this is considered to have been rotated about its horizontal axis through an angle of 90 degrees. Regardless of whether the aerial is of the open or closed coil type, the radiation will take place in the same general way, *loops* (q.v.) being formed and detached as described. (See *Electromagnetic Waves,* also *Height of Aerial.*)

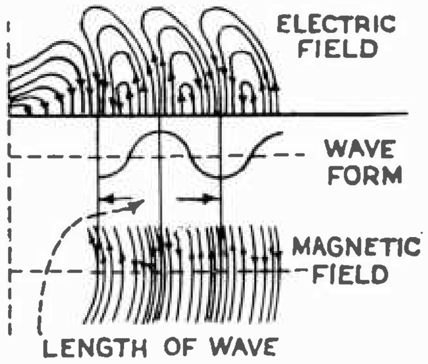


Fig. 1. Electric and magnetic fields about a vertical wire aerial.

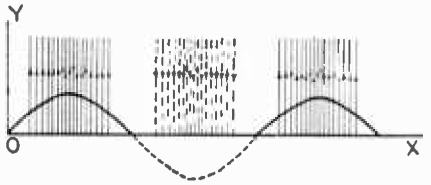

Fig. 2. Electric lines of force shown after the wave has travelled some distance from the aerial.

RADIATION RESISTANCE—The ratio of the total power radiated by an antenna to the square of the effective current at the point of maximum current. The property of an antenna by means of which radiation of energy takes place. Some of the power supplied to a circuit, carrying radio currents, is radiated in the form of electric waves. The radiation is a measure of the useful work obtained from the circuit. The greater the power radiated in comparison with the power dissipated in the circuit itself, the better will be the transmission. At any frequency, the power radiated is proportional to the square of the current flowing, hence the radiative effect may be regarded as causing artificially, an increase in the effective resistance of the circuit. This resistance increase is known as "radiation resistance" and is directly proportional to the square of the frequency or inversely proportional to the square of the wave length. (See *Antenna Resistance.*)

RADIATION TRANSMISSION—See *Radiation from Antenna.*

RADIO—The transmission of intelligence by means of electromagnetic waves through the ether. Radio falls under two general classifications; *radio telephony* (q.v.) and *radio telegraphy* (q.v.). (See *Radio Channel, Radio Communication, Radio Control,* also *Radio Frequencies.*)

RADIO-ACTIVITY—The emanation of energy by certain substances, such as radium, caused by a continuous detachment of electrons from the substance.

RADIOCAST—A term sometimes used instead of *Broadcast* (q.v.). To transmit speech, music or other sounds by *radio telephony* (q.v.).

RADIO CHANNEL—A band of wave lengths or frequencies of a width sufficient to permit of its use for radio communication without the radiation of subsidiary waves of more than a certain intensity at wave lengths or frequencies outside of such a band.

RADIO COMMUNICATION—The transmission of intelligible signals by means of electromagnetic waves. The signals may be in the form of code as in radio telegraphy or in the form of speech or music as in radio telephony. They may be transmitted through the *ether* (q.v.) without the use of intervening conductors as in ordinary radio, or along conductors as in *wired wireless* (q.v.).

RADIO COMPASS—A simple form of radio *direction finder* especially used for marine work. The radio compass depends for its principle of operation upon the directional effect of a coil antenna. Hence a coil antenna mounted on a vertical axis so that it can be rotated freely, is an essential part of the radio direction finder. By rotating the coil while a particular station is transmitting, it is possible to fix the line of direction of the station. The coil may be mounted so that the maximum signal will be received when the transmitting station lies in the plane of the coil. The device may also be set for minimum signal reception in which case the transmitting station lies in a direction perpendicular to the face of the coil. It is possible to obtain a much sharper determination of direction by setting the coil on the minimum position and hence this method is generally used for direction finder work. (See *Goniometer.*)

RADIO CONTROL—The control of motor driven devices such as marine vessels, trains, torpedoes, automobiles, etc., by means of special radio receiving apparatus designed to respond to radio impulses. E. P. Glavin's radio controlled automobile is an example of the radio controlled vehicle. *John Hays Hammond, Jr.* (q.v.) has invented radio controlled torpedoes, radio controlled ships and also radio controlled air craft.

R.F.—Abbreviation for radio frequency.

RADIO FREQUENCIES—Frequencies higher than those corresponding to normally audible sound waves. (See *Frequency, Radio; Frequency, High; Audio Frequency;* also *Frequency, Low.*)

RADIO FREQUENCY COILS—*Inductance coils* (q.v.) used to carry radio frequency currents or to couple radio frequency circuits. Radio frequency *transformers* (q.v.) may be of either iron core or air core types although the air core transformers are more generally used. (See *Low Loss Coils,* also *"D" Coils.*)

RADIO FREQUENCY CURRENT—An alternating current having a frequency of from 20,000 to 2,000,000 cycles per second. There is no hard and fast rule regarding the upper and lower limits, since much higher or much lower frequencies may still be considered as radio frequency currents. (*See High Frequency Current.*)

RADIO FREQUENCY SELECTIVITY—The radio frequency selectivity of a simple element of a receiving system is the ratio of resonant response (in terms of effective voltage or current measured at the indicator) to the nonresonant response when the radio frequency portions of the elements of that system are detuned by one percent of the resonant frequency. In this case, a simple element refers to a combination of an inductance, a capacitance and optionally a resistance.

RADIO FREQUENCY SIGNALS—Currents flowing in a radio receiving circuit up to the point of rectification. The currents flowing in the antenna circuit are radio frequency currents corresponding to the currents flowing in the transmitting aerial. (See *Amplifier, Radio Frequency.*)

RADIO GONIOMETER—See *Goniometer.*

RADIOGRAM—A message sent in code by radio. A radio telegraphic message.

RADIOPHARE—A radiotelegraphic "lighthouse" intended to aid navigation by emitting characteristic signals. By estimating the bearings of two charted radiophares, the mariner may determine the position of his ship.

RADIO TELEGRAPHY—The transmission of messages by means of electromagnetic waves using dot and dash code signals. A transmitter furnishes a source of high frequency alternating current which oscillates rapidly in the antenna system thus sending out electromagnetic waves. These are intercepted at the receiving station by the receiving aerial. At the receiving aerial, the electromagnetic waves are changed back into alternating current which is rectified by a detector in the receiving apparatus, then amplified and made audible in a *head telephone* (q.v.) or *loud speaker* (q.v.). Of course, a means of interrupting the current to produce dots and dashes must be present in the transmitter and suitable tuning devices are used in both the transmitter and the receiver.

RADIO TELEPHONY—The transmission of speech, music or other sounds by means of electromagnetic waves. In the standard systems of radio telephony continuous waves are used of a much higher frequency than those of audible sounds. The amplitude of these is modulated by the connection of a microphone in the transmitting circuit. The receiving apparatus is similar to that employed in radio telegraphy and is arranged so that the head set or loud speaker responds to the modulations of the waves and reproduces the sounds as originally produced at the transmitter.

RADIO TRANSMISSION—The sending of signals, speech, music, or other sounds by means of electromagnetic waves. The transmission of intelligence through the ether. (See *Radio Communication, Radio Control, Radio Telegraphy,* also *Radio Telephony.*)

RAT-TAIL—A single wire, or a group of wires used to connect the main part of an aerial with the *lead-in* (q.v.) wire.

RATIO—Relative values of quantities of the same kind, or number of times one quantity is contained in the other.

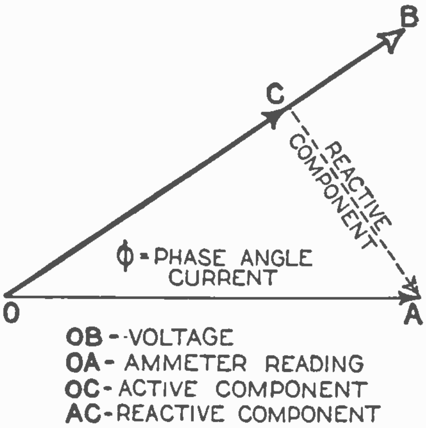
RATIO OF TRANSFORMATION—The ratio between the primary and secondary windings of a transformer. This determines the ratio of the primary to the secondary voltages. Thus if a transformer has a ratio of transformation of 3 to 1, then the secondary will have three times as many turns as the primary and the secondary voltage will be, approximately triple that of the primary voltage.

RATIO OF UNITS—The ratio of the unit pole in the electromagnetic system to the unit pole in the electrostatic system, or of the unit charge in the electromagnetic system to the unit charge in the electrostatic system. Its numerical value is approximately 3 x 10^{10}.

RAYLEIGH, John William Strutt—British physicist. Born at Langford Green, Essex, November 12th, 1842. He was educated at Trinity College, Cambridge. In 1879 he was appointed Cavendish professor of experimental physics in succession to Clerk-Maxwell, a post he held until 1884. In 1887 he became professor of natural philosophy at the Royal Institution and was appointed president of the Royal Society in 1905. In 1908 he was appointed Chancellor of Cambridge University, and died June 30th, 1919. Rayleigh was considered by many to have been one of the most brilliant experimental physicists of the nineteenth century. He not only had a remarkable power of mathematical analysis, but was equally skillful in carrying out the experimental proofs of his theoretical researches. Many of his experiments were made with home-built apparatus. He threw a fresh light on nearly every branch of physics, from the theory of gases to wave theories and electric and magnetic problems. Due to the care with which he carried out his experiments, he was the first to detect the presence of neon in the atmosphere, this being the forerunner of the discovery of a number of inert gases in the atmosphere. The Rayleigh balance for absolute current measurement is as well known as it is important. Lord Rayleigh was one of the original members of the Order of Merit. In 1882 he was awarded the Royal Medal, in 1899 the Copley Medal of the Royal Society and in 1904 the Nobel Prize for physics.

REACTANCE—That property of an electric circuit, aside from its ohmic resistance, which tends to oppose the flow of an alternating current. Mathematically, reactance is defined as the square root of the difference between the square of the *impedance* (q.v.) and the square of the effective resistance of a given portion of an electric circuit. Expressed as an equation reactance $x = \sqrt{z^2 - r^2}$ where z is the impedance and r the resistance of the part of the circuit under consideration. Reactance due to capacity in a circuit is capacity or condensive reactance. The reactance of a condenser of capacity C to an alternating current (of sine wave form) of frequency f is expressed by the equation $X_c = \frac{1}{2\pi fC}$. Reactance due to inductance in a circuit is *inductive reactance* (q.v.). The reactance of an inductance coil of inductance L to an alternating current (of sine wave form) of frequency f is expressed by the equation $X_L = 2\pi fL$. Reactance is measured in *ohms.*

REACTANCE COIL—REACTION COIL—Terms used in England to describe the *tickler coil* (q.v.) used in regenerative sets to couple back part of the energy in the plate or output circuit to the input circuit.



The current represented by vector OA may be considered as divided into two components, OC in phase with the voltage, and CA the reactive component.

REACTIVE COMPONENT—The component of an alternating current used to overcome the reactance of the circuit. This component acts at an angle of 90 degrees from the voltage. It is also known as *wattless current* (q.v.).

REACTIVE CURRENT—See *Reactive Component.*

REACTIVE DROP—The portion of the voltage drop in an alternating current circuit, due to the reactance.

REAL POWER—See *True Power.*

RECEIVER—A term rather loosely applied to cover the entire radio receiving apparatus within a station. Also sometimes used as a synonym for *Detector* (q.v.)

RECEIVING AERIAL—A wire or group of wires suspended at a suitable height and connected to a radio receiving set. The purpose of the receiving aerial is to intercept the electromagnetic waves. It should be placed well above surrounding buildings if possible, and should be well insulated from the ground. (See *Aerial,* also *Directional.*)

RECEIVING CIRCUIT—Any electrical circuit used in connection with the reception of radio. The more important vacuum tube receiving circuits are the *super-heterodyne* (q.v.), the *neutrodyne* (q.v.), the *reflex circuit* (q.v.), the *regenerative circuit* (q.v.) and the *tuned frequency circuit* (q.v.). There are various modifications and combinations of these circuits.

RECEPTACLE—A form of socket into which a plug is inserted for making electrical connections.

RECONSTRUCTED MICA—See *Micanite.*

RECORDER—A telegraphic instrument which automatically records messages sent over a telegraph system.

RECORDING WATTHOUR METER—An instrument for measuring and recording the total amount of electrical energy being consumed in a circuit. (See *Integrating Wattmeter.*)

RECTIFICATION—The changing of alternating current to direct current. In the usual radio receiving circuit rectification is accomplished by means of the vacuum tube, although the ordinary crystal detector rectifies the alternating current also. Before a storage battery can be charged from an alternating current source, the current must first be changed to direct current. Hence the battery charger designed to work on alternating current must be equipped with a rectification device, or rectifier (q.v.).

RECTIFIED CURRENT—An *alternating current* (q.v.) which has been changed to uni-directional or direct current either by preventing alternate waves from flowing or by reversing their direction. (See *Rectified Signals, Rectification,* also *Rectifier.*)

RECTIFIED SIGNALS—Radio signals which have passed through a detector, such as a vacuum tube or a crystal. Rectification of the oscillations results in audible or audio frequency currents which can be heard in a telephone receiver. (See *Rectification, Rectifier, Rectifying Tube,* also *Rectifying Action of Crystal Detector.*)

RECTIFIER—An apparatus for converting alternating current to unidirectional or direct current. Examples of rectifiers are certain crystals used as crystal detectors, the commutators of direct current motors and generators, vacuum tubes, electrolytic devices used for charging batteries, etc. (See *Rectified Signal, Rectification, Rectifying Tube, Rectifying Action of Crystal Detector, Rectified Current, Rectifier, Full Wave, Full Wave Rectification,* also *Half Wave Rectifier, Electrolytic Rectifier, Mercury Arc Rectifier, Charger, Storage Battery; Chemical Rectifier; Tungar; Rectigon.*)

RECTIFIER, FULL WAVE—A device for converting alternating current to direct current, in which both the positive and negative alternations are utilized. This differs from the half-wave rectifier which rectifies by suppressing alternate waves. (See *Full*

Wave Rectification, also *Half Wave Rectifier*.)

RECTIFYING ACTION OF CRYSTAL DETECTOR—The crystal detector has the property of allowing radio frequency alternating currents to flow through it in one direction only. In other words the alternating current is rectified. (See *Crystal Detector-Theory of Operation, Crystal Detector, Crystal Rectifier, Rectified Signals, also Rectified Current.*)

RECTIFYING TUBE—A vacuum tube used to convert alternating current into direct current. Rectification can be accomplished by a two-electrode tube, having filament and plate. In this case the electron flow is from the hot filament to the plate. A two-electrode vacuum tube made especially for rectifying purposes is known as the *kenotron* (q.v.). Another recent type of rectifying tube, known as the *helium tube* (trade name, *Raytheon*) utilizes a different operating principle, known as the "short path" principle, whereby the rarefied gas acts as an insulator between points which are in close proximity. This is in apparent contradiction of the observed phenomenon that the smaller the distance between two points the more readily a spark will jump between them due to the ionization of the gas. However, if the distance is small enough and a suitable gas is used at a low enough pressure, an electron may encounter no gas molecules in its path between the points and there will be no ionization by collision. Consequently, the inert gas helium, may be made to act as a perfect insulator at low pressures. Furthermore, it has been found that when a larger electrode of a gas conduction tube is negative, there is a greater current flow than when the smaller electrode is negative and that the smaller the positive relative to the negative electrode, the smaller is the back current and hence the more complete is the rectification. Figure 1 shows a typical helium tube, while Figure 2 illustrates its construction. The two small positive electrodes *A*, *A*, are carried through two small glass tubes imbedded in a lava insulating block *L* so as to project very slightly into a lava cup *C* whose wells constitute the negative electrode, being connected to the negative terminal through the base. The diameters of the small wires and the diameters and positions of the holes whereby they enter the cup are so proportioned as to give the necessary short path to the negative electrode. The cup *C* contains helium gas at such low pressure as to prevent gaseous conduction. This gives an insulation of great reliability and long life and makes possible extremely small anode surfaces which reduce the back current to a negligible quantity.

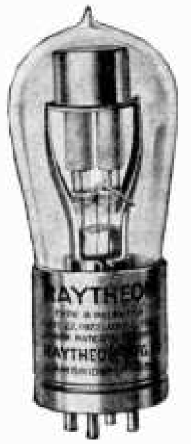


Fig. 1. A Raytheon tube.

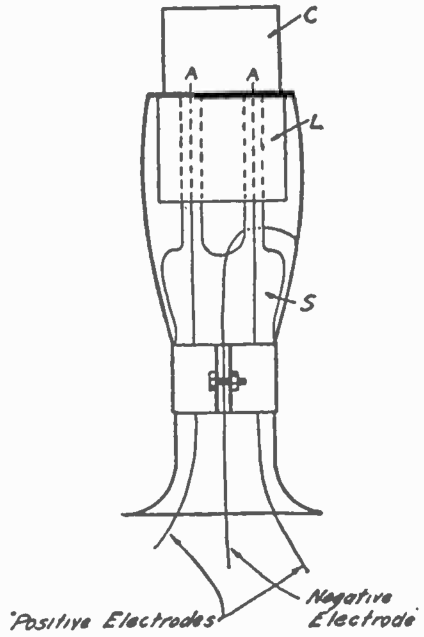

Fig. 2. Construction of the Raytheon tube.

RECTIFYING VALVE—This usually refers to a *rectifying tube* (q.v.) although it may refer to an *electrolytic rectifier* (q.v.)

RECTIGON—The trade name of a storage battery charger which utilizes the vacuum tube rectifier principle. (See *Charger, Storage Battery*, also *Rectifying Tube.*)

RED MAGNETISM—An obsolete term for the lines of force coming from the north pole of a magnet.

REDUCE WAVE-LENGTH OF AERIAL—The wave-length of an antenna may be reduced by the use of series condensers. However, this method should be avoided where possible, since it results in a loss of power. Shortening the aerial is a preferable method of reducing wave-length.

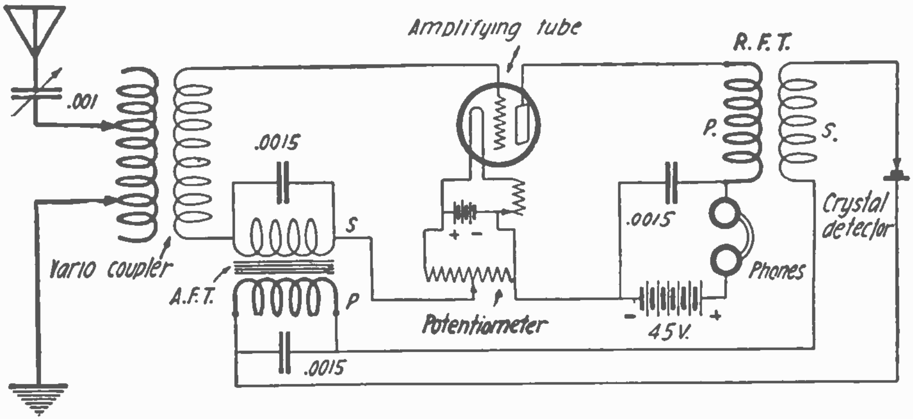
REFLECTING GALVANOMETER—See *Mirror Galvanometer.*

REFLECTION — Radio waves are reflected and also refracted when they pass into a region of different dielectric constant. A perfect conducting sheet would reflect all of the wave energy striking it. A conductor parallel to the direction of motion of a wave serves to guide the direction of the wave. The reflection and other modifications of radio waves serves to explain *fading* (q.v.) and other irregularities of broadcast signals. It has been found that broadcast signals will have most uniform intensity when long waves are used and during the daytime. Moreover, transmission will be better over a uniform conducting surface, such as the ocean. It is assumed that the space through which a radio wave travels is bounded by the surface of the earth and by an upper region which during the day is a fairly good conductor. The transmitted waves are guided by the two conducting mediums but in addition are assisted materially by reflection especially during the time that the air is partially ionized by the radiation of the sun.

REFLECTION COEFFICIENT—(Of a surface of discontinuity between two media.) The ratio of the reflected field intensity near the surface to the incident field intensity near the surface.

REFLEX—See *Reflex Circuit.*

REFLEX CIRCUIT—A radio receiving circuit invented by Marius Latour in which the vacuum tubes are made to perform double duties as both radio and audio frequency amplifiers. The incoming radio frequency current is amplified at radio frequency, rectified by a detector (which may be a crystal detector) and then amplified at audio frequency, using the same tube. A typical four tube reflex set uses the second and third tubes as amplifiers simultaneously for both the radio and the audio frequency amplification. As a result the four tubes are made to produce the effect of six. Reflexing may be accomplished in a number of different ways. In some cases all the tubes are made to work twice. In other cases, only a part of the tubes are used for dual amplification. A variation of the reflex circuit, is the *Inverse Duplex Circuit* (q.v.). In this system the incoming signal reaches the first tube where it is amplified at radio frequencies and passes to the second tube, where it is again amplified at radio frequencies. From the second radio frequency tube, it is passed to the detector tube, where it is converted to audio frequency. The current then flows back to the second radio frequency tube which is now used as an audio frequency amplifier. Thence it flows to the first radio frequency tube which acts as the second



A typical reflex circuit using one tube and a crystal detector.

stage of audio frequency amplification.

REFRACTION—The refraction of electric waves is analogous to the refraction of light. The electric (radio) waves are refracted when they pass into a region of different dielectric constant. That is to say, their direction is slightly altered. (See *Fading, Gliding Theory,* also *Reflection.*)

REFRACTION AND REFLECTION OF ELECTROMAGNETIC WAVES—See *Reflection,* also *Refraction.*

REGENERATION—The amplifying properties of the three-electrode vacuum tube can be used to obtain what is termed *regeneration.* Since it is possible to have greater output energy than input energy, part of the output may be returned to the input side, thus resulting in amplification of energy or in regeneration. By *feeding back* the correct amount of energy and in the right phase relation a constant reamplification may be obtained, and the tube can be made to act as a generator of sustained oscillations. (See *Armstrong Circuits, Feed-Back, Feed-Back Coil, Feed-Back Coupling, Feed-Back Effect,* also *Regenerative Circuit.*)

REGENERATIVE—See *Regenerative Circuit.*

REGENERATIVE CIRCUIT—A method of connecting up vaccum tubes for radio reception in which the amplified variations of the plate circuit are superimposed inductively on the grid or imput circuit thus producing a reinforcing effect which results in increased sensitivity. (See *Armstrong Circuits.*)

REGENERATIVE COUPLING—A radio receiving system designed to increase amplification in a vacuum tube, by coupling the plate or output circuit back to the grid or input circuit thus producing regeneration. (See *Feed-Back, Feed-Back Coil, Feed-Back Coupling, Feed-Back Effect,* also *Regenerative Circuit.*)

REINARTZ CIRCUIT—A selective regenerative circuit devised by John L. Reinartz in which a *spider-web* inductance coil is used, the coil acting as primary, secondary and tickler. Capacity *feed-back* (q.v.) is accomplished by means of a variable condenser. In the improved Reinartz a variocoupler is used, connected as a variometer, in addition to the condenser feed-back.

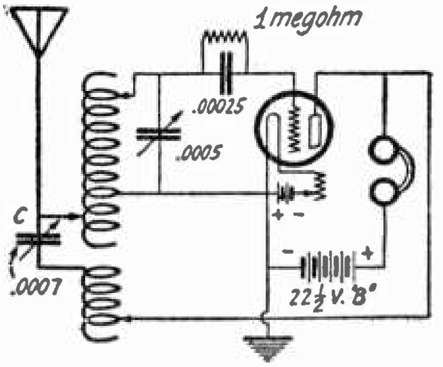


Diagram showing Reinartz circuit

REJECTOR—See *Rejector Circuit.*

REJECTOR CIRCUIT—A circuit consisting of a combination of inductance and capacity for filtering out or preventing the passage of currents of certain frequencies. This circuit is used in connection with a radio receiving set to obtain greater selectivity. The inductance and the capacity are arranged in parallel to form a resonant circuit. The constants of this circuit are chosen so that at the particular frequencies to be filtered, the capacity current will exactly equal the inductive current, thus giving zero resultant current. The primary application of the rejector circuit is as an *interference eliminator* (q.v.) or *wave trap* (q.v.). Figure 1 shows the application of the rejector circuit applied to a radio receiving set. The circuit shown is a combination *acceptor-rejector* circuit. The rejector circuit is shown in heavy lines. The inductance and the capacity are connected in parallel with each other and with the acceptor circuit and this latter is inductively coupled to the receiving set circuit. Both the acceptor and the rejector circuits are tuned to the wave length of the receiving aerial. By using more than one rejector and acceptor circuit increased selectivity can be obtained. A rejector circuit used to filter out undesired spark signals is shown in Figure 2. A small inductance of about ten turns is employed in this circuit and this is inductively coupled to a closed tuned circuit and wired in series with the aerial, and the aerial terminal of the set. If a spider-web coil is used in the closed circuit, a suitable value for broadcast wave lengths is a 50 turn coil, placing the aerial coil in such a position as to get closest coupling. The variable condenser should have a capacity of .0005 mfd. (See *Acceptor.*)

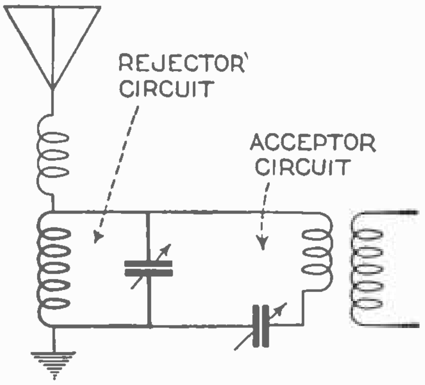

Fig. 1. An acceptor-rejector circuit used as a wave trap.

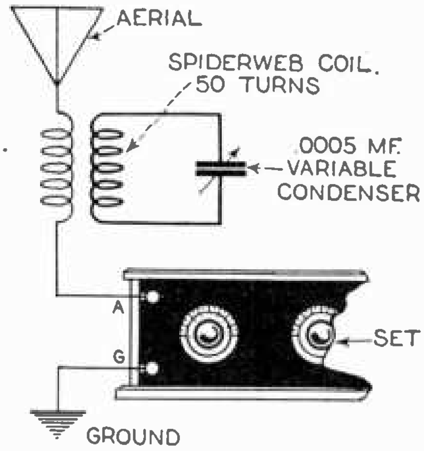

Fig. 2. A rejector circuit designed to filter out undesired spark signals.

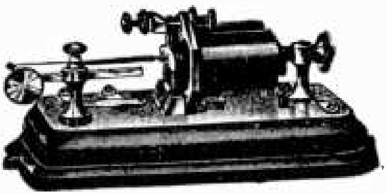
RELAY—An electromagnetic device by means of which contacts in one circuit are operated by a change in conditions in the same circuit or in one or more associated circuits. (See *Magnifier.*)



A telegraphic relay.

RELUCTANCE—Magnetic resistance. The reluctance of a magnetic circuit is analogous to electrical resistance. All magnetic circuits offer reluctance to flux. The name *rel* is widely used as the unit of reluctance. The rel is the reluctance of a magnetic circuit which will have one line of force in it, upon application of one *ampere-turn.* The rel can also be specified as the reluctance of a cylinder of air, or of any other non-magnetic material, one square inch in cross-sectional area, and 3.19 inches long. The flux through a magnetic circuit is equal to the *magnetomotive force* (q.v.) divided by the reluctance. (See *Magnetic Properties.*)

RELUCTIVITY—The *reluctance* (q.v.) per unit length and per unit cross-section. The reluctance per inch^3 or per cm^3. Reluctivity may be defined as specific magnetic resistance. It is the reciprocal of *permeability.* (q.v.).

REMANENCE—The term applied to the magnetism remaining in a magnet after the magnetizing force is removed.

REMOTE CONTROL—A control system whereby a radio transmitting or receiving apparatus may be operated at any desired distance from the apparatus. The chief advantage of remote control lies in the fact that the high tension apparatus and the tall aerial masts may be located in outlying districts whereas the studio can be located at any desired, convenient point. In addition it is possible to broadcast concerts, theatrical entertainments, prize fights, etc., direct from the scenes of action by utilizing remote control.

REPEATING COIL—A transformer of unity ratio used in telephone practice.

RE-RADIATION—The relaying of a radio wave through the action of a receiver employing regeneration. This phenomenon is most commonly observed in receivers of the *super-heterodyne* type.

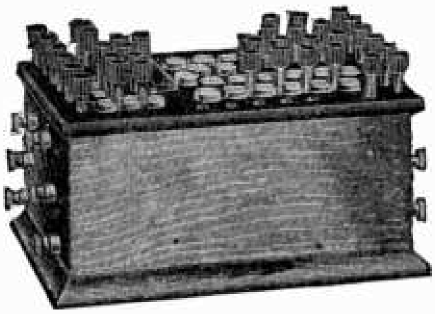
RESIDUAL CHARGE—The residuary electricity retained by a condenser after discharge. This is also known as *electric residue* or *soakage.* After the condenser is discharged in the ordinary way, the residual charge permits a second discharge, smaller than the first. (See *Soaking in.*)

RESIDUAL MAGNETISM—The magnetism retained by a piece of iron, after the magnetizing force is withdrawn. After a mass of iron has become magnetized, some of the magnetism will remain, even though the magnetizing force has been taken away. The amount of residual magnetism depends on the quality of the iron. Pure wrought iron, in general, retains very little residual magnetism, whereas wrought iron which has gone through a hardening process, or which contains a large percentage of impurities and also cast iron possess a much larger amount of residual magnetism.

RESINOUS ELECTRICITY—An obsolete term for negative charges of electricity, adopted because of the fact that resinous bodies become negatively charged by friction. (See *Vitreous.*)

RESISTANCE—Symbol Ω (Omega)—Every conductor of electricity offers opposition to the flow of electricity. Resistance is a property of the conductor itself. It increases with increased length of conductor, decreases with increased cross-sectional area, and is greater or less depending upon the material of the conductor. Resistance is measured in *ohms.* (q.v.). The ohm is equal to 10^9 C.G.S. electromagnetic units.

RESISTANCE BOX—A box containing a number of wire coils of known resistances connected in various combinations, by means of switches or plugs, to produce any desired total resistance.



A resistance box.

RESISTANCE COUPLED AMPLIFIER—A type of *amplifier* (q.v.) which utilizes high resistances for interstage coupling. Resistance coupled amplification is generally used only for audio frequency amplification although it may be used for radio frequencies above 1000 meters. The chief advantage of resistance coupling consists in the purity of tone obtainable and the absence of distortion. In addition radio receivers of this type are comparatively inexpensive to build. It should be noted, however, that with resistance coupled amplification, the amplification per tube is much less than with transformer coupled amplification and furthermore the drain on the "B" batteries is also much greater.

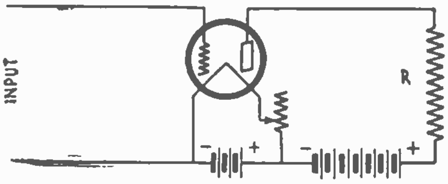


Fig. 1. The introduction of the non-inductive resistance in the plate circuit of the tube is the first step for explaining the principles involved.

Of course, where a "B" eliminator is used "B" battery consumption is not a consideration. The resistances used for resistance coupling are non-inductive and may have resistances of from .1 megohm to 2 megohms.

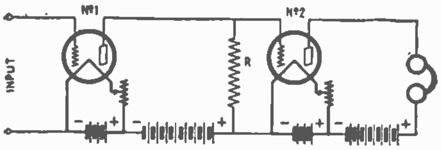

Fig. 2. In this circuit there must be two sets of batteries, but even then the grid of tube No. 2 will have a positive bias, which is undesirable.

Figure 1 shows an elementary circuit utilizing a non-inductive resistance in the plate circuit of the tube. When a signal is impressed upon the grid circuit of this amplifying tube, there is a corresponding voltage set up in the plate circuit. The resistance R in the plate circuit causes a voltage drop to take place in two places in the tube.

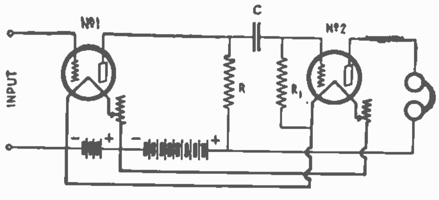

Fig. 3. The resistance coupled amplifier circuit with the introduction of a grid leak and condenser. The reasons for this are explained in the accompanying text.

The total resistance of the plate circuit is equal to the internal resistance of the tube added to the resistance R, and if the "B" battery has 90 volts and if R is equivalent to the tube resistance at that moment the voltage drop across the tube will be 45 volts with the same drop across R. Theoretically it is possible to vary the voltage drop across R from zero to almost 90 degrees. Discounting the small resistances of the "A" and "B" batteries, a changing voltage will occur across the filament and plate when the grid potential varies, and also across the resistance R. Naturally these last variations depend upon the tube resistance and upon the value of the resistance R. These variations will be largest when R has a greater resistance than that of the tube. The resistance or impedance of the tube is constantly in a state of change and can assume very high values. For this reason the value of R should be equal to the higher values of the tube impedance in order to maintain maximum effectiveness. As used with ordinary amplifier tubes, a value of 100,000 ohms has been found to give satisfactory results. The next step is to apply the voltage variations across R to the grid circuit of the next tube. In Figure 2, the resistance R lies in the grid circuit of tube 2 as well as in the plate circuit of tube 1. Hence the magnified changes in tube 1 are transferred from R to the grid and filament of tube 2, thus the latter tube will be affected directly by the output circuit of the first tube and thus there will be amplification in both tubes thereby causing a resultant magnified signal to be heard.

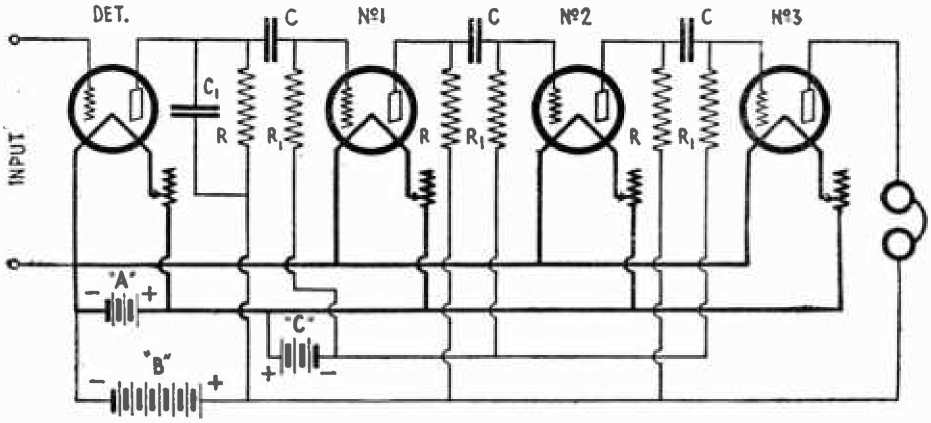

Fig. 4. Diagram showing three stages of resistance coupled amplification.

However, in such a hook-up, the same "A" and "B" battery cannot be used since this would mean that there would be a positive charge on the grid of tube No. 2, which would then be unable to function. Naturally, it would be impracticable to use a circuit having so many batteries, so a means must be found whereby it is possible to have a power supply consisting of but one filament battery and one plate battery for any given number of tubes in an amplifier. In order to do this the grids of the tubes must be separated electrically from the high voltage of the plates of the preceding tubes, but only as far as the steady voltage is concerned, while the fluctuating voltage of these plates must be impressed on the grids of the following tubes. This is done by introducing condensers between the two resistances. These effectively block the direct currents while they afford easy passage to alternating currents. Figure 3 shows the introduction of the condenser between the plate resistance and the grid resistance. Inspection of this diagram shows that although tube No. 1 remains the same, the plate instead of being connected directly to the grid of tube No. 2 is separated from the latter by means of the condenser C. If voltage fluctuations now occur across the resistance R, they will also be effective across the grid and filament of tube No. 2, because R exerts its influence between plate and filament of tube No. 1. As the condenser, C, conducts the variations very easily, the voltage fluctuations against R are then effective across the filament and grid of tube No. 2. It is necessary that tube No. 2 be provided with a grid leak, R_1 for the accumulated negative charges to leak off the grid to the filament. This grid leak at the same time serves the purpose of a by-pass for voltages, occurring due to possible leaks in the condenser C, which would tend to make the grid positive, thus allowing a grid current to flow and stopping the perfect action of the tube as an amplifier. Since the grid leak R_1 is a direct shunt across the grid and filament of tube No. 2, it must have a relatively high value in order to retain the highest possible amplification. R_1 should have a value lying between 500,000 and 2,000,000 ohms. If this resistance is made variable, it will be possible to control the resulting amplification completely. The value of the condenser C, must be chosen so that its resistance to the flow of alternating current will be as low as possible. Figure 4 shows three stages of resistance coupled amplification with a "C" battery used to give proper grid bias. The value of the resistance R, in the plate circuit of the tubes is 100,000 ohms and the value of the resistance in the grid circuits is 1,000,000 ohms (1 megohm). The condenser C has in each case a capacity of 0.05 mfd. The value of the "C" battery is about 4½ volts, but this should be determined by experiment for best results.

RESISTANCE COUPLING—RESISTIVE COUPLING—The transference of electrical energy from one circuit to another, by means of resistance common to both. (See *Resistance Coupled Amplifier.*)

RESISTANCE, HIGH FREQUENCY—The increased resistance of a conductor to high frequency currents, due to concentration of current at the surface of the conductor. This phenomenon is known as *skin effect* (q.v.) Skin effect becomes more pronounced, the greater the frequency of the impressed electromotive force. Skin effect also increases with increased cross-section of the conductor, with increased conductivity of the conductor and with increased magnetic *permeability* (q.v.). As a result of skin effect, the actual resistance of a conductor to alternating currents is greater than to direct currents.

RESISTANCE OF GROUND CONNECTION—The connecting wire leading from the radio apparatus to the ground should be of low resistance. If possible, the ground should be made by burying a copper plate in moist earth. The usual way to obtain a ground is to fasten a copper strap or *ground clamp* (q.v.) around a water or a steam pipe.

RESISTANCE (RADIATION)—This is the ratio of the total energy radiated (per second) by the antenna to the square of the root-mean-square current at a potential node (generally the ground connection).

RESISTANCE, RADIO FREQUENCY—The ratio of the heat produced per second, in watts, to the square of the root-mean-square current (radio frequency), in amperes, in a conductor.

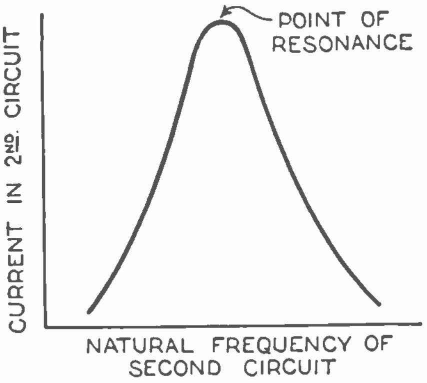
RESISTIVITY—See *Resistivity of a Material*, also *Resistivity, Surface.*

RESISTIVITY OF A MATERIAL—SPECIFIC RESISTANCE—Symbol ρ (rho)—The resistance in ohms of unit length and unit cross-section of the material under consideration. Resistivity may be measured in ohms per inch cube or per centimeter cube, but more commonly it is measured in ohms per *mil-foot* (q.v.). The material of a conductor has an important bearing upon its resistance. Thus a unit length and unit cross-section of aluminum has about one and one-half times the resistance of copper having the same dimensions. Platinum has about six times the resistance.

RESISTIVITY, SURFACE—Referring to an insulating substance, surface resistivity is the resistance between two opposite edges of a surface film, 1 centimeter square. Surface resistivity depends to a considerable extent on humidity.

RESONANCE—A condition which exists in an electrical circuit where the frequency of the applied electromotive force is the same as the natural frequency of the circuit. Resonance is the cumulative effect produced by a periodic force in a circuit, so adjusted in frequency that the effect can attain the highest value. The effect measured is usually the current and the circuit when adjusted for maximum current, is said to be in resonance with the force, or with the circuit from which the force comes. The effect of resonance is to bring the current into phase with the electromotive force. Resonance in a circuit has the effect of bringing the reactance due to the inductance (inductive reactance) in exact opposition to the reactance due to capacity (capacity reactance). The total reactance is therefore zero and therefore the impedance is equal to the resistance. When two or more circuits have the same natural frequency they are said to be in resonance. Resonance of a circuit to a given exciting alternating electromotive force is that condition due to variation of the inductance or capacity in which the resultant effective current (or voltage) in that circuit is maximum. Instead of varying the inductance and the capacity, the frequency of the exciting field may be varied. The condition of resonance is determined by the frequency at which the current or voltage is maximum.

RESONANCE CURVE—A curve showing the relationship between the current induced in an oscillatory circuit and the frequency of the inducing current. In the case of two oscillating circuits placed near each other so that oscillations in one circuit will induce oscillations in the other, the induced oscillations will be weak or strong depending whether or not the second circuit is in tune with the first one. The capacity and the inductance of the second circuit can be varied until it is exactly in tune with the first at which time maximum current will flow in it. The resonance curve is obtained by measuring the current in the second circuit for various noted oscillation constants, and plotting the curve with the ordinates representing the current and the abscissae the corresponding natural frequency of the second circuit. The diagram shows a typical resonance curve. The peak of the curve is the point where the two circuits are in tune, or in other words, the point of resonance.



A typical resonance curve.

RESONANCE INTENSIFIER—An automatic receiver used for the reception of high-speed radio telegraph signals.

RESONANCE TRANSFORMER—Any loose-coupled tuning inductance having a primary and secondary each with a variable condenser in the circuit. Tuning the secondary circuit brings it in resonance with the primary, thus enabling signals to be heard with greatest volume.

RESONANT—See *Resonance.*

RESONATOR—A device for detecting by resonance, oscillations produced by an oscillator. This term is also used to refer to the sound box employed with the telegraph sounder.

RESONATOR, ACOUSTIC—A vessel containing a volume of air which can easily be set into vibration by sound waves or by the oscillation of a solid object. Typical forms are cylindrical or spherical and the ear is applied to a small tube opening into the air chamber.

RETARDATION COIL—A reactance coil used in a circuit for the purpose of selectively reacting on currents which vary at different rates.

RHEOSTAT—A variable resistance used to control current flow. Rheostats may be made of resistance wire or of carbon or for special purposes liquids may be used. In radio work, rheostats are connected in series with the filaments of vacuum tubes and the "A" battery in order to control the amount of current flowing in the filaments.

A rheostat constructed of resistance wire.

R. M. S.—Abbreviation for *Root Mean Square* (q.v.)

ROBERTS, Joseph Harrison Thomson—Born in 1890, he was educated at Liverpool and Cambridge Universities. He carried out many physical researches at the Cavendish Laboratory, Cambridge, and did a great deal of work on thermionics and other radio problems. He is a doctor of science and a Fellow of the Institute of Physics. He has several radio patents to his credit and is an expert in electrical, optical and acoustical sciences.

ROBINSON, James—British radio inventor. Born in 1884, he was educated at Durham and Gottingen Universities. He was appointed lecturer in physics at Durham University, 1906-07, lecturer in physics Sheffield University, 1910-12, and lecturer in physics at the East London College, London University, 1912-15. Robinson is known chiefly for his direction finding apparatus. He is a member of the Radio Society of Great Britain.

ROBINSON, Samuel S.—Rear-Admiral, U.S.N. He was born May 10th, 1867, and was educated at the United States Naval Academy, from which he graduated. He wrote the Manual of Wireless Telegraphy for Naval Electricians, and was in charge of the Bureau of Equipment, Navy Department.

ROOT MEAN SQUARE—The square root of the mean value of the square of an alternating current or voltage. An alternating current whose root-mean-square value is one ampere has the same heating effect as a direct current of one ampere. Root mean square is also referred to as *effective* or *virtual value.* The root mean square is derived as follows. In electrical measurements, it is necessary to compare direct and alternating currents. Moreover, the same units of measurement, the *ampere* (q.v.) and the *volt* (q.v.) are used in referring to both direct and alternating currents. However, in a direct current, a certain voltage will produce a steady current, whereas in an alternating current, both the voltage and the current are constantly varying both in magnitude and direction. The common basis of measurement is found in the value of the alternating current which will produce the same amount of heat as a certain direct current. Heating effect, according to *Joules Law* (q.v.) is directly proportional to the square of the current. Hence, in an alternating current varying according to a sine law, it is necessary to square each ordinate, find the mean or average value of these squares, and then extract the square root of this mean. Stated in concise terms, it is necessary to find the root mean square. An alternating current having a *maximum* value of one ampere would have a root mean square value of .707 amp. (See *Form Factor.*)

ROOT-MEAN-SQUARE VALUE—See *Root-Mean-Square.*

ROTARY CONDENSER—A synchronous motor used on a power line to advance the *phase* (q.v.) of the current. As a result there is an improvement in the *power factor* (q.v.). The action of the synchronous motor is similar to that of a condenser, whence the name rotary condenser.

ROTARY CONVERTER—A device for converting alternating current into direct current or vice versa. The rotary converter is also known as a *synchronous converter.* It is built like a direct current generator, except that it has certain commutator segments or conductors in the armature, connected to slip rings. Two, three, four, or six rings may be used. When the armature is rotated there is an alternating voltage between the rings. If the converter is driven by a motor or by an engine, it may be used as a *double current generator,* direct current being obtained from the brushes and alternating current from the slip rings (collector rings). When the collector rings are supplied with alternating current, the converter runs as a synchronous motor and direct current can be obtained from the brushes on the commutator. It should be understood that there is only one set of windings on the rotary converter which act simultaneously as alternating current motor and direct current generator. A converter which is used to convert direct current to alternating current is called an *inverted converter.* In the *single-phase* converter, there are two slip rings connected to the windings by as many equally spaced taps as there are poles. In the three-phase converter, three rings are used, with three equally spaced taps for each pair of poles. The single phase rotary converter must be brought up to synchronous speed by external power as it will not start itself. The polyphase converter will start itself from the alternating current side, but since it draws a very great lagging current, it should be started whenever possible from the direct current side. (See *Converter.*)

ROTARY CURRENT—A term infrequently used to denote *polyphase* (q.v.) current.

ROTARY DISCHARGER—A rotating disc discharger used in wireless transmitters in which the sparks occur between metal studs mounted on a motor driven disc. (See *Disc Discharger.*)

ROTARY FIELD—A magnetic field rotating in space. It may be due to rotating windings or stationary windings properly spaced through which polyphase currents are flowing.

ROTARY GAP—A form of rotating spark gap utilizing two or more rotating discs carrying studs between which the sparks pass. Spark gaps of this type were formerly used in wireless telegraph transmitters. (See *Discharger,* also *Disc Discharger.*)

ROTARY HYSTERESIS—Hysteresis (q.v.) produced by a rotating field as distinguished from that produced by a changing field.

ROTARY SPARK GAP—See *Rotary Discharger.*

ROTARY TICKER—A *ticker* (q.v.) in which the interruptions are produced by the chattering of a springy brush on a rapidly rotating metal wheel.

ROTOR—The rotating part of any electrical apparatus. It may refer to the revolving portion of a *motor* (q.v.) or *generator* (q.v.) or to the rotable part of a variable *condenser* (q.v.). The rotor in a direct current motor or generator is the armature. In an alternator or an alternating current motor, the rotor may be either the armature or the field.

ROTOR, GROUNDED CONNECTION—This refers to the grounding of the rotors of variable condensers in a radio receiving set. This is often done to eliminate hand capacity. Sometimes the rotors are connected to the shielding, which is grounded.

ROUGH CALIBRATION—Meters such as voltmeters, ammeters, etc., are often calibrated by comparison with standard instruments. In case such instruments are not available, it may be necessary to use less accurate methods. As an example of rough calibration, an experimental wave meter could be calibrated roughly by tuning in on various broadcasting stations whose wave lengths are known. (See *Calibration.*)

RUHMKORFF COIL—See *Induction Coil.*

RUTHERFORD, Sir Ernest—British physicist. Born at Nelson, New Zealand, he was educated at Canterbury College, Christchurch, New Zealand University, and Trinity College, Cambridge. From 1898 to 1907 he held the position of MacDonald professor of physics at Manchester University. In the latter year he was appointed Cavendish professor of physics and director of the Cavendish laboratory at Cambridge. Rutherford is an extremely brilliant physicist and has carried out a series of researches on the ultimate composition of matter. Many of these experiments have confirmed the researches of J. J. Thomson and others. Some of Sir Rutherford's experiments have revolutionized the theories of matter. He has received many honors for his brilliant researches including the Nobel prize for chemistry awarded to him in 1908. He has written extensively on radio activity, his books including "Radioactivity," 1904; "Radioactive Transformations," 1906; "Radioactive Substances and their Radiations," 1913; as well as many papers for technical journals. Sir Ernest was knighted in 1914.

S

SAFETY GAP—A spark gap which is connected in parallel with a condenser or other apparatus, and which protects the apparatus from excessive voltage. When the voltage exceeds a predetermined limit, the gap breaks down, thus passing the current around the apparatus. (See *Gap, Micrometer.*)

SAL AMMONIAC—A term commonly used for ammonium chloride. This substance is a white crystal, very soluble in water, and is used as an electrolyte in primary cells and also in many electroplating processes. (See *Cell.*)

SATURATED—The magnetic condition of a substance when increase of magnetizing force produces no further increase in flux density. A point is reached in every magnetic material, where further increase of magnetic intensity will not produce any increase of flux density. At this point, the material is said to be saturated. Cast iron becomes saturated at a lower flux density than steel or wrought iron.

SATURATION—See *Saturated.*

SATURATION, MAGNETIC—See *Saturated.*

SECONDARY CELL—A unit consisting of a positive and a negative electrode immersed in an *electrolyte* (q.v.) which becomes active only after the passage of an electric current. The electrodes are of metal or of a metallic compound. An electric current, flowing into a secondary cell causes certain chemical actions to take place whereby electrical energy is transformed into chemical energy. This process is termed "charging." After the cell is charged, the reverse action takes place and chemical energy is transformed into electrical energy. In this case, the cell is able to deliver an electric current to an outside circuit. This process is termed "discharging." The secondary cell is also known as an *accumulator* or *storage cell.* However, the cell does not store electricity. It merely holds or stores the chemical energy for immediate transformation into electrical energy. It is usual practice for several positive plates to be connected in multiple to form one positive electrode and for several negative plates to be connected in parallel to form a single negative electrode. The *storage battery* consists of two or more storage cells. The operation of the storage cell depends upon the fact that certain metals immersed in an electrolyte may differ in potential. In the secondary cell, no electrical action takes place until after charging. Thereafter, chemical action maintains a difference of potential until the stored energy has been retransformed. While the negative electrode is used up to a certain extent during the process of discharging, it is replaced electrochemically during the charging process, due to the flow of current through the electrolyte in the opposite direction to that of discharge. The two principal types of storage cells are the lead cell and the nickle-iron-alkaline (or Edison Cell). In lead cells, the negative electrode is made of spongy lead and the positive electrode is of lead peroxide. The electrolyte is dilute sulphuric acid. The following chemical action takes place within the lead cell. When the cell is charged, hydrogen is released at the negative plate, and oxygen at the positive plate. The oxygen combines with the lead of the positive plate to form lead peroxide while the hydrogen reduces the oxide in the negative plate. When the cell is discharged, both electrodes are changed to lead sulphate and the liberated hydrogen combines with the oxygen to form water. Care must be taken not to allow the cell to discharge too far as in this case, too great an amount of lead sulphate may form and this may cause buckling of the plates or may make it very difficult to recharge the cell. The indications of a completely charged cell are increased gassing of electrolyte together with a stop in the rising of the voltage and the specific gravity. In the Edison-type secondary cell, the active materials are of nickel and iron. Nickel hydrate forms the active material of the positive plate, while iron oxide forms the active material of the negative plate. The electrolyte is a 21 per cent. solution of potassium hydrate combined with a small amount of lithium hydrate. The chief advantage of the *Edison cell* (q.v.) is that it can be left idle indefinitely in a fully charged, semi-charged, or fully discharged state without any harm to the cell. In addition it is lighter and smaller than the same capacity lead cell. The unit used for measuring the capacity of storage cells is the *ampere-hour* (q.v.). This is based on the rate of discharge normally used in measurement, the eight-hour rate. As an example, an 80 ampere-hour storage battery will furnish a continuous current of 10 amperes for 8 hours. If the battery is discharged at a more rapid rate, it will not have the rated capacity.

SECONDARY CURRENT—The current flowing in the secondary windings of inductive apparatus. Current induced in a secondary winding due to the action of *primary current.* (See *Current, Primary.*)

SECONDARY ELECTRON EMISSION—See *Secondary Electrons,* also *Secondary Emission.*

SECONDARY ELECTRONS—Electrons emitted by the plate of a vacuum tube when struck by the electron stream from the filament. (See *Negative Resistance,* also *Secondary Emission.*)

SECONDARY EMISSION—Electron emission in which the exciting agency is bombardment of the emitting material by electrons. The emission of electrons from cold electrodes under the impact of other electrons. (See *Negative Resistance.*)

SELECTIVE—See *Selectivity.*

SELECTIVITY—The sharpness with which a radio receiving set can be tuned to a particular wavelength. A selective set is one which tunes sharply, whereas a non-selective set tunes broadly. Too long an aerial will often result in making a set tune broadly. A short aerial makes the receiving set more selective but reduces the volume.

SELECTOR—A tuning device connected in a radio receiving circuit for the purpose of eliminating undesired stations. (See *Wave Trap.*)

SELENIUM CELL—A cell constructed of a thin layer of the metal selenium. This metal is extremely sensitive to light. In its crystalline form, it is a conductor of electricity, its conductivity varying with the amount of light allowed to fall on it. As a result it is possible to regulate the flow of current in a circuit by varying the light. The selenium cell thus offers a means of transmitting pictures by wire or radio. Selenium cells are also being used in experimental devices for the transmission of motion pictures and for obtaining *television* (q.v.).

SELF-CAPACITY—The capacity of a circuit or a portion of a circuit. Every electrical circuit possesses inherent capacity, which varies in degree, depending upon the shape, size, etc., of the circuit. Self-capacity is also referred to as *distributed capacity* (q.v.). In general self-capacity is detrimental, especially in radio circuits, since it introduces losses. By using special forms of windings, the self-capacity of coils can be greatly reduced. (See *Low Loss Coils.*)

SELF-EXCITED GENERATOR—A generator which depends upon its own current for its field excitation. Such a generator must build up its magnetic field and hence its voltage, gradually. In order to get a start, it depends upon the *residual magnetism* (q.v.) present in the iron of the poles. There are three types of self-excited generators, the *shunt generator* (q.v.), the *series generator* (q.v.) and the *compound generator.* (See *Compound Wound.*)

SELF-HETERODYNE—A system of reception of continuous wave signals by the production of audio frequency beats, through the use of a device which is both a radio frequency generator and a detector of the audio frequency beat currents produced.

SELF-INDUCTANCES—See *Inductance, Self.*

SELF-INDUCTION—Inductance due to the field produced by the circuit itself. Changes in current are always accompanied by self-induction. When the current is decreasing, the electromotive force of self-induction is in the same direction, thus tending to prevent the decrease. When the current is increasing, the electromotive force of self-induction tends to prevent the increase. (*See Inductance, Self; Mutual Inductance,* also *Induction.*)

SELF-INDUCTION COEFFICIENT—The ratio of the number of lines of induction produced by a current flowing in the circuit divided by the current in the circuit. The coefficient of self-induction of a conductor of finite cross-section may be defined as the ratio of twice the energy of the magnetic field produced by the current flowing to the square of the current. The following factors affect the coefficient of self-induction of a circuit: the cross-section and shape of the conductor, the size and shape of the circuit, the permeabilities of the surrounding medium and of the conductor itself. Where the skin effect is large, the frequency of the current and the specific resistance of the conductor will also affect the coefficient of self-induction.

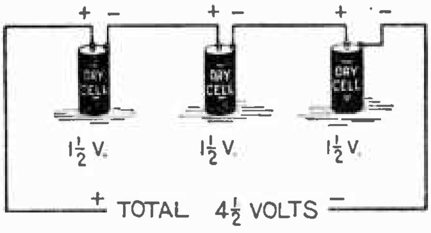
SELF-OSCILLATION—The tendency for the vacuum tubes in a radio receiving set to act as generators of radio frequency oscillations. (See *Body Capacity,* also *Bolitho Circuit.*)

SENSITIVE SPOTS—Points on the mineral of a crystal detector which show a greater response to incoming oscillations than others. Dust, grease, or dampness reduce the sensitivity of these spots and therefore the crystal should be properly protected.

SEPARATELY EXCITED GENERATOR—A generator in which current for producing the magnetic field is obtained from some source external to the generator itself. This source is either another generator or else a storage battery. Separately excited generators are generally used only for special work such as battery charging, electroplating and testing.

SERIES—See Series Connection.

SERIES CONNECTION—When two or more parts of an electrical circuit are so connected that the same current flows through them they are said to be in *series* and the circuit is called a *series circuit,* the connection being a *series connection.* In order to connect primary or other cells in series, it is necessary to connect the positive terminal of one to the negative terminal of another, etc. In this case, the total voltage of the battery equals the sum of the separate voltages.



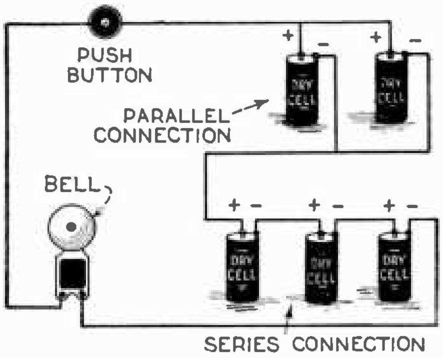
The three dry cells are here shown connected in series.

SERIES GENERATOR—A generator in which the exciting winding is connected in series with the armature and the load. This type of generator is of small commercial importance being used mainly for certain constant current systems.

SERIES MOTOR—A commutator-type motor having the field and armature windings connected in series. Ordinarily, the series motor is a direct current motor, but with minor modifications, such as lamination of the field as well as armature, this motor can be used for alternating current also. With the applied voltage constant, the greater the load, the less will be the speed of a series motor. As the load is lessened, the motor will speed up, and if the load is entirely removed, it will "run away." The *torque* (q.v.) characteristic is the most important feature of a series motor. Instead of varying directly with the current as in the shunt motor, the torque increases with the square of the current.

Hence, if the current is doubled, the torque will be increased four times, while if the current is quadrupled, the torque will be increased sixteen times. For the same current, the torque of the series motor is higher than that of the shunt and in addition, the series motor has a much better starting torque.

SERIES-PARALLEL—This refers to a circuit which is a combination of a *series circuit* and a *parallel circuit.* The term *series-parallel* is generally used to indicate a series circuit having certain minor branches in parallel; the term *parallel-series* denotes a parallel circuit having certain minor branches in series. The illustration shows a series parallel circuit having two dry cells in parallel and three dry cells in series. The push button and the bell are also in series. (See *Parallel Connection, Series Connection,* also *"A" Battery.*)



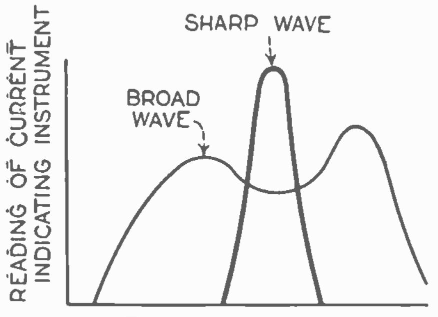
A series-parallel circuit. The three dry cells are connected in series with each other and with the bell and the push button. They are also in series with the other two dry cells, these latter being in parallel with each other.

SERIES RESONANCE—When a single lumped capacity and a single lumped inductance are connected in series between terminals to which an alternating electromotive force is applied, and the inductance or capacity or frequency is varied, the condition of series resonance exists, when the current is a maximum. (See *Resonance,* also *Resonance Curve.*)

SHARPNESS OF RESONANCE—A quantity expressing the fractional change of current in a simple series circuit for a given fractional change in either capacitative or inductive reactance.

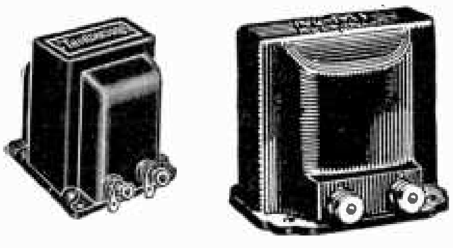
SHARPNESS OF TUNING—See *Selectivity.*

SHARP WAVE—A wave in which the energy radiated is confined to a single frequency of oscillation. Tight coupling of the oscillation transformer tends to give a broad wave, whereas loose coupling gives a sharp wave. (See *Decrément.*)



Graph showing difference between sharp and broad waves.

SHIELDED TRANSFORMER—An audio or a radio frequency transformer surrounded by a metal casing. Shielding of radio frequency transformers prevents interference from external fields and also keeps body capacity from affecting the tuning. Audio frequency transformers are shielded mainly to prevent interaction between the flux from the transformer and other parts of the radio set.



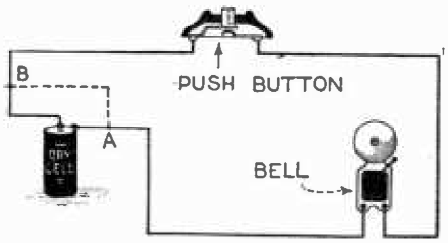
Typical shielded transformers.

SHIELDING—Metallic screening placed around radio apparatus to prevent interference from stray electromagnetic or electrostatic fields. In radio sets, the inside surface of the panel is often shielded by means of a metallic lining, thus eliminating body capacity. It is usual to ground the shielding. In sets having more than two stages of radio frequency amplification complete shielding is essential. (*See Induction Screen.*)

S.H.M.—Abbreviation for *Simple Harmonic Motion* (q.v.).

SHOCK EXCITATION—See *Impact Excitation.*

SHORT—See *Short Circuit.*



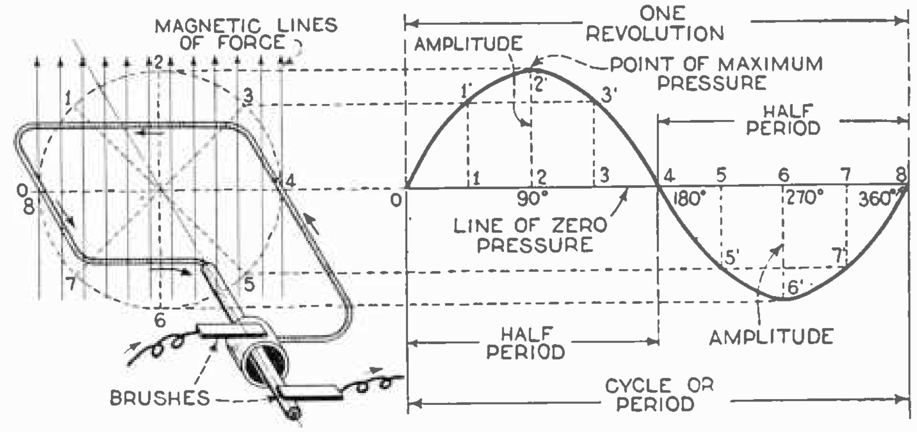
The dotted line between A and B represents a conductor short-circuiting the dry cell.

SHORT CIRCUIT—A short circuit refers to a condition of an electrical circuit whereby an external path of low resistance is connected across the source of electrical energy. A short circuit is accompanied by an increase in current flow, although this current is no longer usefully employed. Apparatus may be protected from short circuits by means of *circuit breakers* (q.v.) or *fuses* (q.v.).

SHORTENING CONDENSER, or ANTENNA TUNING CONDENSER—A condenser connected in series with the antenna and the ground, for the purpose of diminishing the natural wave length.

SHUNT WOUND GENERATOR—A generator in which the field winding is shunted across the armature terminals. The resistance of the shunt winding is made high enough so that only a small percentage of the load current flows through it.

SHUNT WOUND MOTOR—A motor in which the field winding is connected in parallel with the brushes (and the armature winding). The speed of a shunt motor is practically constant, but falls to a slight extent as the load is increased. The drop in speed may be only a few per cent between no load and full load, for large motors, while for small ones it may be as high as 15 per cent. As the load on a shunt motor is increased, the torque which the motor develops will increase and the armature current will also increase in almost direct proportion.



A sine curve is shown at the right. At the left a coil is shown rotating in a magnetic field. As the coil cuts the magnetic lines it generates the varying electromotive force represented by the sine curve.

S.I.C.—Abbreviation for *Specific Inductive Capacity* (q.v.).

SIDE BANDS—A group or band of frequencies formed by the interaction of the *Carrier Wave* (q.v.) and the modulations above and below the main carrier wave frequency. (See *Harmonics.*)

SIGNAL, STRAY RADIO—See *Strays.*

SILICON—A metalloid occurring widely in nature. It is a component of most of the rocks forming the earth's crust. Silicon crystals are used as detectors in radio work. (See *Crystal*, also *Silicon Detector.*)

SILICON DETECTOR—A *crystal detector* (q.v.) using silicon as its crystal. The silicon is used in a crystalline state and a *cat-whisker* (q.v.) is generally used to locate the ***sensitive spots*** (q.v.) and make contact.

SIMPLE HARMONIC—Referring to a *simple harmonic motion* (q.v.). If a point moves at a uniform rate around a circle and the point be projected in a straight line in the plane of the circle, the back and forth motion of the projected point is referred to as ***simple harmonic motion.*** True simple harmonic motions are the motions of a pendulum, a vibrating tuning fork, particles of water in a wave, etc. Other motions which are not precisely simple harmonic motions may be treated as resulting from several such motions. Examples of these are motions occurring in alternating currents in light waves, in electric waves and in sound waves.

SIMPLE HARMONIC MOTION—Abbreviation S.H.M.—The motion executed by the foot of a perpendicular let fall on the diameter of a circle from a particle moving with uniform velocity in that circle. The piston rod of a steam engine, turning a crank uniformly approximates a simple harmonic motion.

SIMPLE HARMONIC VIBRATIONS—The vibrations of a body such as a tuning fork which follow the law of ***simple harmonic motion*** (q.v.). (See *Angular Velocity*, also *Simple Harmonic.*)

SINE CHARACTERISTIC OF ALTERNATING CURRENT—See *Sine Curve*, also *Sine Wave.*

SINE CURVE—A curve whose perpendicular at any point is proportional to the sine of the angle corresponding to that point. The sine curve is used to represent the changes in direction and strength of an alternating current or voltage. The coil illustrated at the left in the accompanying diagram generates a sine wave current as it revolves through the magnetic field shown by the arrows. When the coil is moving parallel to the magnetic flux, no electromotive force is induced and hence current flow is zero. As the coil is rotated in a clockwise direction, it cuts the flux at a greater and greater angle, until the maximum is reached when the flux is cut at a right angle. This gives a gradually increasing electromotive force (and hence current) until maximum is reached, then when the angle at which flux is cut decreases, the electromotive force decreases until the coil again moves parallel to the flux, at which point electromotive force is again zero. Then when the coil starts to cut the flux in the opposite direction, electromotive force is reversed, increasing to a maximum and then decreasing to zero thus completing the ***cycle*** (q.v.). Current or electromotive force in one direction (positive) is represented by the height of the ordinates of the sine curve above the line, while current in the reverse direction is represented by the height of the ordinates below the line. The horizontal distances (abscissae) represent time generally measured in phase angles (position of coil at any particular instant). (See *Alternating Current,* also *Curve of Sines.*)

SINE WAVE—As referring to an alternating current, a sine wave or a simple alternating current, is a current whose wave shape is sinusoidal. The wave shape is the shape of the curve obtained when the instantaneous values of the current are plotted against time in rectangular co-ordinates. The wave shape is independent of the frequency and of the scale to which the curve is plotted.

SINE WAVE OF ALTERNATING CURRENT OR E.M.F.—See *Sine Wave.*

SINGING ARC—See *Duddell Singing Arc.*

SINGING SPARK—A spark used in a wireless telegraph transmitter which produces a singing note in the receiving head set. A spark which occurs at regular intervals and at an audible frequency such as that obtained in a quenched spark system of wireless telegraphy.

SINGLE CIRCUIT TUNER—A regenerative receiving circuit in which the antenna and grid circuits are conductively coupled. *Feedback* (q.v.) is obtained by placing the plate circuit in inductive relation with the primary.

SINGLE-PHASE—This term is used to refer to an alternating current, an alternating current system of distribution, or to alternating current apparatus. A single phase system or circuit is one energized by a single alternating electromotive force. A single phase circuit is usually supplied through two wires. The currents in these two wires counted outwardly from the source, differ in phase by one-half a cycle (180 degrees). In the single phase generator the voltage per phase is the same as the voltage between the lines and the current per phase is the same as the current per line. Since there is a great saving of copper in the use of three phase transmission of power, three phase generators are more frequently used than single phase machines. (See *Alternator.*)

SINOIDAL VIBRATION—See *Simple Harmonic Motion.*

SIPHON RECORDER—A moving coil galvanometer originally used for recording messages sent over long submarine cables. The received currents are passed to a coil suspended in a strong magnetic field. This coil carries a fine glass syphon which discharges ink onto a moving paper tape. In cable signaling, dots and dashes are usually indicated by opposite deflections which result in a wavy line being produced on the tape.

SKINDERVIKEN TRANSMITTER BUTTON—A small carbon grain microphone (q.v.) button less than an inch in diameter and about half an inch high containing a polished metallic button affixed to a mica diaphragm and a surrounding case of brass, the space between the case and the polished button being partially filled with a good grade of carbon granules. The button is very sensitive to sound waves when it is attached to any form of a diaphragm, thus making it applicable wherever a sensitive telephone transmitter should be used. Fig. 1 shows the external appearance, full size, of the Skinderviken button. This transmitter button has a number of applications in radio work and can be used in connection with speech amplifiers, telephone transmitters, detectaphones, etc. It can be made to transmit in any position, either horizontal or vertical. It is small enough to be readily concealed. Fig. 2 shows how radio music can be re-transmitted to distant points and incidentally amplified at the same time. The microphone button is shown fastened to a cone and mounted in front of the loud speaker. The leads from the button are connected in series with several dry cells and another loud speaker at a distant point. Fig. 3 shows how the transmitter button can be attached to an ordinary receiver to produce the same effect. In this case also, the leads are connected in series with several dry cells and with a low resistance phone at the distant end. In Fig. 4 the transmitter button is shown in use as a grid leak in a regenerative circuit. Where it is desired to get greater sensitivity and volume for either radio telephone transmitting or for ordinary phone transmission the system illustrated in Fig. 5 will be found highly suitable.

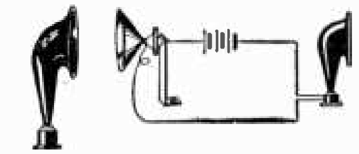

Fig. 2. Retransmitting radio programs.

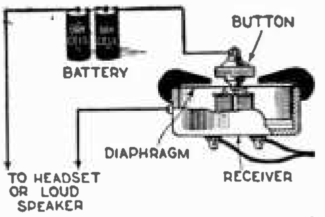

Fig. 3. Retransmission from ear phone.

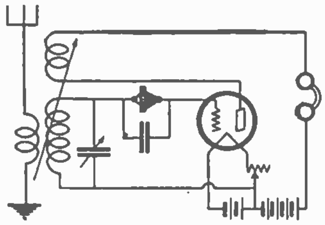

Fig. 4. Button used as grid leak.

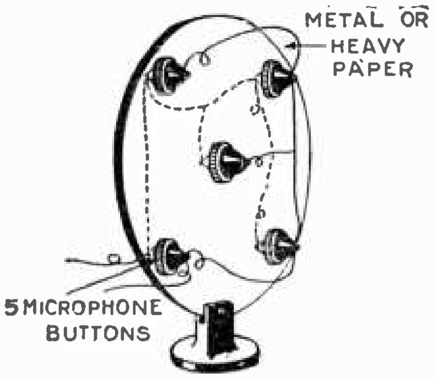

Fig. 5. Combining buttons to form sensitive microphone.

Fig. 6 shows the construction of a hand microphone for transmitting sets or for inter-departmental telephone circuits. A very simple circuit closer is mounted in the handle of the microphone which in this particular case is simply an ordinary piece of wood hollowed out to receive the switch and the wires. This wooden handle is then fastened to the rubber case of a telephone receiver. The coils and magnets in the telephone receiver are removed, a small hole is drilled or punched in the diaphragm, and the transmitter button is fastened as indicated in the diagram.

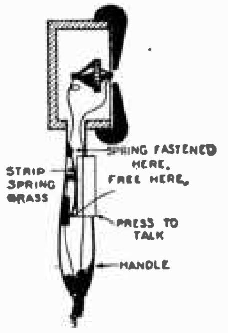

Fig. 6. Construction of hand microphone.

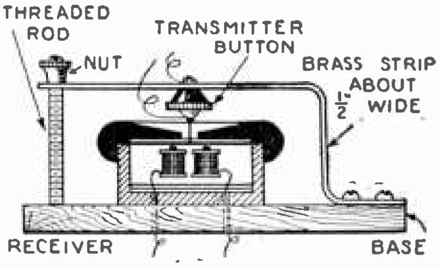

Fig. 7. Method of fastening a button to ear 'phone.

Another method of fastening a transmitter button to a telephone receiver is illustrated in the diagram in Fig. 7. Here the transmitter button is mounted on a brass strip which is bent so that the center of the button will rest upon the diaphragm of the telephone receiver fixed to the base. A threaded rod and nut regulate the pressure of the button against the diaphragm. In the event that it is not desired to make any changes to a pair of telephone receivers, the transmitter button can be fastened in the shell of an old receiver, B in Fig. 8, and the head phone may be rested on the shell. For

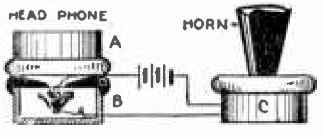

Fig. 8. A simple form of amplifier.

use with a Baldwin receiver, a microphone transmitter button is fastened to it in the following manner: The diaphragm of the Baldwin receiver is first removed, and a thin rod is soldered to the lever, as indicated in Fig. 9. The transmitter button is then soldered to the rod as shown. Another way of making a loud speaker set from an ordinary one-tube receiving set is illustrated in Fig. 10. Where a phonograph is available, the hook-up illustrated may be employed, placing the reproducer of the phonograph on the receiver, which should be placed in a suitable position on the turntable. Inasmuch as the movement of the diaphragm of the seventy-five ohm receiver is an up and down one, the reproducer of the phonograph should be turned as it would be for "hill and dale" records. A tiny drop of solder should be dropped upon the diaphragm of the seventy-five ohm receiver and a small nick placed in the center of the solder for receiving the needle of the phonograph reproducer.

Fig. 11. An effective radio amplifier.

Very often it is desired to further amplify the music or sounds picked up by a transmitter button. For this purpose, microphone transformers, or as they are better known, modulation or telephone induction transformers, are employed. In Fig. 11 this instrument is illustrated, together with the circuit for its use. Here the incoming radio signals are made to operate the microphone fastened to the receiver. The current which the microphone passes then goes through the primary of the microphone transformer, the secondary of which is connected to another receiver similarly fitted with another transmitter button. The output of the second microphone transformer is then connected to a loud speaker. A diagram for using but one stage of amplification through transformers is illustrated in Fig. 12. For the better class of work, however, it is desirable to use a standard vacuum tube amplifier as illustrated in Fig. 13. Here the microphone button is placed in series with the primary of a modulation transformer, and in series with several dry cells or flash light batteries. The secondary of the modulation transformer then connects to the grid and filament, the same as it would in a standard vacuum tube amplifying circuit. The music from the output is, of course, very loud.

TO AMPLIFIER

Fig. 14. A tuning fork oscillator.

A very splendid oscillator is illustrated in Fig. 14. Here a tuning fork of standard frequency is mounted on a suitable holder in a cigar box. Two low resistance coils, about five to seventy-five ohms, are then placed under one prong of the tuning fork. These are connected in series with the transmitter button fastened in the cigar box, which serves as a base for mounting the tuning fork. The batteries may be concealed in the cigar box. Thus when the tuning fork is struck, it will continue to vibrate as long as the current is applied to the microphone. To use this as an oscillator, a pair of magnets from a telephone receiver and the permanent magnets are mounted near the other vibrating prong. The current constantly being changed by means of the vibrating bar of steel produces a standard frequency, which when amplified can be used for making radio measurements of different kinds. Fig. 15 shows the transmitter button connected in a radio circuit for use as a detector of radio waves. Fig. 16 shows a method of making a code practice device. An audio frequency howl is produced which will enable an instructor to teach an entire classroom the radio code. Sometimes the key, instead of interrupting the circuit, merely shunts a small portion of the current passing through the transmitter button, and for this purpose the key would have to be placed directly across the transmitter button and in series with a small resistance. Fig. 17 shows how the transmitter button may be used in Heising modulation. Fig. 18 indicates its adaptation to the variation of grid voltage of the oscillator tube and Fig. 19 shows how the transmitter button may be hooked up to modulate the output current. These last three figures indicate the use of transmitter buttons in vacuum tube transmitters.

SKIN EFFECT — The name given to the crowding of alternating or oscillatory currents into the surface layers of a solid conductor. This phenomenon increases with increased frequency. As a result the resistance of solid conductors is much higher at high than at low frequencies. (See *High Frequency*, also *High Frequency Resistance.*)

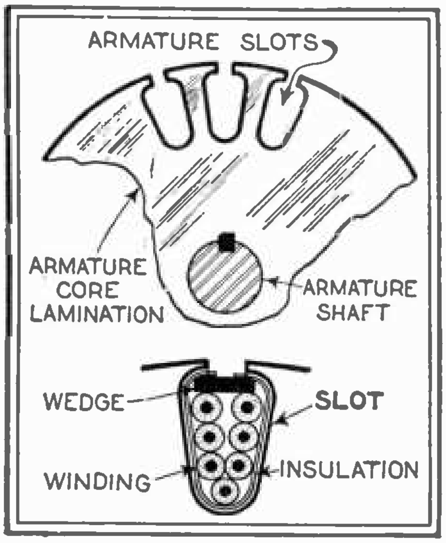
SLABY-ARCO-SYSTEM — A system of wireless telegraphy which used a quenched spark gap. This system is now obsolete.

SLABY-ARCO-VACUUM COHERER — A filings coherer enclosed in a sealed glass tube from which the air has been extracted.

A Slaby-Arco vacuum coherer.

SLIP RINGS — Metallic rings, separated by insulators, from which collecting brushes pick up current generated by an alternator. Slip rings take the place of the commutator used on the direct current generator.

SLOTS—Channels cut in the armature core discs and into which the windings fit.



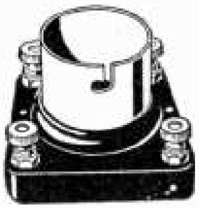
Details of armature slot.

SLUDGING OF TRANSFORMER OIL —The thickening of the oil used for cooling in large transformers. A muddy deposit is formed due to oxidation. The presence of metallic copper in contact with the oil is considered to hasten this action catalytically.

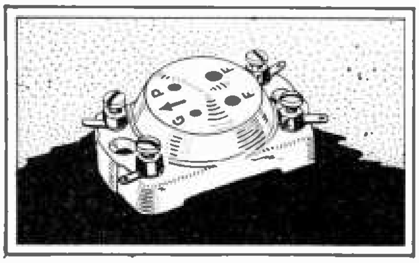
SOAKING-IN—An increase in a condenser charge above its initial value, which takes place gradually if the potential is kept applied. Soaking-in takes place due to a change in the *dielectric* (q.v.).

SOAKING-OUT — A gradual continuation of the discharge of a condenser after the first rapid discharge. In this case, the dielectric is returning to its original state.

SOCKET—A receptacle for holding and making electrical connections with a vacuum tube, an incandescent lamp, or a connection plug. Vacuum tube sockets are made of bakelite, hard rubber, porcelain, pyrex and other suitable *dielectrics* (q.v.). They are usually molded. One type of socket is composed of a shell of insulating material, or in some cases of metal. Four contact blades extend within the base of the socket, for making contact with the prongs of the tube. These blades may be of strong phosphor bronze. Their outer ends are attached to binding posts. It is important that the base supporting the binding posts and contacts be of good insulating material such as bakelite or hard rubber. Modern sockets are of the *spring* or *shock absorbing* type. This construction protects the tube and does away with microphonic sounds. One type of spring socket consists of two molded bakelite parts, the outer one square with a binding post at each corner and the inner one circular with holes for the tube prongs and steel spring contacts fastened underneath the holes. The circular molding is suspended within the square one by means of two rubber pads. Other types of shock absorbing sockets use spring suspension instead of rubber.



A metal shell socket.



Shock absorbing or spring-type socket.

SOFT IRON INSTRUMENTS — Ammeters, voltmeters and other measuring instruments which depend upon the magnetic force between a current carrying coil and a movable core of soft iron to produce the deflection of the needle or pointer. The movement of the iron may be controlled by a spring or by gravity. These instruments may be used for either direct or alternating current measurements. They are not as accurate as instruments of the dynamometer type.

SOFT TUBE — A vacuum tube which contains a gas content instead of being highly evacuated. Soft tubes were formerly recommended for use as detector tubes but at present have been superseded for this use by the ordinary amplifying tube.

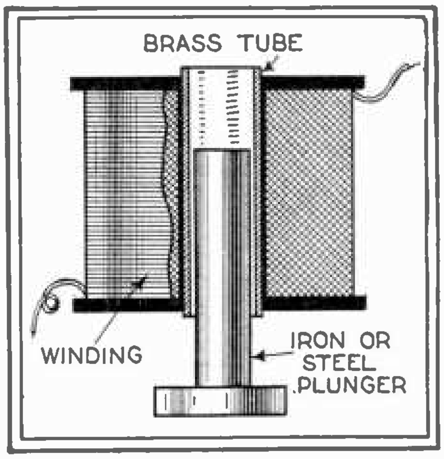
SOLDER—An alloy of lead and tin used for making good electrical connections.

SOLDERED JOINT — A connection between two metallic surfaces, cemented together by means of solder. Where the joint is between two electrical conductors, it must be made both mechanically and electrically secure.

SOLDERING — The process of joining together two or more conductors or other metallic surfaces by means of solder, so as to give a good electrical or mechanical connection, or both. After the surfaces to be united are carefully cleaned, a flux is applied to dissolve the oxides which occur on the surface of the parts to be joined with solder.

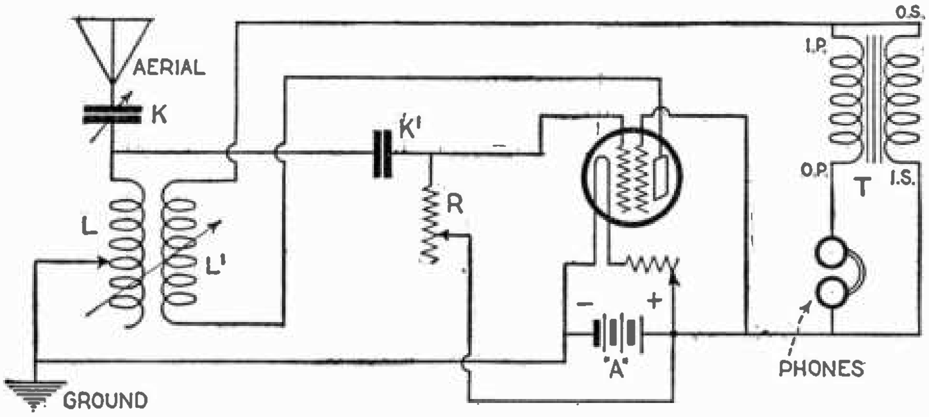
SOLDERING FLUX—A substance used to dissolve the oxides on the surfaces of the metals to be soldered. When these oxides are dissolved, the flux enables the solder to enter the minute pores of the metal surface, effectually sealing it against the penetration of oxygen. Fluxes range in character from very strong acids to very mild acid bearing substances. For radio use, it is necessary to use a flux which is non-corrosive and which in its use will leave a residual matter that will have no tendency to collect moisture, dust, or other foreign material. Rosin has been found to be very suitable as a flux in radio soldering. (See *Flux, Soldering.*)

SOLENOID — A coil of wire of helical form used as an electromagnet, generally to attract a movable iron plunger, which is drawn within the solenoid when the current flows through the windings. The solenoid never has a fixed core. A coil wound on a cylinder so as to give uniform magnetic field within it when traversed by a current is often called a *straight solenoid.*

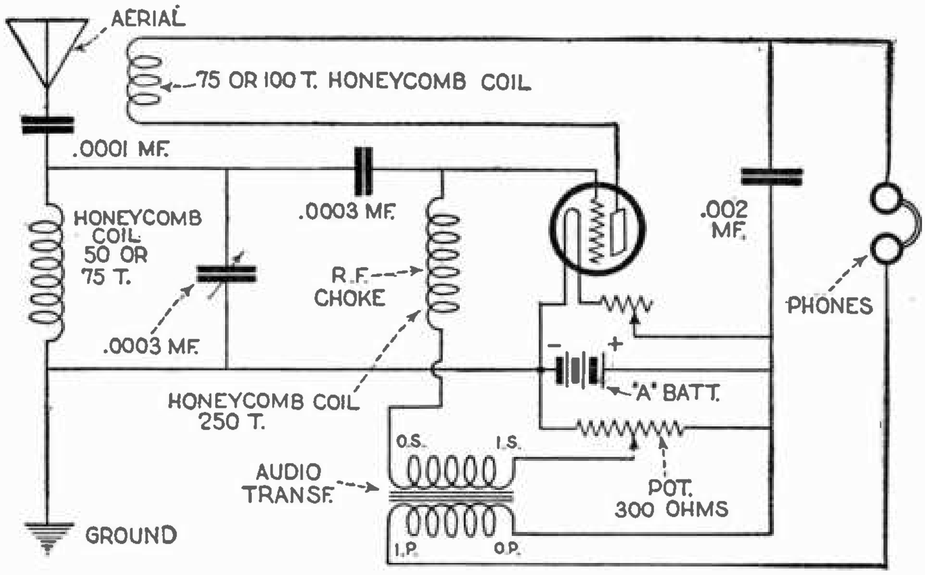


A typical solenoid.

SOLODYNE—A radio circuit which dispenses with high-tension or "B" batteries and which utilizes a double grid vacuum tube. The solodyne principle is also known as the *Unidyne.* The theory of the solodyne is as follows: The small plate current due to the electron emission from the lighted filament passes through the tickler coil which feeds back to the main grid circuit in the usual way, the primary of a step-up transformer, through the telephone receivers, and then back again to the filament of the tube. The electron stream passing from the filament to the plate inside the tube must pass the two grids. The first of these, which may be referred to as the additional grid, is primarily made positive by connecting it directly to the positive terminal of the "A" battery. This in itself tends to assist the electron stream, to reduce the resistance of the vacuum of the tube. But the additional grid is assisted in its work by having impressed upon it the stepped up voltage from the plate circuit, due to the transformer, the secondary of which is in direct connection with the additional grid. Thus a building up process is introduced, every possible electron primarily due to the electron emission of the filament of the tube being made use of and ultimately passing through the telephone receivers to be reproduced in the form of audible signals. The main grid functions in the usual manner, except that this too, can be made to help the additional grid as well, by giving it a strong positive bias. A typical Solodyne circuit is shown in Figure 1. In this circuit L and L^1 may be honeycomb coils or a variocoupler. In Figure 2 is shown the Cowper Solodyne circuit which utilizes standard tubes. In this diagram, the numbers printed near each coil indicate the size of honeycomb or duo-lateral coils to use in each circuit. (See *Four Element Tube.*)

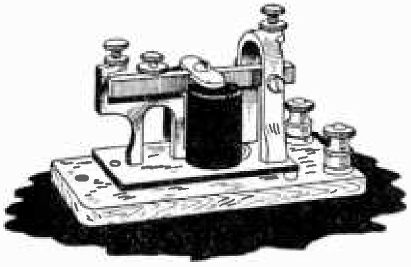


A Solodyne circuit. L and L^1 may be honeycomb coils or a vario-coupler.



The Cowper circuit uses no "B" battery and is quite stable in operation.

SOUNDER—An instrument used for receiving telegraph signals which utilizes the attraction of an armature by an electromagnet to make sounds as the armature hits against stops at the beginning and end of each current impulse. The sounds thus produced form the characteristic dots and dashes of the telegraph code and can be easily read by the experienced telegraph operator.



Telegraph sounder.

SOUND WAVE—A wave of alternate condensation and rarefication through an elastic body such as air, water, etc. Sound waves travel at the rate of 1090 feet per second in air.

SOUTH MAGNETIC POLE—Situated in Latitude 70 South and Longitude 102 East. The South Magnetic Pole does not coincide with the geographic South Pole.

SOUTH POLE—When referring to a magnet, the pole which tends to point to the south when the magnet is freely suspended.

SOUTH SEEKING POLE—See *South Pole.*

SPACE CHARGE—The difference between the number of electrons and positive ions in unit volume, multiplied by the charge per ion. This is also called the volume density of electrification. Let us consider the distribution of electrons in a vacuum tube, between the hot filament and the plate. An electron close to the surface of the plate is attracted to the plate by two forces, attraction from the plate and repulsion from the electrons located between it and the filament. An electron close to the surface of the filament, however, is repelled by the electrons between the plate and itself, although it receives some attraction from the plate. It may either move towards the plate or go back to the filament. This will depend upon whether the plate voltage is high enough to result in a force of attraction sufficiently great to overcome the repulsive force of the space charge.

SPACE CURRENT—Current which flows between the cathode and the anode in a vacuum tube. Space current is the result of the motion of electrons through space. It does not follow the same laws which govern the flow of current in a metallic circuit, deviating from Ohm's law to a certain extent, depending upon the relation between the impedances of the tube and the metallic portion of the circuit and also upon the nature of the discharge.

SPAGHETTI—A varnish-impregnated cloth tubing used to insulate bare conductors. (See *Cambric, Varnished.*)

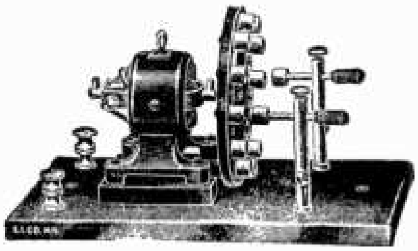
SPARK—See *Spark Discharge.*

SPARK COIL—An *induction coil* (q.v.) used to produce *spark discharges* (q.v.).

SPARK DISCHARGE—A passage of electrical current between two conductors across a previously non-conducting space. The discharge is accompanied by light, heat and sound. It may take place through a liquid, a solid or a gas but whenever it occurs, it means that there has been a breaking down of the dielectric stress. A spark passing through a solid will puncture it. The passage of a spark through a liquid does not affect the dielectric properties of the liquid. On the other hand, a spark passing through a gas, usually ionizes the gas for a period of time after the passage of the discharge and as a result a continuous arc may follow the first spark. An *oscillating current* (q.v.) may produce a rapid train of sparks which persists until the oscillations are damped out. (See *Sparking.*)

SPARK DISCHARGER—A form of *spark gap* (q.v.) such as a *rotary discharger* (q.v.) or a fixed gap, such as a *quenched spark gap* (q.v.). (See *Discharger*, also *Disc Discharger.*)

SPARK GAP—A break in an oscillating circuit which acts as an automatic safety valve to the condenser. Since the air between the gap has a high resistance, the condenser cannot discharge until the potential is sufficient to break down its insulation, thus permitting only heavy discharges to take place. (See *Quenched Spark Gap, Fixed Discharger*, also *Safety Gap.*)



A rotary spark gap.

SPARKING—The production of spark discharges, especially when an inductive circuit is broken. Sparking at the brushes of a motor or generator is caused by armature reaction and self-induction. Sparkless commutation can be obtained by shifting brushes or by the use of *interpoles* (q.v.). Sparking is injurious to contact surfaces and should be avoided if possible. Sparking between contacts of induction coil vibrators is usually reduced by placing a condenser across the gap.

SPARK MICROMETER—A graduated adjustable spark gap for determining sparking distances for various voltages, etc. This device also permits the approximate measurement of high voltages provided the sparking distances for the particular type of terminals, are known.

SPARK RATE, SPARK FREQUENCY, or GROUP FREQUENCY—The number of sparks per second occurring in a spark system of wireless telegraph transmission. It refers to the *Group Frequency* of the wave train rather than to the waves themselves.

SPARK RECORDER—An instrument for recording telegraph signals, in which sparks from an induction coil pass through and mark a paper tape carried on a drum which turns under a metallic pointer. The use of a spark recorder dispenses with the use of ink, thus doing away with the friction of the pen on the paper.

SPARK TRANSMISSION—A wireless telegraph transmitting system which uses a succession of spark discharges in an oscillating circuit, to produce oscillations. These traverse an aerial system and a series of short trains of damped waves are emitted.

SPECIFIC GRAVITY—abbreviation S.G.—The weight of a body compared with that of another, having equal bulk, considered as a standard. The standard for liquids and solids is water, while hydrogen or air is the standard for gases. The specific gravity test of the radio storage battery is an important means of testing the condition of the battery. A *hydrometer* (q.v.) is used for this purpose.

SPECIFIC INDUCTIVE CAPACITY—symbol k—abbreviation S. I. C.—A measure of the degree to which a body permits electrostatic induction through it. The ratio between the capacities of two condensers, one employing the material under consideration as the dielectric and the other using an air or vacuum dielectric. The Specific Inductive Capacity of a material is the *inductivity* (q.v.) of that material relative to that of air. (See *Inductive Capacity* also *Dielectric Coefficient or Constant*.)

SPECIFIC RESISTANCE—The resistance in ohms, of unit length and unit cross-section of a conductor. (See *Resistivity of a Material*, also *Resistivity, Surface*.)

SPECTRUM—An image formed by rays of light or other radiant energy in which the parts are arranged according to their refrangibility or wave length. The image may be visible or invisible. The arrangement is such that all parts of the same wave length fall together, while those of different wave lengths are separated from each other forming a regular series. The spectrum produced by the light of the sun passing through a triangular glass prism and falling on a screen is one of the most common forms. The various colors, since they are unequally refracted, are spread out into a band, showing the seven rainbow colors. The red is at one end (that of the least deviation), while the violet is at the other end.

SPEECH AMPLIFIER—An audio frequency amplifier designed especially for public address systems, where addresses are to be heard over a comparatively wide area. By means of speech amplifiers, it is possible for one speaker to address an unlimited number of listeners.

SPEECH MODULATION—The modulation of radio frequency currents, as utilized in radio telephony. The production of speech modulated waves calls for a source of undamped waves and a method of causing variations in the current output of this source which will accurately correspond to the vibrations of the voice. The source of undamped waves may be a high-frequency alternator or an electron tube generator, the latter being in most common use. The radio frequency antenna current may be varied by inserting a speech-controlled variable resistance, such as a microphone, in the antenna circuit at the transmitter. The microphone may be put in the direct current power supply of the generating system, so that the radio frequency output of the system will be varied as the power input is varied. (See *Modulation*, also *Modulation Frequency Ratio*.)

SPEECH VIBRATIONS—The wave corresponding to a given sound. There are various methods of obtaining graphically, the picture of the wave form of any particular sound. One method is to make a phonograph record of the sound and then as the sound is reproduced from the record, to magnify the movement of the needle, using a lever to trace the form of the waves.

SPIDER WEB COIL—A form of inductance coil in which the wires are wound on a frame consisting of radiating arms similar to the spokes of a wheel. The wire is wound in successive turns in and out around the arms, starting from the center, until it reaches the ends of the arms. An odd number of turns are used so that alternate turns will follow the same wave; that is to say, adjacent turns will be on opposite sides and separated by an arm. Coils of this type have comparatively low distributed capacity and in addition have the advantage of being extremely compact. Figure 1 illustrates the frame on which the wire is wound. This is known as the *spider*. A spider cut from $\frac{1}{16}$th inch bakelite, as shown in Figure 2, can also be used, although, owing to a smaller number of divisions, the latter does not have such a large inductance as the former. In winding, the wire is fastened around one of the pegs and is then taken in and out around the pegs, as shown in Figure 3. When starting the second turn, the wire will be around the pegs the opposite way to the first turn, and all successive odd-number turns will be on the same side as No. 1, while all successive even number turns will be on the same side as No. 2. The finished coil is shown in Figure 4. Spider web coils are also known as *basket wound* (q.v.), *basket woven*, or *stagger wound* coils.

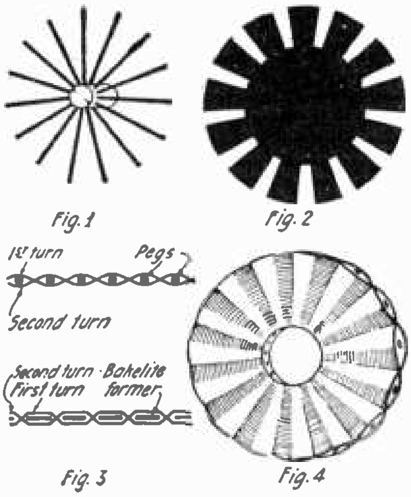


Fig. 1 Fig. 2

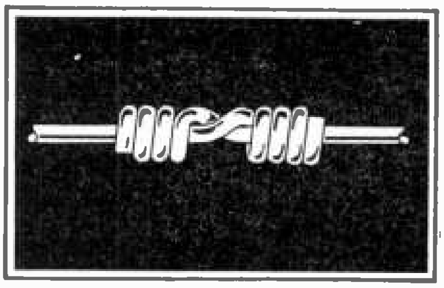
Fig. 3 Fig. 4

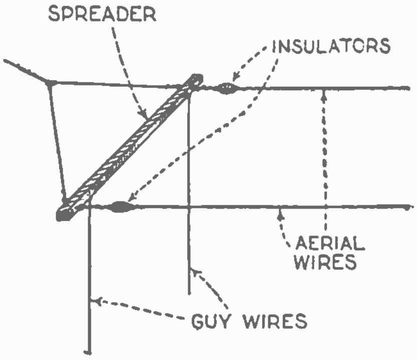
Details of spider web coil construction.

SPLICE—A method of joining two or more conductors by interweaving or entwining the strands, in a similar manner to that of splicing a rope.



A strong splice.

SPREADER—A spar or pole used on an aerial, where two or more wires are used, to keep these wires properly spread out and parallel to each other.



Aerial showing use of spreader.

SQUARE MIL—A square mil is the area of a square, one mil, or 0.001 inch on each side. (See *Circular, Mil*.)

SQUIER, MAJOR-GENERAL SIR GEORGE OWEN—American radio authority. He was educated at the Johns Hopkins University and became a research student under Professor Rowland and Sir William Preece at the British General Post Office. In 1904 he published his famous paper on the absorption of electromagnetic waves by living vegetable organisms and showed how trees could be used for the reception of radio messages. In 1911 he read a paper on multiple telephony before the American Institute of Electrical Engineers. In 1912 he was awarded the Elliot Cresson Gold Medal for his researches in multiplex telephony and in 1919 the Franklin Medal of the Franklin Institute. Major-General Squier was awarded

Major-General George Owen Squier.

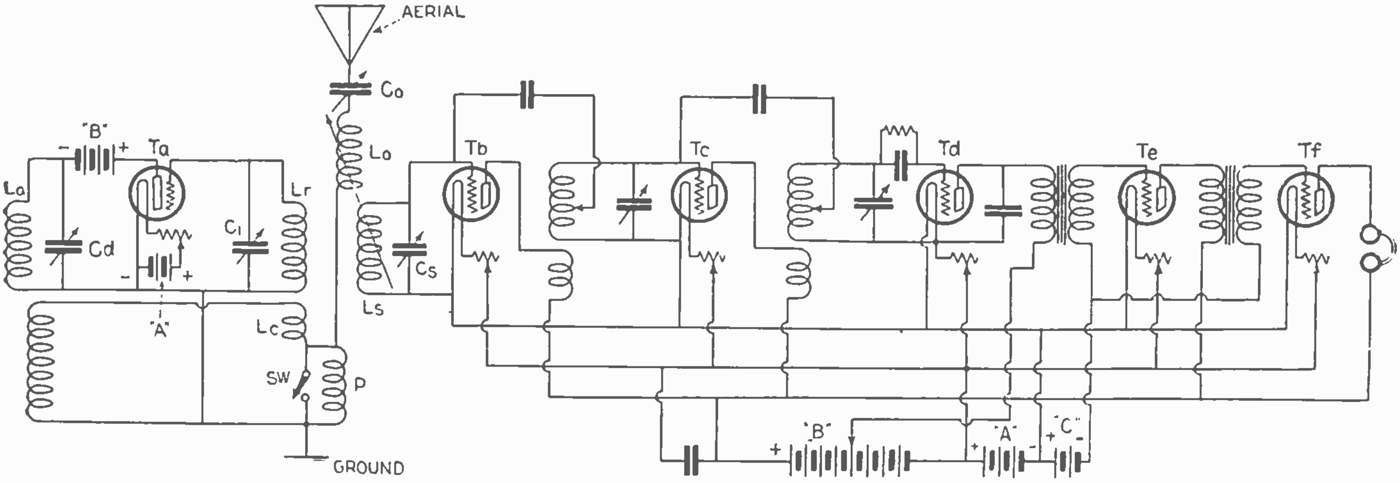
the K. C. M. G. for distinguished services during the World War. He is a member of the National Academy of Sciences and the International Electrotechnical Commission. He is the inventor of *Line Radio* (q.v.) which is also known as *Wired Wireless, Wire-Radio Telephony, Guided Wave Telephony*, and *Carrier Current Telephony.*

SQUIRREL CAGE INDUCTION MOTOR—A type of induction motor having a rotor consisting of copper bars connected to rings at each end so as to form a short-circuited system. There are no windings in this type of rotor nor are there any external connections through slip rings. These motors are used for constant speed work, where starting is necessary only at infrequent intervals. The squirrel cage motor draws a large starting current, but has a relatively small starting torque. It is possible, however, by properly designing the rotor so as to have enough resistance, to use small motors of this type for loads requiring frequent starting, rapid acceleration and high starting torque.

SQUIRREL CAGE ROTOR—See *Squirrel Cage Induction Motor.*

STAR GROUPING—A method of connecting up polyphase apparatus or circuits. One end of each phase is connected to a common point, usually called the neutral point. This method of connection is called a "Y" grouping, in the case of a three-phase system.

STATIC—An irregular disturbing noise, heard in the radio loud speaker or head set due to atmospheric discharges, lightning and similar phenomena. A common form of static produces an intermittent crashing sound. Other types cause grinding noises or hissing sounds. Nearby lightning is usually accompanied by a sharp snap in the loud speaker. Various methods have been devised for eliminating or reducing static, although it cannot be said that any of these has been entirely successful. The combination of coil and ground aerials results in the reduction of static; also the use of *beat reception*, using continuous waves as in certain methods of wireless telegraphy. Static is also referred to under various other names, such as *strays, atmospherics, X's*, etc.



Arrangements of a static reducing device employing repeater circuits.

STATIC CHARACTERISTIC—The curves obtained by the use of a steady direct-current potential for showing the performance, efficiency, etc., of a vacuum tube. The static characteristics of the tube itself are obtained when the resistance of the external circuit is very small in comparison to the plate resistance of the tube. In cases where the external circuit contains reactance, the true characteristic could not be obtained using direct current. In this case, an alternating electromotive force is impressed on the grid and the curves obtained are known as *dynamic characteristics* (q.v.).

STATIC ELECTRICITY—Electricity which is stored in a circuit, manifesting itself in the form of charges at high potential. Electricity, as produced by frictional or influence machines.

STATIC ELIMINATORS—A device for eliminating or reducing the effect of *static* (q.v.). Various circuits have been proposed for accomplishing static elimination. Some of the most recent and successful of these are the McCaa anti-static circuits described in the July, 1925, issue of RADIO REVIEW, on page 63. There are two types of McCaa circuits, one applicable to radio telegraphy and the other to radio telephony. Both have for their object the reduction of signal static ratio. The wiring diagram shown is that of a standard five-tube neutrodyne receiver plus a McCaa anti-static device of the receiver type. In this diagram Ta is the repeater tube, Tb and Tc are the two radio-frequency amplifier tubes, Td is the detector tube and Te and Tf are the two audio-frequency amplifier tubes. The circuit from tube Tb on is unchanged and is the same as any standard neutrodyne receiver. The input circuit of tube Tb, however, and also the antenna circuit, have been altered to make possible the installation of the anti-static device.

For the neutroformer which usually couples the first tube of a neutrodyne to the antenna circuit, the coils Lo, Ls and Lp have been substituted. These coils may either be homemade coils or honeycomb coils. If honeycomb coils are selected each may have fifty turns. The coupling between Ls and Lp should be fixed so that the coils are about an inch apart and some arrangement should be made for changing the coupling between Lo and Ls. If homemade coils are used each coil should have approximately sixty turns of No. 22 d. c. c. wire on a three-inch diameter tube and they should be coupled the same as the honeycomb coils.

The coils Lr and Lc are also coupled and may be either 50 and 10 turn honeycomb coils, respectively, or 60 and 10 turn homemade coils wound on a three-inch diameter tube with No. 22 d. c. c. wire. The coupling between these coils is not variable. After the proper value of coupling has been found by experiment it may be made permanent.

Coils Ld and Lq are also shown coupled in the diagram. They may be 50 and 75 turn honeycomb coils, respectively, or 60 and 90 turn homemade coils wound on a three-inch diameter tube with No. 22 d. c. c. wire. The coupling between these coils is also fixed after the proper value has been determined by experiment.

The proper values for the various capacities used in this circuit are as follows: Co., .001 mfd. (43 plate); Cs, .000035 mfd. (17 plate); Cr., .00035 mfd. (17 plate); Cd, .00035 mfd. (17 plate).

In building this set it is advisable to place both the anti-static device and the receiver in the same cabinet. This cabinet must be shielded and the shield should be connected to the ground. It is also advisable to shield the anti-static device from the receiver proper. The batteries should also be shielded either by placing them inside the cabinet or in metal boxes which are connected to the ground. The wires from the batteries to the set may be effectively shielded by using BX cable, the outside covering of which should also be connected to the ground. For the phone wires special phone cords which are shielded with a flexible copper braid are desirable.

STATOR—The stationary plates of a rotary condenser. The fixed portion of a motor or a generator, which carries a winding. In induction motors, that portion of the motor which is fixed in position and which carries the winding connected to the external circuit. (See *Rotor*, also *Alternator.*)

STATOR PLATES—The plates of a condenser which remain stationary in position as differentiated from the plates which rotate. (See *Shielding*, also *Stator.*)

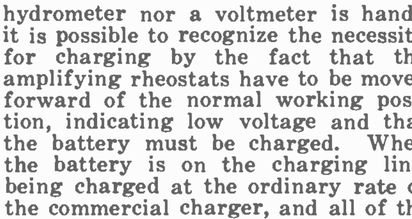
STOPPING CONDENSER—A condenser which opposes or prevents the flow of direct current, but which allows alternating current to flow in a circuit.

STORAGE BATTERY—See *Secondary Cell.*

STORAGE BATTERY TESTS—The testing instrument most commonly used in storage battery work is the *hydrometer* (q.v.). The purpose of the hydrometer is to determine the state of the charge of the battery, as indicated by the *relative* specific gravity of the electrolyte. The specific gravity of a fully charged battery is not a fixed value but depends entirely upon the standard specific gravity employed by its manufacturer which may be anywhere from 1.250 to 1.300. The user should always ascertain the correct specific gravity for the make of battery before attempting to test it with a hydrometer. A voltmeter may be employed as a means of testing a storage battery provided it is of the proper type and is used correctly. It must be accurate with sufficient length of scale to read tenths of a volt clearly. Voltmeters are obtainable which may be used for both the "A" and "B" batteries whether dry or storage. It is not possible to test the storage "A" battery with cheap types of so-called pocket voltmeters. It must be kept in mind that a voltmeter reading on a storage "A" battery is of value only when the battery is either charging or discharging, except when the battery is practically dead. A voltmeter reading taken when the battery is not connected to the circuit, either charging or discharging, may be misleading. If a reading is taken with the filaments lighted and the voltmeter indicates a full six volts, the battery is charged. Under the same conditions, if the voltmeter lags appreciably below six volts the battery should be charged in order to keep it in the best condition. When it falls to 5.4 volts the battery is discharged and cannot possibly operate the set with any degree of satisfaction. When the battery is connected to the charger and the voltmeter shows from 7.5 to 7.8 volts the battery is fully charged. It is possible to test roughly without instruments. If neither a hydrometer nor a voltmeter is handy it is possible to recognize the necessity for charging by the fact that the amplifying rheostats have to be moved forward of the normal working position, indicating low voltage and that the battery must be charged. When the battery is on the charging line, being charged at the ordinary rate of the commercial charger, and all of the cells of the battery are bubbling, this is an indication that the battery is charged. An interesting meter has recently been placed on the market which should prove of considerable use to owners of storage batteries. It is an ammeter of special design which is to be connected in series with the storage battery on charge. There is a third terminal on back of the instrument by means of which the same instrument can be used to measure the current consumption of the filaments. By pressing a small button in the center of the meter, the needle swings over to the right-hand portion of the scale and indicates whether the battery is fully charged, half charged or low.

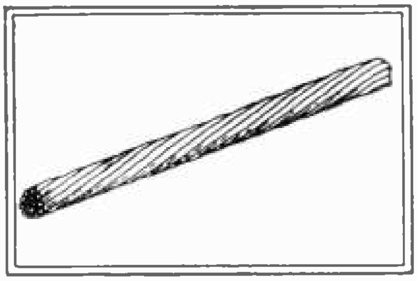
STORAGE CELL—See *Secondary Cell.*

STRAIN INSULATOR — An insulator used under tension, as for example the insulators to which the guy wires of an aerial are attached. The simplest form of strain insulator consists of a cylinder or ball having an eye-bolt at each end. Where the aerial guy is fastened to a strain insulator, the purpose of the insulator is to prevent the guy from having a natural wave length nearly the same as the wave length of the antenna. A common form of strain insulator is of nearly spherical form and is so grooved as to carry the two wires firmly, without permitting them to come into contact.



A strain insulator.

STRANDED WIRE — A wire made up of a number of smaller wires, twisted or braided together. An uninsulated, large stranded wire is generally referred to as a bare cable. Stranded wires are of four general classes; (1) wire braid, (2) bunched wire, (3) rope-lay cables, (4) concentric-lay cables. Wire braid is used to afford protection to the insulation of various types of cable. In flat form, it is used as a flexible lead. Bunched wire is a type of cable also referred to as a cord. This form of cable is very flexible, since the individual wires are small. Rope-lay cables are made up of a central core of stranded wire, having one or more layers of stranded wire wound helically about it. Concentric-lay cables are formed in the same way as the rope-lay type, except that the core and layers are of individual solid wires instead of stranded. Stranded wire is very often used in radio work as aerial wire. It has the advantage of being more flexible than solid wire and it also has a lower resistance at high frequencies because of *skin effect* (q.v.). A greater cross-sectional area is available in the stranded conductor than in the solid conductor of the same weight, for carrying current. If used for radio frequency currents, however it is essential that the individual strands be enameled if the lower resistance is to be attained.

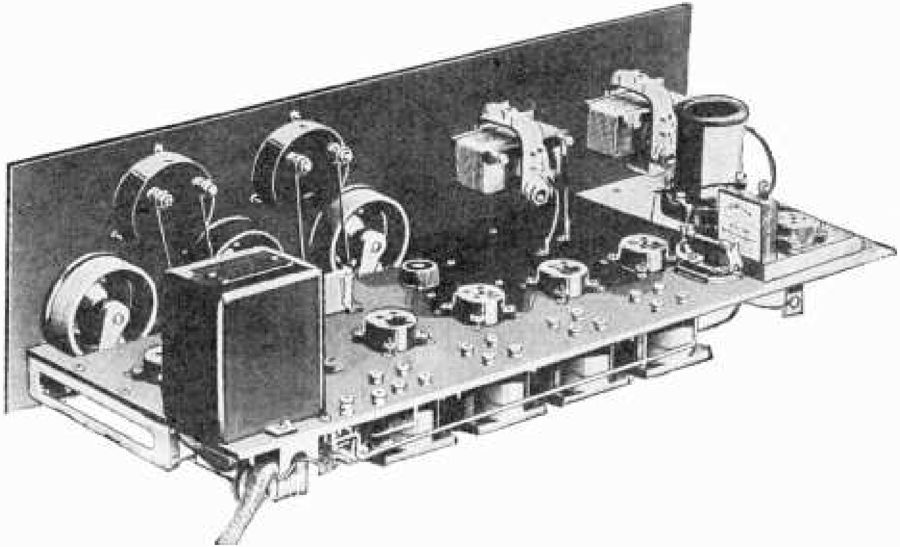


Stranded wire.

STRAY CURRENTS—Currents induced by stray magnetic fields such as eddy currents. Such currents always result in an energy loss. In electric railway systems, the currents returning through the earth, through piping, etc., rather than through the path provided are known as stray currents.

STRAY FLUX—Magnetic flux which is not usefully employed. The *leakage flux* or *leakage lines* (q.v.) which stray from the closed magnetic path provided in a transformer or other electromagnetic or magnetic apparatus. (See *Magnetic Leakage.*)

STRAYS—Atmospheric disturbances which manifest themselves as noises in the radio loud speaker or head set. (See *Static.*)

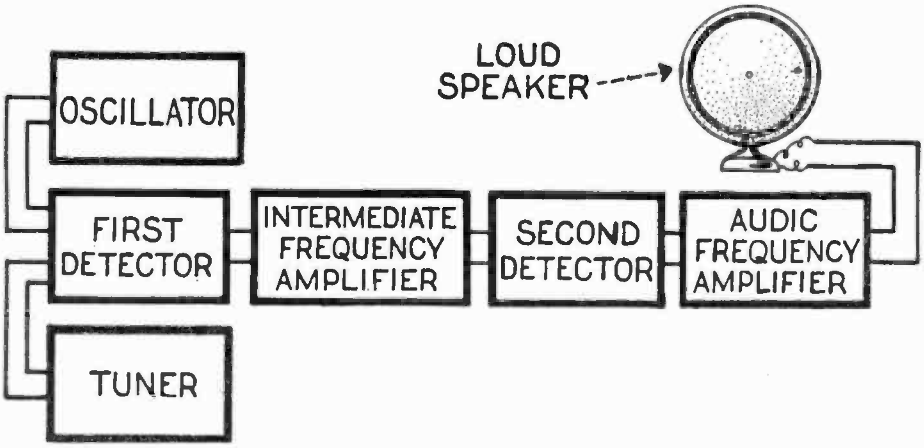


This is the rear view of the Callies Super. Note particularly the long wave transformers at the rear of the set and how they support the sub-panel.

SUB-PANEL—A secondary panel in a radio set, mounted at an angle with the main panel. The sub-panel usually carries the transformers, sockets, grid condenser and grid leak. Sub-panels are made of bakelite or composition, hard rubber, etc. (See *Panel.*)

SUPER-HETERODYNE—See *Super-Heterodyne Receiver.*

SUPER-HETERODYNE RECEIVER—A circuit used in radio reception in which the wave lengths of the incoming signals are increased to several thousand meters, by the aid of a local source of oscillations. It is a recognized fact that radio signals at "radio frequencies," that is, the original signals as they are impressed on the receiving set from the aerial, must be amplified or built up in some way to operate the detector. However, signals at low wave lengths such as in use for broadcasting, cannot be amplified very efficiently at radio frequencies. By changing the waves from the ordinary broadcast band between about 200 and 550 meters to wave lengths of from 4,500 to 10,000, it is possible to obtain more complete amplification. As a result the receiver is more sensitive and greater distance can be received. In the super-heterodyne receiver, a *difference frequency*, termed a *heterodyne note*, is created. This is done by an arrangement for generating oscillations locally. When the incoming oscillations are combined or superimposed with the local oscillations in such a manner that there is a difference in frequency, this difference will be in the form of a new set of oscillations. If the receiver is arranged in such a form that the new set of oscillations has a comparatively low frequency, the wave length will be correspondingly high. In a standard super-heterodyne receiver the action can be imagined as follows: the signal energy



OSCILLATOR

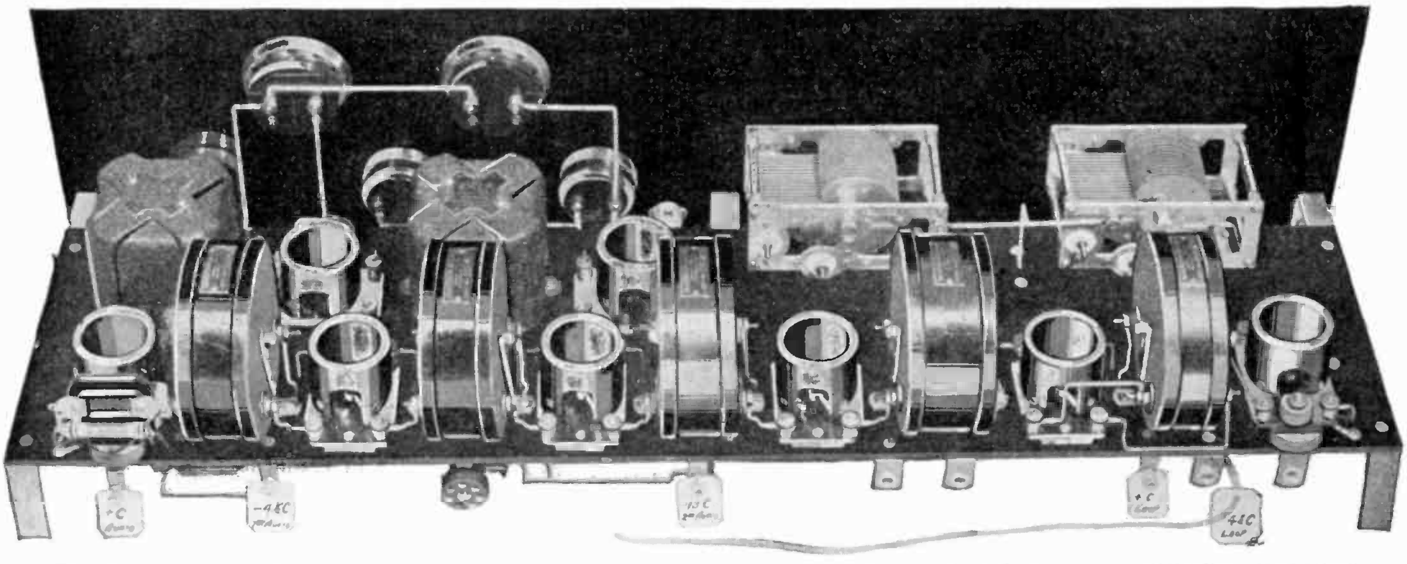
from a certain transmitting station is gathered on an antenna or loop aerial. These signals are tuned in by means of a condenser in the case of a loop aerial, or by a regular tuning device such as a coupler and condenser in the case of an outside antenna. The energy thus obtained is passed through to the grid member of a vacuum tube, which is known as the first detector tube. (In some cases the energy is first amplified by a radio frequency amplifier, consisting essentially of a vacuum tube and a radio frequency transformer). At this point in the circuit, between the tuning device and the first detector, the apparatus for producing the heterodyne action is located. This part of the outfit consists of a vacuum tube with coupled coils in the grid and plate circuits, with a variable condenser (the heterodyne condenser) connected across them, having a suitable value for obtaining any desired local frequency. In this way, the difference between the incoming oscillations and the locally generated oscillations may be adjusted to a prearranged value or frequency. In inductive relation to the grid and plate coils, another coil is arranged, referred to as a *pick-up* coil. The energy obtained from the first detector tube signals having a frequency equal to the difference between that of the incoming signals and the local oscillations, is sent to a *filter transformer* or *tuned filter*. The construction of this filter and the number of windings used is of the utmost importance, as it determines the frequency of the new set of oscillations and will permit the passage of no other frequency than the desired band. This is a very essential feature, as it is necessary to pass only the desired frequency in order to permit maximum transfer of energy. The energy at this predetermined frequency is then passed to the *intermediate frequency amplifier* (q.v.). After being amplified or built up by the intermediate frequency amplifier consisting of tubes and transformers, the energy is then passed to the second detector tube and rectified or changed from radio frequency. The audio frequency signals are now amplified by one or two audio frequency amplifiers consisting of amplifying tubes and transformers and the resulting signals, speech or music



The photograph above shows an eight-tube super-heterodyne set of extra fine quality. Each of the heteroformers are shielded in nickel-plated metal shields. The two variable condensers for tuning the aerial and oscillator circuits should be of the straight line frequency type. The two audio frequency transformers are extra large concert type, the first stage of audio being all that is necessary for average reception on a loud speaker.

are used to operate the loud speaker. Figure 1 shows the general arrangement of the various sections or units of a typical Super-Heterodyne receiver. To go a little more fully into the action of the receiver, let us suppose that a certain station is broadcasting on a wave length of 400 meters. Every wave length is equal to a certain frequency.

That is to say, every wave has a certain number of vibrations per second. The frequency of a wave 400 meters in length will be about 750,000 cycles or 750 kilocycles. By adjusting the wave length condenser, the aerial or loop circuit is placed in resonance with this particular wave length or frequency. This energy is passed through the oscillator pick-up coil and the local oscillations super-imposed on it.

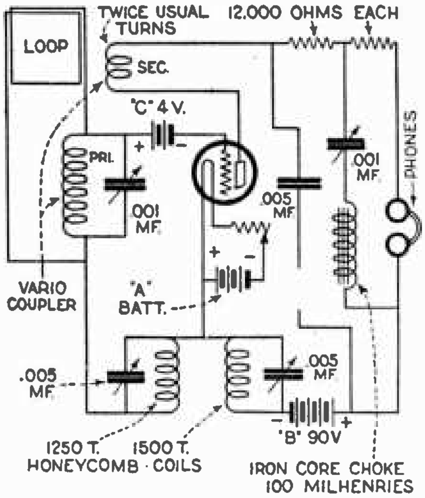
The oscillator condenser, let us say, has been adjusted to permit the oscillator circuit to produce oscillations of a frequency such that the difference between the incoming oscillations and the local ones will be in resonance with the windings of the tuned filter. For instance let us suppose that the tuned filter is arranged for tuning to 10,000 meters, which corresponds to 30,000 cycles.

Now the oscillator circuit must be tuned either 30,000 cycles above or below the incoming wave frequency. In other words, if the incoming wave frequency is as stated—750,000 meters, the oscillator circuit will be tuned to either 780,000 or 720,000 cycles so that the difference between the two frequencies will be 30,000 cycles. No matter what the frequency of the incoming oscillations, the local oscillating circuit will be tuned in a manner to produce the definite difference of 30,000 cycles. These signals will then be passed to the intermediate frequency amplifier and built up before being passed to the second detector tube for rectification.

After this, the signals that are now of audio frequency can be further amplified or built up by the audio frequency amplifier. The two operations that are of the utmost importance in receiving with the super-heterodyne are first, the tuning of the incoming signals and second, the adjustment of the oscillator circuit to produce the difference between two frequencies according to a definite plan. Figure 2 shows the hook-up of a typical Super-Heterodyne receiver.

SUPER-REGENERATION—See *Super-Regenerative Circuit.*

SUPER-REGENERATIVE CIRCUIT—A radio receiving circuit which permits reception under conditions of operation, which in an ordinary regenerative set would result in howling. In the regenerative set, which is tightly coupled, the signal strength increases to a maximum, and thereafter a still further increase in regeneration will result in greatly increased signal strength for a minute fraction of time, followed by violent oscillations. In the super-regenerative circuit, the signals are received at the point of very high amplification by suitably controlling the set. The great advantage of the super-regenerative circuit is the enormous amplification obtainable. Another advantage is the fact that radio code signals are not amplified to the same extent as radio telephony. The super-regenerative circuit was devised by Major Armstrong. The *Flewelling Circuit* (q.v.) is a modification of the Armstrong circuit. (See *Armstrong Circuits.*)



Flivver Armstrong Super-Regenerative circuit.

SURFACE MAGNETISM—A synonym for *Free Magnetism* (q.v.).

SUSTAINED WAVES—Continuous or undamped waves. Waves in which similar current cycles follow each other continuously instead of being broken up into groups like *damped waves* (q.v.). The sustained waves may be interrupted by means of a sending key and thus used for sending radio telegraph messages or they may be modulated and thus utilized in radio telephony. Sustained waves are obtained by the use of high frequency alternators, arc condensers, or thermionic electron tubes (vacuum tubes). The use of sustained waves has made radio telephony practicable. Sustained waves permit sharper tuning, require less energy at the transmitter than in the case of undamped waves, and permit the use of "beat" reception and other sensitive methods of reception. (See *Continuous Waves.*)

S.W.G.—Abbreviation for Standard Wire Gauge. The full name of this wire gage is the *British Standard Wire Gauge*. It is also referred to as the *New British Standard*, the *Imperial Wire Gauge*, and the *English Legal Standard.* It is the legally adopted standard of Great Britain. The following table shows a comparison between the American Wire Gauge (B. & S. Gauge and the Standard Wire Gauge:

Gauge No.	*American Wire Gauge Dia. in Mils*	*Standard Wire Gauge Dia. in Mils*

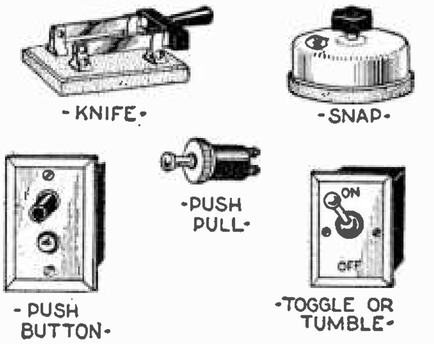
SWITCH—A device for conveniently making or breaking an electrical circuit. Switches must be designed to carry their rated current without overheating or undue voltage drop, to handle overloads, to prevent arcs on being opened and to properly insulate live parts when switch is open. The most common form of switch is the *knife switch* (q.v.). A switch which opens or closes but one circuit, that is operating in only a single position, is called a *single throw switch.* One operating when thrown in either of two positions is called a *double throw switch* (q.v.). A switch which controls only one side of a circuit is a *single pole switch;* both sides of a circuit, a *double pole switch.* The abbreviation for a single pole, single throw switch is S. P. S. T. The abbreviation for a double pole, double throw switch is D. P. D. T., etc. There are various types of switches ranging from *oil switches* used to handle enormous currents to the small push button or snap switches for turning on or off electric lights. Among the switches used in radio work may be mentioned the *ground switch* (q.v.), *aerial switch* (q.v.), *quick break switch* (q.v.) and *anti-capacity switch.* This latter usually consists of a small handle with a cam attached to its other end which serves to press together or release spring contacts. The electrostatic capacity between the springs is low, due to the construction used. The *plug* (q.v.) and *jack* (q.v.) constitute a form of switch extensively used in radio equipment. The *push-pull switch,* operating as its name implies, is often used to control the filament lighting circuits of radio receiving sets.



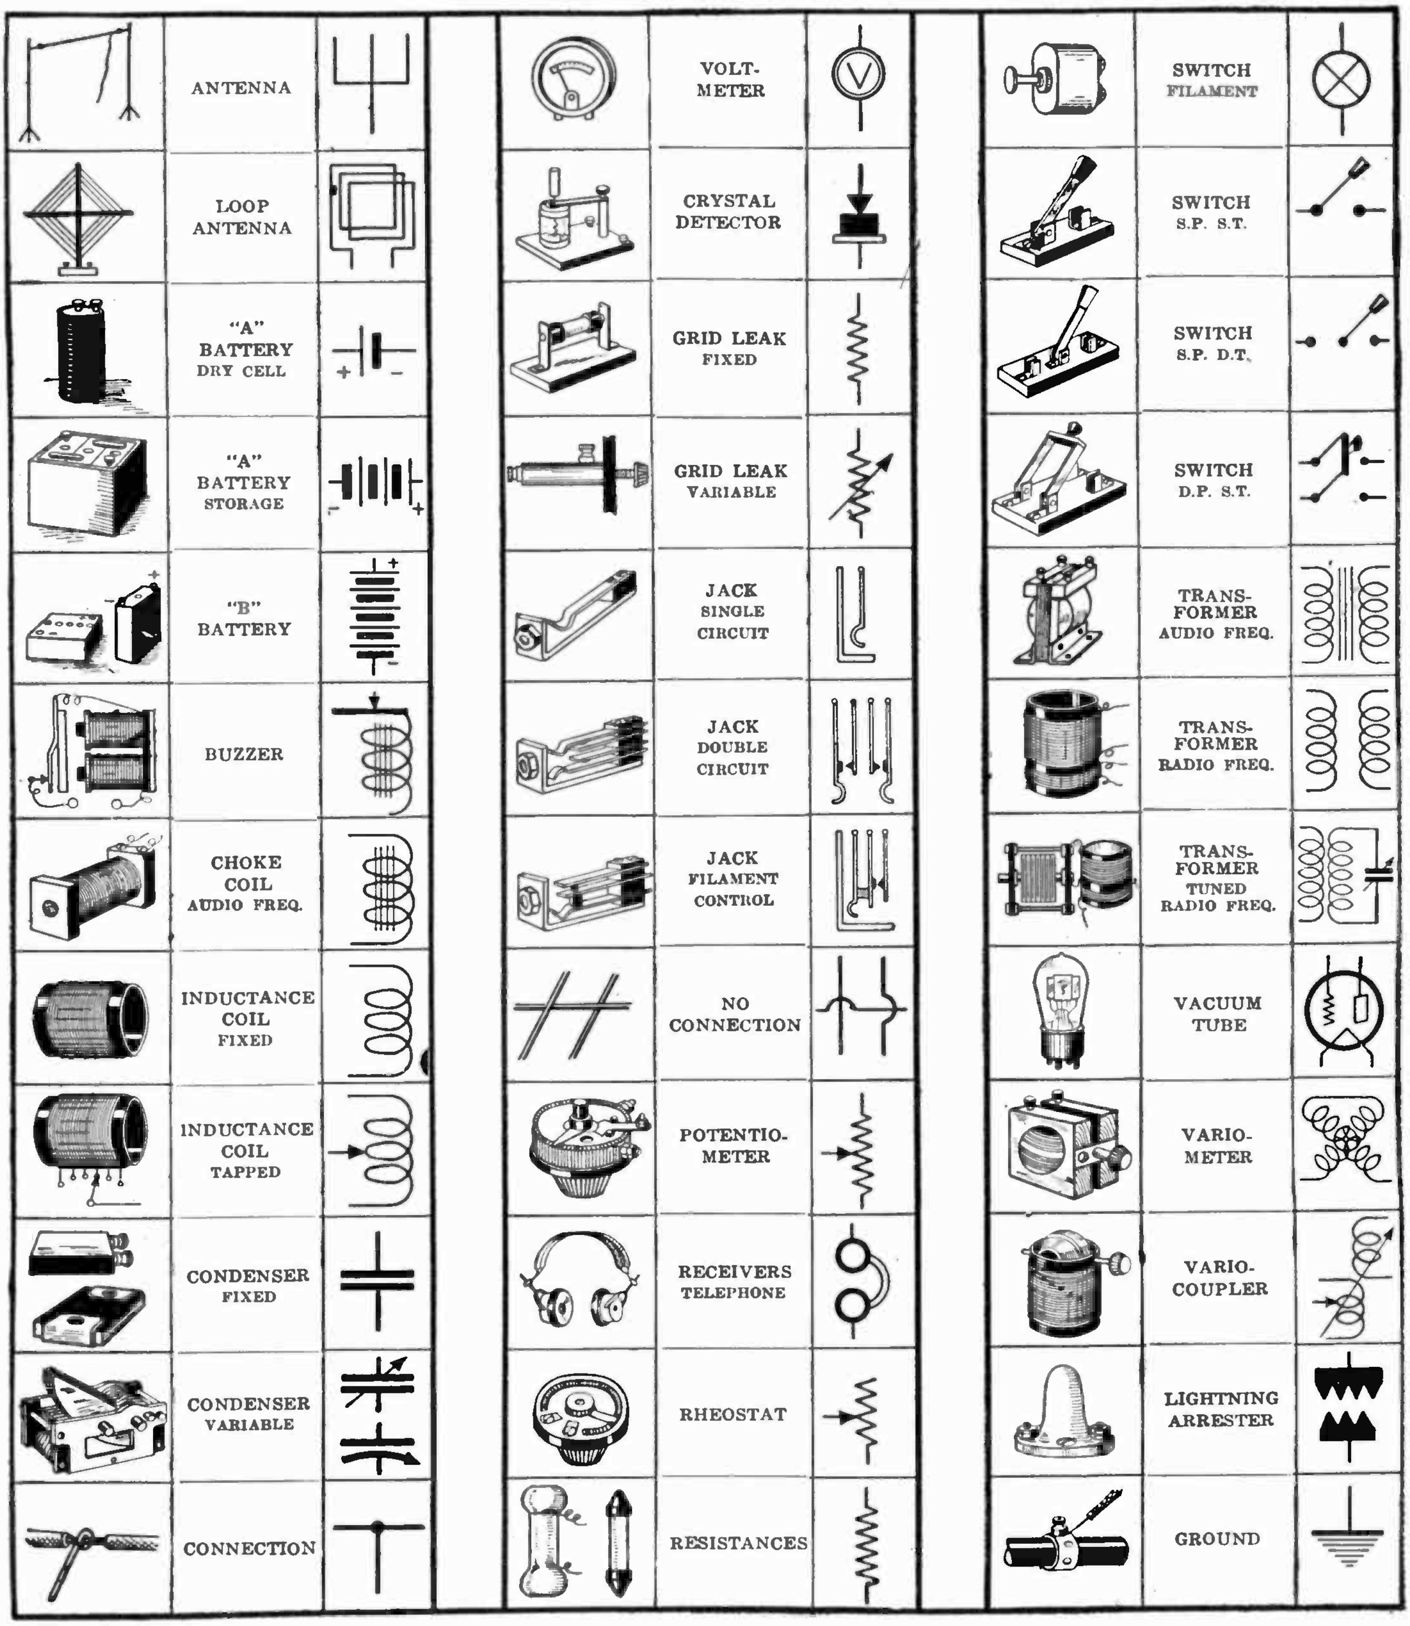
Various types of switches.

SWITCHBOARD—In its broadest sense, this term is applied to any collection of control, operating and measuring apparatus mounted on a panel or panels for the purpose of starting, stopping or otherwise controlling an electrical installation. In a small electrical plant, all control and switch gear may be mounted on a single structure, which is referred to as the switchboard. Switchboards are used at the radio broadcasting station to carry the various meters, control rheostats, switches, etc. (See *Panel.*)

SWITCHGEAR—Apparatus used in connection with the control of an electrical installation, such as switches, rheostats, starters, circuit breakers, etc.

SYMBOLS—Conventional signs used in radio hook-ups to represent various electrical and radio apparatus. The use of symbols has been standardized and results in clearer and more easily drawn diagrams. A table of symbols is given below:

Table of Radio Symbols



ANTENNA	VOLT-METER	SWITCH FILAMENT
LOOP ANTENNA	CRYSTAL DETECTOR	SWITCH S.P. S.T.
"A" BATTERY DRY CELL	GRID LEAK FIXED	SWITCH S.P. D.T.
"A" BATTERY STORAGE	GRID LEAK VARIABLE	SWITCH D.P. S.T.
"B" BATTERY	JACK SINGLE CIRCUIT	TRANS-FORMER AUDIO FREQ.
BUZZER	JACK DOUBLE CIRCUIT	TRANS-FORMER RADIO FREQ.
CHOKE COIL AUDIO FREQ.	JACK FILAMENT CONTROL	TRANS-FORMER TUNED RADIO FREQ.
INDUCTANCE COIL FIXED	NO CONNECTION	VACUUM TUBE
INDUCTANCE COIL TAPPED	POTENTIO-METER	VARIO-METER
CONDENSER FIXED	RECEIVERS TELEPHONE	VARIO-COUPLER
CONDENSER VARIABLE	RHEOSTAT	LIGHTNING ARRESTER
CONNECTION	RESISTANCES	GROUND

SYNCHRONOUS—As applied to alternating currents, these are said to be synchronous when of the same *frequency* (q.v.) and exactly in *phase* (q.v.).

SYNCHRONOUS DISCHARGER—A rotary gap discharger driven by a synchronous motor from the same line supplying the transformer in a radio telegraph transmitting system or a rotary gap mounted on the shaft of the alternator supplying the 500 cycle or higher frequency current. (See *Disc Discharger.*)

SYNTONY—The relationship between two oscillating currents when one resonates to the waves produced by the oscillations of the other.

T

TABLE OF DIELECTRIC STRENGTH—A table showing the voltages at which certain thicknesses of various materials will break down or puncture. The following table has been obtained from Pender's Handbook for Electrical Engineers:

MATERIAL	DIELECTRIC STRENGTH Specimen thickness mm.	Kv. per mm. (a)
Ambroin	0.84	6.0
Asbestos paper	1.2	4.2
Asphalt (Byerlyte)	3.6	14.0
Bakelite, C-1		up to 27.5
Bakelite, wood molding mixture		17.7 to 21.6
Bakelite, asbestos molding mixture		up to 9.8
Bakelite, Continental	3.2	15.7
Bakelite, Micarta-213		up to 31.4
Bakelite, Micarta-21D		5.9
Bakelite, Micarta-21H		15.7
Bakelite-Dilecto-X	3.2	25.6
Bakelite-Dilecto-XX	3.2	25.6
Celluloid (clear)	0.25	12 to 28
Celluloid (colored)	0.25	10.2 to 18.9
Condensite (molded)	5.7	19.7
Condensite (celoron)	5.7	29.5
Conite	0.13	15.7
Copal	3.0	3.2
Empire cloth, canvas	.41	28.9
Empire cloth, linen	.15	54.0
Empire cloth, muslin	.38	48.0
Empire cloth, silk	.15	48.0
Faturan	3.	10
Fiber, vulcanized, including hard fiber all colors	0.79	8.9 to 16.7
	3.2	4.9 to 10.8
	6.4	3.9 to 8.9
	12.7	3 to 5.9
Galalith (white)		6 to 8.5
Glass (ordinary)		8 to 9
Hermit		2 to 3
Jute (impregnated)	6	1.2
Lava		3 to 10
Litholite	4.5	4.5
Marble		6.5
Mica	6	21 to 28
Micabond, plate	1.6	37.5
Micabond, flexible	1.6	23.1
Micanite, plate	1.6	37.5
Micanite, flexible	1.6	23.1
Minerallac		39.4
Paper	0.13	8.7
Paraffin (parawax)		11.5
Porcelain	20	8
Pressboard (oiled)	0.25	39.3
Pressboard (oiled)	1.58	29.2
Pressboard (oiled)	3.17	21.1
Pressboard (varnished)	0.25	26.3
Pressboard (varnished)	1.58	15.5
Pressboard (varnished)	3.17	9.5
Presspahn		5.2 to 9.3
Redmanol (molded)	5.1	11.8 to 18.5
Redmanol (laminated)	0.8	41 to 51
Rubber (hard)	0.5	70
Slate	10.3	1.3
Vulcabeston	1.9	31.5 to 7.1
Wood (maple), paraffined	15.2	4.6

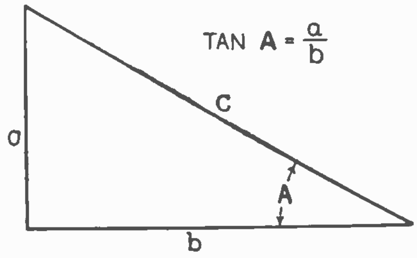
(a) To obtain volts per mil, multiply kilovolts per millimeter by 25.4.

"T" ANTENNA—A flat top antenna in which the down lead is taken from the center of the horizontal portion. (See *Aerial*, also *Flat Top Aerial.*)

TAILS—Name given to small iron wires forming core of *induction coils* (q.v.).

TANGENT GALVANOMETER—A type of galvanometer in which the strength of the currents which pass through the coil is proportional to the tangent of the angle of deflection of the magnetic needle in the center of the coil. In construction, the tangent galvanometer consists essentially of a small magnetic needle suspended in the center of a large circular coil made of the few turns of insulated wire. Attached to the needle is a light aluminum pointer which allows the deflections to be read on a horizontal scale. The coil is placed in the magnetic meridian with the needle and the coil in the same plane. When the current passes through the coil, the pointer is deflected and the angle of deflection recorded. Knowing the constant of the galvanometer, it is possible to calculate the current in absolute units or in amperes by multiplying the constant by the tangent of the angle recorded.

TANGENT OF AN ANGLE—In a right angle triangle having the given angle as one of its angles, the tangent of the angle under consideration is equal to the ratio of the side opposite the angle to the base of the triangle.



The tangent of angle A is the ratio of side a to side b.

TAP-TAPPING—The connection made to an intermediate point in a winding thus permitting the number of turns in the circuit to be varied at will. Variometers, variocouplers and other coils are made with taps, also transformers, armatures of rotary converters, etc.

TAPPED—See *Tap*, also *Tapped Inductance.*

TAPPER—An electromagnetic device, similar to an electric bell, but with gong removed, arranged so that a hammer gently taps a coherer thus decohering filings after the passage of incoming oscillations. This device was formerly used as a detector of wireless telegraph signals.

TAPPING-BACK—The application of a light blow to a filings coherer to decohere the filings. (See *Tapper.*)

TELEFUNKEN SYSTEM—A wireless telegraph system employing a *quenched spark gap* (q.v.) and giving a singing spark of rather high note. This system has been developed and used by the Germans.

TELEGRAPH—Any system of transmitting intelligence from one point to another over a distance. The word was at one time applied to visual systems such as wig-wagging and semaphore, but at the present is used only to refer to electrical systems. The one exception to this rule is the use of the term to refer to signals sent either mechanically or electrically from the bridge of a ship to the engine room.

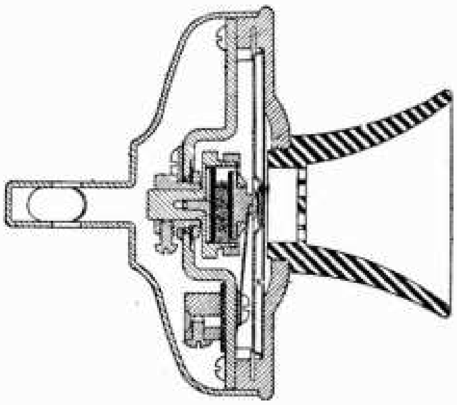
TELEGRAPHONE—A magnetic phonograph in which speech currents or signal currents are recorded as permanent magnetic impressions on a moving steel wire. Instruments such as this have been used for recording telephone conversations and also in high speed automatic wireless telegraph transmission. (See *High Speed Reception and Transmission.*)

TELEGRAPH NAUT—A nautical mile of 2,029 yards or 1.1528 statute miles. (See *Nautical Mile.*)

TELEGRAPHY, RADIO—See *Radio Telegraphy.*

TELEPHONE CONDENSER—In radio work, this is a fixed condenser shunted across the head set or loud speaker. Used in this connection, the condenser is also referred to as a by-pass condenser since it offers a path of low resistance to the radio frequency currents. By-pass condensers are usually made of tin foil with a mica or paper dielectric. Condensers used for ordinary telephone work are also referred to as telephone condensers.

TELEPHONE RECEIVER—An electromagnetic instrument by means of which variations of current are caused to reproduce sound waves corresponding to words spoken into a transmitter at a distant point. The essential features of the telephone receiver are an electromagnet, a permanent magnet and a diaphragm held in a suitable case. The diaphragm is supported by the rim of the case, at a short distance from the face of the magnet and it is attracted by the magnet when it is energized by the current flowing in the windings. The steady magnetic flux of the permanent magnet draws the diaphragm to the pole pieces, leaving a small gap between, so that the diaphragm is held under tension. The currents passing through the electromagnet are modulated in accordance with the transmitted speech. These change the tension of the diaphragm due to the change in magnetic pull and as a result the diaphragm vibrates giving forth speech or music. The telephone receivers used in radio work are of the *watch case* type. (See *Head Telephone or Head-Phone.*)



A cross sectional view of a telephone transmitter showing details of construction.

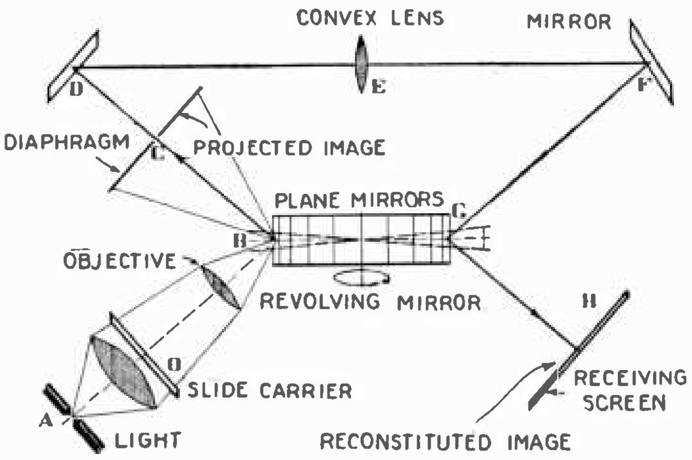
TELEPHONE TRANSMITTER—A sound-wave operated or vibration-operated device designed to produce electromagnetic waves or vibrations which correspond to the sound waves or vibrations actuating it. The standard transmitter used in ordinary telephone work is known as the "solid-back" transmitter. A gong-shaped back supports the transmitter and carries all the parts. A mouth piece of hard rubber is screwed into the front. Just to the rear of the front is placed an aluminum diaphragm which fits into a receptacle cut out for it. An insulated cushion seat of rubber is placed above and below the diaphragm. The diaphragm is held securely by damping springs having soft rubber cushions at their tips, so that it can only assume forced vibrations. An auxiliary diaphragm of mica is used which is fastened to the front electrode of the transmitter button. Both the front and the rear electrodes are made of carbon discs, between which carbon granules are placed in a cylindrical chamber lined with varnished paper. A rigidly connected pin communicates the vibrations of the diaphragm to the front electrode. The movement of the electrode varies the pressure on the carbon granules, thus giving the required variation of resistance which in turn varies the current. The *microphone* (q.v.) used in radio broadcasting is a modification of the telephone transmitter.

TELEPHONE, TUNED—See *Tuned Telephone.*

TELEPHONY, RADIO—See *Radio Telephony.*

TELEVISION—Electric vision at a distance. The transmission by wire or by radio of vision—that is to say the ability to see objects at any distance by changing the light waves to electric currents or to electromagnetic waves, transmitting these to the distant receiving point, and then retransforming them back to the original light waves. Television is still in the experimental stage. Of course, the sending of pictures by radio has been accomplished by Capt. Ranger, in this country, Belin in France, Karolus in Germany, Baird in England, and several others. Both Belin and Baird have been working on the problem of television and are reported to be nearing success. In this country, Mr. C. Francis Jenkins, of Washington, D. C., has constructed a non-commercial (that is in its present stage) machine which will send motion pictures by radio. This is practically the last word in the present development of television. It is possible to broadcast a film picture with this device at the rate of sixteen pictures per second showing the moving outlines as silhouettes, but without the intermediate tones. The method by which a photograph is transmitted by radio in the Jenkins system may be illustrated by the example of a coin covered by a thin sheet of paper on which serried pencil lines are drawn. The design of the coin appears in lines varying in intensity. The variations in the lines may be transformed into pulsing electric current by means of a light sensitive cell passing over the lines in question. Place the lines end to end and the current can modulate a carrier wave. The forming of the continuous line presented a difficulty which was solved in the following way. The inventor proceeded along the line that a prism bends a ray of light and that an image will appear upon a photographic lens placed before a picture. From this it follows that a prism placed near a lens will cause the image to be displaced sideways, the extent of the displacement being dependent on the angle of the prism. If the prism could change its angle, the result would be motion on the part of the image. The prism used is circular, with rapid change of form across the prismatic section. Around the circumference of the disc, the prism changes in thickness according to a graduated scale. Revolving the disc causes the image to move in a straight line. When the end of the prism passes the lens, there is instantaneous snapping back of the picture and the journey is repeated. If a small hole be made in the screen, the light from a given point on the picture will pass through and can be made to operate a light sensitive cell at the back of the screen. When the image is made to move down over the screen by the prismatic ring, the aperture will admit light of varying intensity, according to the light value along a line crossing the picture. This means that the light falling on the photo cell as the image travels will represent a line across the picture from top to bottom. This leads to the creation of the successive lines that make up the picture as a whole. The image is moved along from side to side by means of a second prismatic ring working along at right angles to the first, but at much lower speed. This second prism makes but one revolution during the time that the first makes one hundred, producing the hundred lines assumed to be necessary for making the picture. The cell used may be selenium or thalium oxide. The former requires twenty minutes to cover the picture, the latter six. It is obvious that to reproduce the picture at the other end the process must be reversed, the lines being replaced side by side by means of a pair of prismatic discs similar to those at the transmitting end. As noted above, the main difference between sending photographs and motion pictures is in the necessary speeding up. For this purpose, Mr. Jenkins uses a potassium light-sensitive bulb, the action of which is much more rapid than that of either selenium or thalium oxide. The cell is composed of a bulb with its inner surface coated with metallic potassium. The bulb has a high vacuum. The device has two electrodes, one being a wire through the stem, ending in a loop in the center of the bulb; the other passing through the side of the bulb and connecting with the potassium deposit. Absence of the potassium from a small part of the surface forms a "window" opposite the last named contact. Application of a positive potential to the central electrode, attended by connection with the potassium coating, permits no current to flow as long as no light enters the bulb. The admission of light frees electrons from the potassium, in numbers proportionate to the strength of the light. In this way a current flows through the bulb when light enters the "window." In this cell, there is no appreciable lag due to the amazing speed of the electrons.

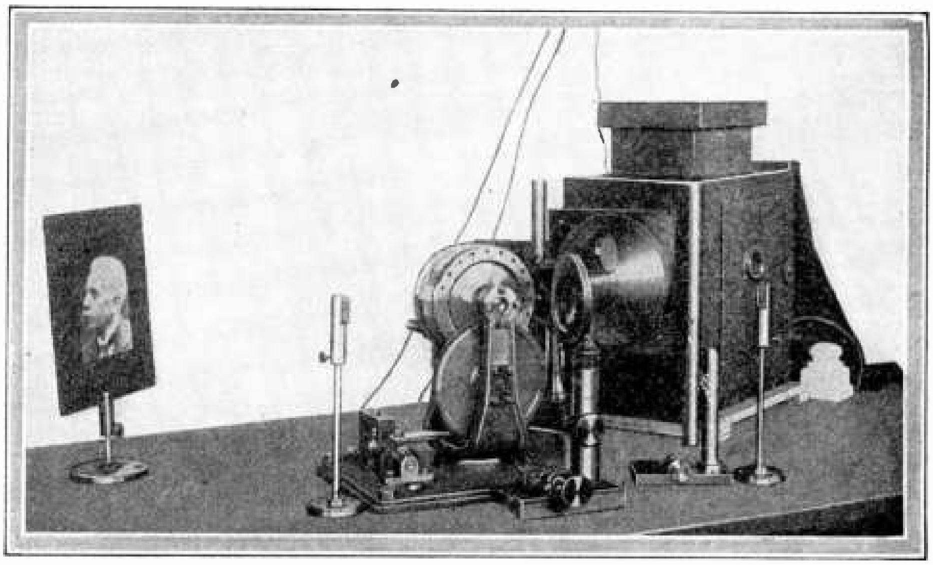
The cylinder is covered with plane mirrors, revolving downward on the side toward the lantern. One ray' at a time from 1/25,000 of the area of the image, passes through the opening in C. The fixed mirrors D and F send it back to the mirror G, opposite B on the cylinder, and it is finally reflected against H in a position corresponding exactly to the portion of the image from which it was first taken. The effect of continuous vision is produced.



The sending station has a motion picture projector, a small machine used to cut up the image, a light-sensitive cell, and a transmitter. The receiving station has a radio receiving set, a machine for reassembling the picture, and a screen for the reproduction of the image.

The lamp required for the receiving station must be able to pass swiftly from darkness to extreme brilliancy, and the ordinary filament lamp could not attain the tremendous speed involved. The lamp used by Mr. Jenkins is the creation of Professor McFarlane Moore, and is capable of handling complete cycles at the rate of 75,000 to the second. This lamp has a glass bulb containing two concentric cylinders, the larger almost filling the bulb, and the smaller almost filling the larger. The inner cylinder has a small axial hole, drilled almost to the bottom and forming a deep cup. The principle of this lamp is much the same as that of the Amrad "S" valve.

It is a truism that the fundamental principle of cinema pictures is that the human eye continues to see an image



This apparatus is diagrammed above: the projecting lantern at the right; the drum of mirrors, center; and the adjusting stands for diaphragm and fixed mirrors in front. At the left a continuous image appears on the screen, although only 1/25,000 of it is actually projected at any instant.

after that image itself has disappeared. In the case of an electric spark lasting one ten thousandth of a second, the image lasts for at least one-sixteenth of a second as visualized by the eye. Mr. Jenkins assumes that if 10,000 dots of light and shade flash successively on a screen with sufficient speed, the eye will see the picture to which the dots belong even though but one dot is on the screen at a time. He, therefore, aimed at flashing the 10,000 dots on the screen within the space of one-sixteenth of a second.

Theoretically, this feat might be accomplished by halving the slow disc revolving rate to 960 revolutions per minute, keeping the faster disc at a rate exactly one hundred times greater. But the glass disc would be shattered by the centrifugal force before the attainment of a speed of 96,000 revolutions per minute.

Mr. Jenkins gets over this difficulty by the use of forty-eight lenses attached to a large aluminum disc rotating in front of the prismatic disc, thus giving the effect of a slow-moving lens. Each of these forty-eight lenses makes a line across the plate, which thus becomes the screen of the motion picture apparatus. This makes it possible to reduce the speed to one forty-eighth of that which would otherwise be required, that is, to one of 2,000 revolutions per minute.

At the receiving station, the modulated wave is received by a set but slightly different from many in common use. The last amplifier tube is one of 5 watts. By the use of the McFarlane Moore light already described, the modulations in the plate circuit of the last valve are transformed into light, and the rays are distributed over the screen by prismatic and lens discs similar to those used at the sending station. In actual practice, the picture appears on a screen about 6 in. by 8 in. More powerful lamps would allow of larger pictures.

The process described is for sending photographic pictures. But it can be adapted for the sending of direct views without the intervention of photography.

All that is done in this case, is to remove the projector and focus the lens so that it will throw the view as an image.

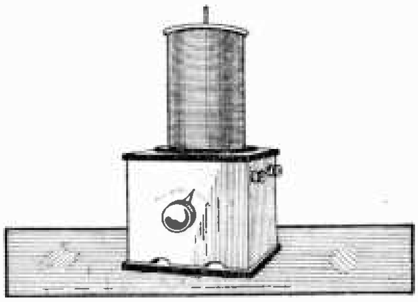
So far as radio features of the transmission are concerned, there is little to be explained. At the receiving station the circuit resembles the superheterodyne. The picture is at 75 kilocycles frequency and does not interfere with broadcasting.

The carrier wave may be modulated with voice frequency, so that the voice can travel with the picture, which enables vocal explanations to be given simultaneously with the flashing of the film or actual scene being transmitted.

TEMPORARY MAGNETS—Magnets which lose their magnetic properties as soon as the magnetizing force is removed. Soft iron displays the properties of a temporary magnet and hence is ideal for use as the core of electromagnets. (See *Magnet*, *Electromagnet*, also *Permanent Magnet*.)

TERMINAL—A binding post or other fitting attached to the electrodes, ends of windings or other parts of electrical apparatus so as to permit the external circuit to be connected to the apparatus.

TESLA COIL—An oscillation transformer for producing high potential discharges from oscillations of low potential. The *Tesla Coil* or *Tesla Transformer*, as it is sometimes called, is somewhat similar to the ordinary transformer, although it is much more heavily insulated and has the ends of the secondary connected to a condenser which discharges across a spark gap, thus increasing the rapidity of the oscillations, which then pass into a secondary induction coil. This second coil has no iron core. The Tesla Coil consists essentially of a primary winding having a relatively small number of turns of heavy wire and a secondary having a large number of turns of fine wire. An air, glass, or ebonite dielectric separates the primary and the secondary. Due to the sufficient thickness of the dielectric, there is no possibility of a direct discharge between the two windings. Both the primary winding and the secondary winding consist of but one layer each. The primary winding forms part of an ordinary oscillation discharge circuit. A high frequency electromotive force is induced in the secondary winding, due to the high frequency oscillating currents which flow in the primary winding thus setting up an oscillating magnetic field. Due to the high ratio between the windings of the primary and the secondary, very high voltages are set up in the secondary, in some cases as high as a million volts, and hence a very powerful brush discharge can be obtained.



Tesla coil.

TESLA, NIKOLA—American electrical and radio expert. Tesla was born at Smiljan, in Jugo-Slavia, 1857, and was educated at Graz and Prague Universities. He entered the Austrian Telegraph Service and in 1884 he came to the United States where he became an assistant to Edison. He specialized in the study of high frequency and high potential alternating currents. Tesla is noted for his many revolutionary inventions which include polyphase alternating current systems, the rotating field alternating current motor, arc lighting, the *Tesla transformer* (q.v.), and radio apparatus of many kinds including *radio control* (q.v.) devices.

Nikola Tesla.

TESTING CIRCUIT (BUZZER)—A circuit in which a buzzer is used for the purpose of testing or of locating faults in radio apparatus. A buzzer connected in series with a dry cell can be used for locating open circuits and also for testing for short circuits. A buzzer connected in series with a battery and an inductance coil, so as to form a closed circuit and having the inductance coil placed so as to be coupled with the antenna coil of a crystal detector receiving set, can be used to determine the most sensitive point of contact of the crystal. A *tuned buzzer tester* is sometimes used in connection with radio direction finder systems.

THEORY OF CURRENT FLOW—While it is assumed for convenience, that an electric current flows along a conductor from the positive terminal of the source and back to the negative terminal, modern theory is that the electrons actually travel in the opposite direction. Whenever there is a flow of electricity in a conductor, it is believed that extremely small particles of electricity, called *electrons* (q.v.), pass along this conductor. Matter is made up of atoms, which in turn are composed of electrons. The electrons are minute particles of negative electricity revolving around a positive particle. All electric current flow is based upon the motion of electrons within a conductor.

THEORY OF DETECTOR ACTION (OF VACUUM TUBE)—The vacuum tube used as a detector performs a two-fold purpose—it rectifies the current so that it is capable of actuating a telephone receiver and in addition it amplifies or strengthens the current. The rectification takes place due to the fact that the electron flow is only possible from the filament to the plate, but not in the reverse direction. The radio frequency currents applied to the grid regulate the number of electrons passing from the filament to the plate, the variation being exactly in accordance with the variations of the radio frequency current. (See *Detector, Vacuum Tube*.)

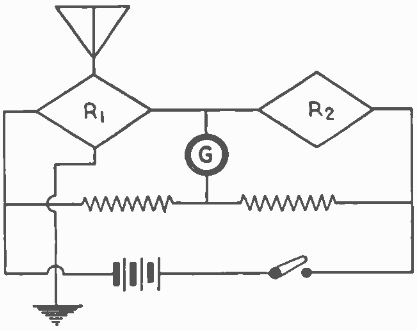
THEORY OF OPERATION OF VACUUM TUBES—The operation of the three-electrode vacuum tube depends upon the emission of electrons from the hot filament to the plate and the control of the flow of these electrons by means of the potential variations applied to the grid. The vacuum tube consists of an evacuated bulb containing a tungsten filament treated with thorium, an anode or plate, which may be in the form of a cylinder or plate, and a grid consisting of a wire grating inserted between the filament and the plate. When the filament is heated it gives forth electrons which are attracted to the plate under the influence of a difference of potential by which the plate is maintained positive with respect to the filament. The grid is an automatic control, regulating the flow of electrons from filament to plate. Potential variations applied to the grid serve to vary the electron flow between the filament and the plate. The circuit in which the vacuum tube is used may be divided into two parts, the input circuit connecting the filament to the grid through the secondary of a transformer or other method or applying potential changes to the grid, and the output circuit between filament and plate. The vacuum tube may be used as a detector or rectifier, as an oscillator or generator of high frequency oscillations, as an amplifier, as an electrostatic voltmeter, as a voltage and current regulator, a power limiting device, etc.

THEORY OF PROPAGATION OF ELECTROMAGNETIC WAVES—Waves are due to vibrations transmitted through a continuous elastic medium. Electromagnetic waves are due to vibrations caused by an oscillating electric charge in a circuit (the transmitting aerial circuit). The current flowing in the aerial is oscillating (surging back and forth) at an enormously high frequency and in addition to its induction field, the aerial has associated with it a *radiation field* which spreads out in all directions from the aerial. The strength of the radiation field decreases in inverse proportion to the distance from the aerial. At any given point the strength is directly proportional to the frequency. The transmission of electromagnetic waves is considered as due to the motion of the lines of force. There is a displacement of electricity along these lines against the elastic force of the medium, termed for convenience the *ether* (q.v.). Displaced electricity continuously tends to go back to its position of rest under the action of the elastic forces. There is pressure at right angles to the lines of force in addition to the tension along them. The pressures may be considered as due to the repulsion between the displaced charges of the same sign in neighboring lines of force.

THEORY OF RECEPTION OF ELECTROMAGNETIC WAVES—As electromagnetic waves cut across a receiving aerial, the electric field intensity along the aerial alternates in value. There is an alternating potential between the aerial and the ground which gives rise to the flow of an alternating current. Another explanation is based on the principle of induction. The magnetic and electric fields, in cutting the aerial, induce electromotive forces which cause current to flow. This is radio frequency current and it is passed to the grid of the detector tube and rectified as explained under *Theory of Detector Action* (*of Vacuum Tube*). (See *Electromagnetic Waves.*)

THEORY OF VACUUM TUBE OPERATION—See *Theory of Operation of Vacuum Tubes.*

THERMAL—Pertaining to heat. There are various electrical and radio devices which depend upon heating or thermal properties. The *thermal ammeter* (q.v.) is described under the heading *Hot-Wire Ammeter.* The *thermal detector* is taken up under *Barreter* and *Liquid Barreter.*



A thermal detector. By means of the change of resistance of a conductor, due to heating, electro-magnetic waves are detected. R_1 and R_2 are two rectangles of very fine iron wire.

THERMAL AMMETER—A current meter, in which the current or a fixed proportion of the current in question, passes along a fine wire. This heats the wire, causing it to expand or sag. This deflects a pointer or mirror across a calibrated scale. The thermal ammeter can be used for measuring direct or alternating currents. (See *Electrothermal Meter,* also *Hot-Wire Ammeter.*)

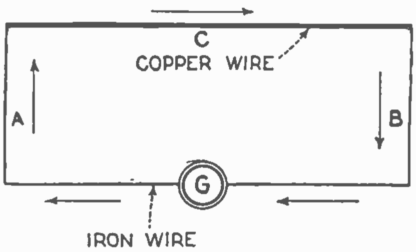
THERMAL DETECTOR—A radio *detector* (q.v.) which depends for its operation upon the heating of a fine wire by the passage of electrical oscillations. (See *Barreter.*)

THERMAL JUNCTION—**THERMO-ELECTRIC JUNCTION**—The contact *point* or joining point of the two dissimilar metals of a *thermo-electric couple* (q.v.). (See *Klemencic Thermal Junction.*)

THERMAL TELEPHONE—A telephone receiver in which the movements of the diaphragm are regulated by the variations of expansion of a wire heated by the telephone currents thus reproducing sound waves. In another type of thermal telephone, the diaphragm is dispensed with, sound waves being reproduced directly through the expansion and contraction of air in contact with the heated wire. This device is also known as a *thermal receiver* or a *hot-wire telephone.*

THERMIONIC EMISSION—The emission of a stream of negative electrons from a heated filament (cathode) in a vacuum tube.

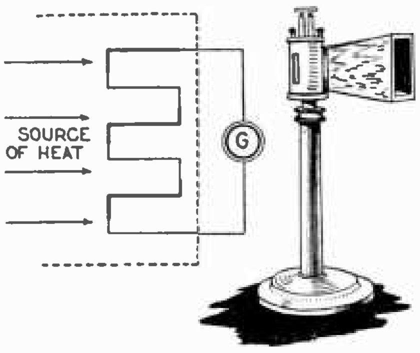
THERMO-ELECTRIC COUPLE—**THERMO-COUPLE**—A pair of dissimilar metal pieces placed in contact and connected by electrical conductors in a closed circuit. When the junction of the two dissimilar metals is heated, an electric current will flow.



A current is caused to flow by heating the junction of two dissimilar metals. If the end at B is heated the direction of flow will be as shown by the arrows.

THERMO-ELECTRIC CURRENT—A current which is caused to flow due to an electromotive force set up at the junction of two dissimilar metals when these metals are at different temperatures. (See *Peltier Effect.*)

THERMOPILE—A device for magnifying the effect of the thermo-couple by connecting a number of these in series and exposing one set of alternate junctions to the heat, thus causing the electromotive forces to add up.



At the left is shown method of joining thermopile junctions to multiply the effect. At the right is a sensitive thermopile.

THOMSON EFFECT—The phenomenon of the appearance or disappearance of heat when a current flows from a cold towards a hot part of a conductor. If copper is unequally heated, heat is liberated at a point when the current and the heat flow in the same direction and is absorbed when they flow in opposite directions. The Thomson effect is measured by a quantity termed "the specific heat of electricity."

THORIUM—A rare metal which in certain compounds in radio-active. This metal has a specific gravity of eleven and an atomic weight of 232.5. Thorium is used for coating Welsbach mantles and is also used in connection with the coating of the tungsten filaments used in vacuum tubes. (See *Filament, Thoriated,* also *Thorium Treatment of Filaments.*)

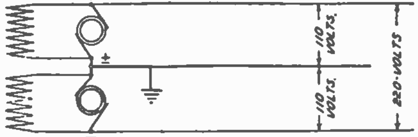
THORIUM TREATMENT OF FILAMENTS—A compound of thorium, thoria (ThO_2) is used extensively in the manufacture of filaments for vacuum tubes. Sometimes thorium nitrate is used for this purpose. The filament so treated is termed thoriated tungsten. Since the rate of electron emission from a thoriated tungsten filament at a given temperature is several thousand times greater than in the case of the ordinary tungsten filament, it is possible to use the former at a much lower temperature. (See *Filament, Thoriated.*)

THREE CIRCUIT TUNER—A *regenerative circuit* (q.v.) in which the primary, the secondary or grid circuit, and the plate circuit are capable of being tuned in resonance with each other.

THREE-ELECTRODE THERMIONIC TUBE—An evacuated bulb or vessel containing a combination of a heated cathode, a relatively cold anode and a third electrode for controlling the current flowing between the other two electrodes. (See *Triode,* also *Vacuum Tube.*)

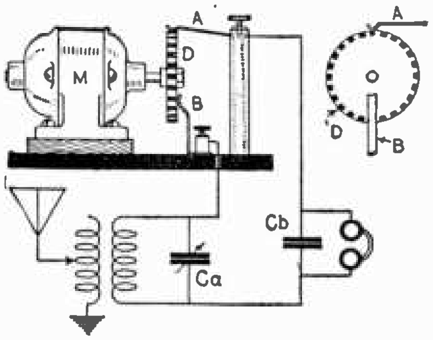
THREE-ELECTRODE TUBE—The three element thermionic vacuum tube having a filament or cathode, a plate or anode, and a grid. This tube can be used with minor modifications as a *rectifier* (q.v.) or *detector* (q.v.) of radio signals, an *amplifier* (q.v.), an *oscillation generator* (*oscillator* (q.v.)), an *electrostatic voltmeter* (q.v.), as a *power limiting device,* etc.

THREE WIRE SYSTEM—In direct current work, a system of transmitting electrical energy, which utilizes three wires, one of which is maintained at a potential, midway between the other two. A part of the load is connected between one wire and the neutral and part between the other wire and the neutral. As a result the neutral wire only carries current equal to the difference in the loads. The main advantages of this system are a saving in copper and availability of double voltage. Thus 110 volts may be required for lights, whereas 220 may be wanted for electric motors. In alternating current work reference is sometimes made to a two-phase three wire system. In this system there are two single phase currents which differ in phase by 90 degrees. Each current has a separate outgoing wire, but unites in a common return wire. (See *Neutral Wire.*)



THE EDISON THREE WIRE SYSTEM

TICKER or TIKKER—A form of interrupter or an equivalent apparatus, used in sustained wave telegraphy. It is really a commutator interrupter. In a commercial type illustrated, a disk is mounted on a motor shaft. The disk has a number of teeth filled in between with fibre or other insulating material. The radio frequency currents flow from one brush to the other through the disk which interrupts them at the rate of from 300 to 1000 times per second. A charge is built up in the condenser C_a by resonance with the aerial system and this discharges into the telephone condenser C_b at regular intervals. The telephone condenser then discharges through the head set, thus producing a single sound corresponding to the charge accumulated. Since the tikker discharges the condenser, C_a at different places on the cycle of the incoming oscillations, the note produced is not uniform and is hard to read through atmospheric interference. (See *Chopper.*)



A simple Poulsen ticker. This is used to interrupt circuits of a receiving tuner at a uniform rate per second.

TICKLER—TICKLER COIL—A coil placed in the plate circuit of a regenerative receiver and coupled inductively in the grid coil in order to obtain regeneration. (See *Feed-Back, Feed-Back Coil, Feed-Back Coupling, Regenerative Circuit, Regenerative Coupling,* also *Regeneration.*)

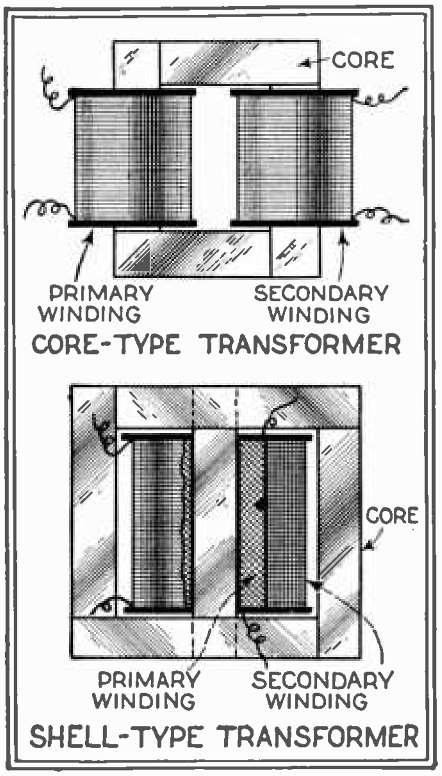
TIME CONSTANT—The ratio, in an electric circuit, of the inductance in henries to the resistance in ohms. It is the time, in seconds, required for a current to attain 63.2 per cent of its ultimate value as given by Ohm's Law. (See *Impulse E.M.F.*)

TONE WHEEL—An apparatus used in the reception of wireless telegraph signals in continuous wave systems, utilizing a wheel in which the conducting teeth are separated by insulating material. A brush is used to make contact with the wheel. The tone wheel is similar in principle to the *tikker* (q.v.) except that it converts the incoming oscillations to audio frequency currents, thus doing away with the non-uniform note of the tikker. In addition to this the tone wheel utilizes more of the incoming energy than does the tikker. The tone wheel is run at such a speed that the frequency of the interruptions differs slightly from that of the incoming oscillations thus giving *beats* (q.v.) which produce audio frequency currents which can be heard in the telephone receiver. Since the tone wheel mechanically converts radio frequency currents into audio frequency currents it is sometimes called a *frequency transformer.*

TORQUE—The moment of a system of forces tending to produce rotation. It is usually measured in foot-pounds. Torque may also be defined as that which produces or tends to produce torsion. Thus if a force acts at a tangent to the periphery of a circle, thus producing a turning moment about the center of the circle, the product of the force and the radius of the circle is called the torque.

TRAIN RADIOPHONE—Communication by means of radio between moving trains and ordinary land-line telephone systems. Such a system is in operation commercially in Germany on trains operating between Berlin and Hamburg. The voice frequency currents from the telephone are impressed on a carrier wave by a method similar to the *Heising Modulation* (q.v.) system. Each train has a special wave length assigned to it. The modulated wave is emitted through a four-wire antenna, strung along the roofs of two coaches. The nearby telegraph wires pick it up and carry it to the receiving sets, located in stations along the line. The ground for the system is obtained through contact of the car wheels with the rails. In reverse order, the voice frequencies of messages from the telephone at the other end are used to modulate a carrier wave (using a different frequency) at the nearest train-telephone switchboard. They are then transmitted over the wires and inductively to the train. An arrangement is provided to prevent interference between the sending and the receiving sets.

TRANSFORMER—A type of induction apparatus, usually stationary, having primary and secondary windings, ordinarily insulated from each other. These are wound about an iron core. The function of the transformer is to change the electrical energy either increasing or decreasing the voltage, current, frequency or phase. Transformers can only be used in connection with alternating currents. Transformers for changing voltage have a different number of turns in the primary than in the secondary. In the step-up transformer, the primary usually consists of a small number of turns of comparatively heavy wire, while the secondary consists of a larger number of turns of fine wire. The ratio of the primary and secondary windings determines the ratio between the input and the output voltages; thus a 10 to 1 step-up transformer could be used to step a primary voltage of ten to a secondary voltage of 100. There are various methods of classifying transformers, namely, according to their operating characteristics, according to their method of cooling, or to their construction. Transformers which are meant to give a constant voltage on the secondary side are known as *constant potential transformers.* Those meant to give constant current are called *constant current transformers.* Transformers may be air cooled, water cooled or oil cooled. In some cases a natural air draft is used as in transformers of the smaller types. Larger transformers may be designed with special ducts through which blowers force a current of air. Oil cooled transformers may have the cores and windings immersed in oil, or the oil may be circulated through external coils. Water cooled transformers are immersed in oil, but have pipes carrying running water submerged in the oil. According to construction, transformers are of the core type and the shell type. The core type transformer is used more for high voltage, low capacity work, while the shell type is used for low voltages and high capacities. Transformers find a wide application in radio apparatus. *Audio transformers* are used to couple audio frequency circuits as for example in the case of an audio frequency amplifier. Audio transformers have an iron core and may be *shielded* or *unshielded. Radio frequency* transformers are used to couple radio frequency circuits. They are usually of air core type, although in special instances iron cores are used. Transformers are also used in alternating current chargers, in "A" and "B" battery eliminators and in power sets which operate directly from alternating current houselighting circuits. (See *Charger, Storage Battery, Audio Amplifier, Coupling Transformer, Jigger, Intermediate Transformer, Inductive Coupler, Oscillation Transformer, Air Core Transformer, Core Transfomer, Ratio of Transformation,* also *Shielded Transformer.*)



Two standard types of transformers.

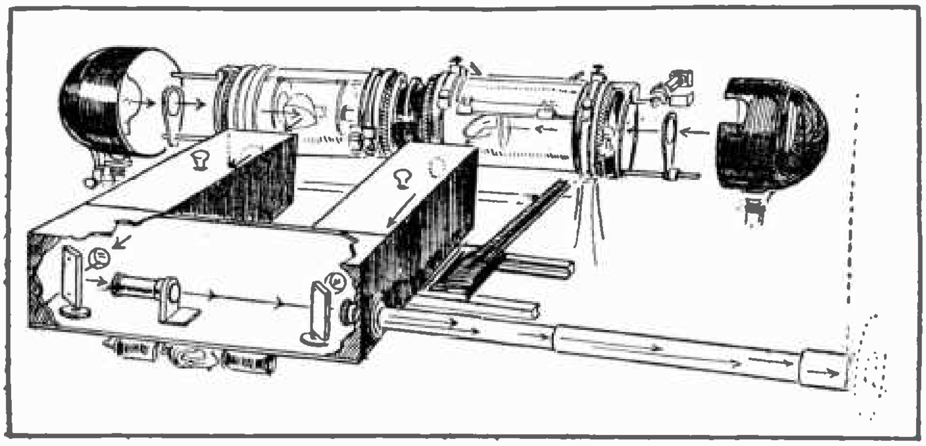
TRANSFORMER COUPLING—A method of transferring the electrical energy of an alternating current from one circuit to another inductively by means of a transformer, one of whose windings is connected in one circuit, the other winding being connected in the second circuit. Radio frequency circuits are usually coupled by *radio frequency transformers, audio frequency transformers* being used to couple audio circuits. (See *Coupling,* also *Amplifier, Intermediate Frequency.*)

TRANSFORMER STEEL—A special steel usually containing a high silicon content used for stamping out transformer laminations. (See *Eddy Currents.*)

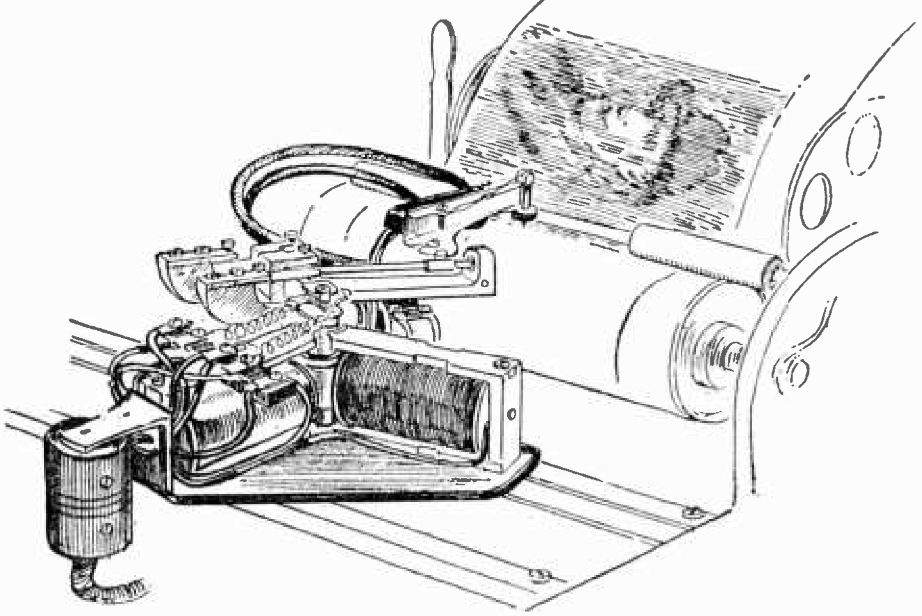
TRANSFORMER, TUNED—See *Resonance Transformer.*

TRANSMISSION—As applied to radio communication, this is the sending of signals, speech or music from one point to another by means of electromagnetic waves. (See *Radio Telephony, Radio Telegraphy, Theory of Propagation of Electromagnetic Waves.*)

TRANSMISSION OF PHOTOGRAPHS BY RADIO—Various methods have been devised and are now in use for the transmission of photographs by radio. Among these may be mentioned the systems of *Belin* (q.v.), *Baird*, and *Jenkins*. The principles underlying the Jenkins system are explained under the heading of *Television*. Using the system developed by Capt. R. H. Ranger, photographs were transmitted by radio from Honolulu to New York, a distance of 5,136 miles. Recently commercial picture transmission service has been inaugurated between New York and London using the Ranger apparatus. Two distinct methods have been applied for analyzing the picture in the process of transmission. One arrangement consists of producing an image as a non-conducting deposit upon a metal foil which is traversed by a stylus, while the other method makes use of an opaque image deposited upon a transparent film which is traversed by a beam of light, the light interruptions being recorded by a light sensitive cell. The Ranger system makes use of this latter method. The image is photographically recorded upon a celluloid sheet large enough to accommodate easily a picture of half-plate size. In the case of sketches and written messages the image for transmission is made directly by writing upon a piece of transparent film with a dense black ink. The image is then secured to the face of a glass cylinder, and by means of a lamp, focussing lens and reflecting prism, a narrow pencil of light is passed through the film. The cylinder is mounted on a carrier which is caused to be moved backward and forward so that the beam of light is concentrated in turn on all parts of the picture. A rotary motion is applied, as well as the transverse motion, the cylinder being given a slight rotation when it completes each transverse motion. The beam of light is passed through a special photo-electric cell. This consists of a spherical globe, coated on the inside with potassium hydroxide, which is very sensitive to light. The coating is connected to the grid of a vacuum tube, while an "electron collector" near the center of the tube is joined to the plate of the first amplifier. When no light is falling on the deposit on the inner surface of the globe, the grid acquires a negative charge, stopping the flow of electrons between filament and plate, and hence no current flows in the external circuit. The ray of light, however, causes an electron stream to flow between the coating and the collector, and since the coating is connected to the grid, the electron flow constitutes a discharged circuit, so that the grid becomes less negative. The first amplifying tube is a direct current potential amplifier, and is resistance coupled. The grid and plate connections of the amplifier are connected across a condenser which becomes discharged with the fall in the grid to plate resistance of the valve brought about by the grid potential fluctuations. A charging circuit is connected to the condenser and is controlled by a valve, the grid circuit of which operates by variations of the potential across the condenser. The charging current is fed through the plate circuit of this valve, in which a relay is connected, which working through other mechanical relays in cascades, controls the radio transmitter. Wave trains from the transmitting station after detection and amplification, are applied to the picture recorder. The recording mechanism, in order that it may be sensitive to exceedingly small currents, comprises, a small moving coil, in a magnetic field created by three electromagnets. The coil of wire, in moving in the field, as the received fluctuations are applied through its windings, operates a stylus while travelling across the surface of the paper. The stylus traverses the paper in perfect synchrony with the carriage of the transmitter, the paper being lifted each time the stylus completes a forward and backward movement across the paper. A small flashing neon lamp is used to indicate the correct speed adjustment of the driving motor.



A pencil of light traverses the picture which is attached to the glass drums and is analyzed by a slow rotating action as well as a backwards and forwards movement of the carrier.



The recording mechanism of the receiver. Three electromagnets produce the magnetic field in which a moving coil controls the stylus.

TRANSMITTER—An apparatus for sending out electrical messages. As applied to radio telegraphy or radio telephony, the transmitter refers to the entire sending apparatus. The term transmitter is often used to refer to a *telephone transmitter* (q.v.). (See *Automatic Transmitter*, also *Wheatstone Transmitter.*)

TRANSMITTING AERIAL—A wire, or more usually a group of wires, suspended at a suitable height and connected to a radio transmitting set. The purpose of the aerial is to facilitate the radiation of the electromagnetic waves generated by the high frequency oscillating current which flows in the aerial. (See *Directional*, also *Receiving Aerial.*)

TRANSMITTING JIGGER—An *oscillation transformer* (q.v.) having a variable secondary, permitting of various degrees of coupling, by adjustment, between the two circuits. (See *Jigger*).

TRANSMITTING KEY—A telegraph key, used in the sending of radio code messages. This key must be of rather heavy construction since it handles larger currents than those used in ordinary wire telegraphy. Pressing the key, closes the circuit, and by holding the key down for a longer or a shorter period, the dots and dashes of the continental code are reproduced. (See *Code, Key, Key High Speed.*)

TRANSMITTING TUBE, POWER RATING—The useful power output from an oscillating tube is the power expended by the oscillating current in the resistance of the output circuit. The power input to the tube, not counting that expended in heating the filament, is the product of the plate supply voltage and the average plate current during an oscillation.

TREMBLER—A springy metallic blade carrying a soft iron armature. The spring makes contact with a fixed contact point, but when current passes through the electromagnet, the armature is attracted and the contact is broken. The spring then resumes its normal position, re-establishing the contact and the same process is repeated again and again. (See *Interrupter.*)

TRIGGER BATTERY—A term (seldom used) denoting a small battery inserted in the grid circuit to give the grid its initial charge when a tube is being used for radio transmission. In this connection, the battery is used to replace the potentiometer. (See *Grid Battery,* also *Grid Bias.*)

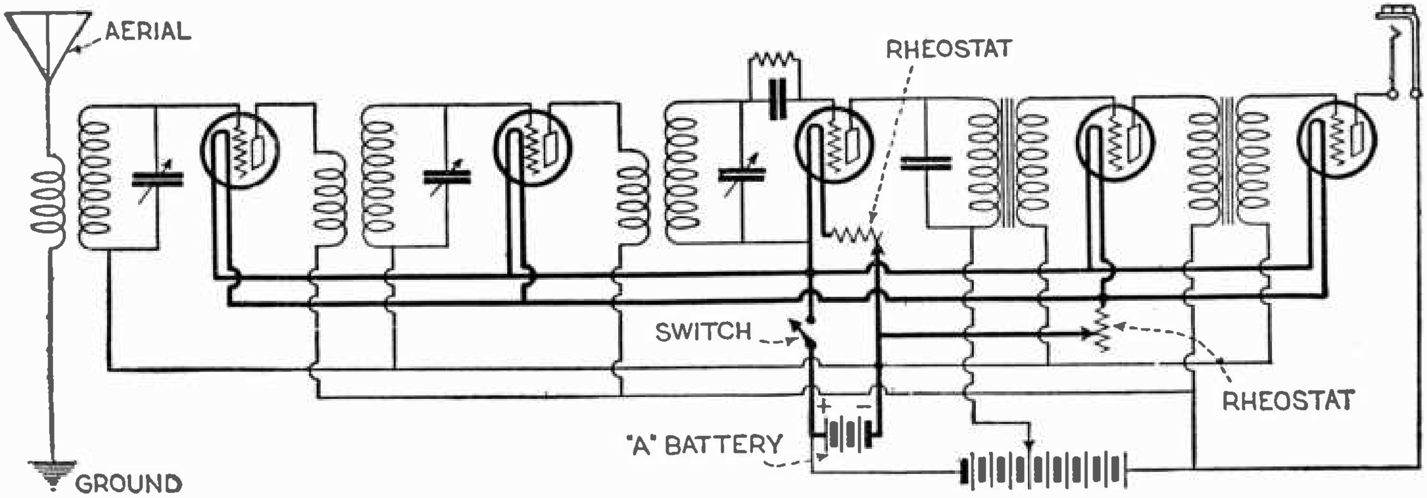
TRIODE—A name used to designate the three-electrode type of *thermionic tube.* Other names sometimes applied to the same device are *audion* (q.v.), *audiotron, aerotron, electron relay* (q.v.), *electron tube* (q.v.), *pliotron* (q.v.), *thermionic valve, oscillion* (q.v.), *vacuum tube* (q.v.), etc. (See *Three-Electrode Thermionic Tube.*)

TRUE POWER—The product of the *apparent power* and the *power factor* (q.v.) in an alternating current circuit. (See *Power, True,* also *Power, Apparent.*)

"T" TYPE AERIAL—See *"T" Antenna.*

TUBE OF FORCE—A theoretical conception, similar to *Line of Force* (q.v.) used in mathematical considerations of electrostatic or electromagnetic fields.

TUBE RECTIFIER—A vacuum tube or gas filled tube used to change or rectify alternating current to direct current. The principle of the vacuum tube rectifier is the fact that the electrons will flow from the hot filament to the plate, but not in the reverse direction. Tubes are made for half-wave or full-wave rectification. (See *Rectifying Tube.*)



A standard five tube tuned radio frequency circuit.

TUBE, THREE ELEMENT—See *Triode,* also *Three-Electrode Thermionic Tube.*

TUBE, TWO ELEMENT—See *Fleming Valve.*

TUBING—In general, this refers to the bakelite or hard rubber forms used to wind inductance coils on. Another type of radio tubing is defined under *Spaghetti.*

TUDOR ACCUMULATOR—A storage battery having special positive plates formed by the *Plante* process and negative plates of the *Faure* or pasted type. The Tudor positive is of the cast-lead type. This plate has no central web and is made by casting pure soft lead in a mold. Casting is advantageous since it permits the distribution of the metal in the plate without limitations in the manufacturing process. After the plate is removed from the mold, its surface consists of a large number of short vertical ribs which run entirely through the plate. These are bound together by short transverse ribs for the purpose of giving strength to the plate. This gives a large surface and since there is no central web, the electrolyte is enabled to circulate through the plate thus working the active material uniformly.

TUNED ANTENNA—A transmitting aerial, having a loading inductance or a variable condenser or both in series with it, for the purpose of changing the antenna wave length.

TUNED IMPEDANCE—This refers especially to a circuit, or to a method of radio frequency amplification in which a tuned inductance connected in parallel with a variable condenser is used as the method of coupling rather than transformer or resistance coupling. (See *Impedance Coupled Amplifier.*)

TUNED RADIO FREQUENCY—See *Tuned Radio Frequency Circuit.*

TUNED RADIO FREQUENCY AMPLIFIER—A combination of a *radio frequency transformer,* a variable condenser and an amplifying vacuum tube in a radio receiving circuit for the purpose of increasing the intensity or amplifying the radio frequency signals.

TUNED RADIO FREQUENCY CIRCUIT—A radio receiving circuit employing radio frequency amplification in which the radio frequency amplifier circuits may be tuned to the desired wave lengths by varying the inductance or the capacity, or both although the usual method of tuning is by means of a variable condenser in parallel with the secondary of the radio frequency transformer. A typical five-tube tuned radio frequency circuit is shown in the accompanying illustration. This consists of two stages of tuned radio frequency amplification, a detector and two stages of audio frequency amplification.

TUNED RADIO FREQUENCY TRANSFORMERS—An air core *transformer* (q.v.) shunted by a variable condenser used in a *tuned radio frequency circuit* (q.v.). (See *Fixed Coils,* also *Low Loss Coils.*)

TUNED TELEPHONE—One in which the diaphragm is adjusted to vibrate at the same frequency as the current impulses to be indicated. In addition the telephone circuit may have its inductance and capacitance chosen to have the same electrical frequency, and a tuned acoustic resonator may intervene between the diaphragm and the ear.

TUNED TRANSFORMER—See *Resonance Transformer.*

TUNGAR—A trade name for a two-electrode vacuum tube especially designed for rectifying purposes. Tungar tubes are made in two ampere and five ampere capacities. They are used in *chargers* (q.v.) and also in radio sets operating directly from the lighting socket without the use of batteries. (See *Rectifying Tube.*)

A typical rectifier tube of the Tungar type. The screw-base allows it to be inserted in a standard lamp socket from which current is obtained for the filament. Connection is made to the graphite disc by means of a Fahnestock connector which clips on to the wire post projecting from the other end of the tube.

TUNING—The process of regulating the inductance and the capacity of a radio circuit in order to be in unison with a desired wave length.

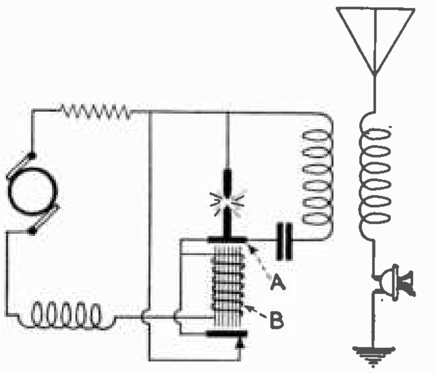
TUNING, BROAD—Reception of a signal over a wide range, that is on a number of wave lengths, rather than on a single one. A receiving set which tunes broadly cannot be used where the broadcasting stations are transmitting on wave lengths near to one another. Too long an aerial may result in a receiving set tuning broadly. (See *Selectivity.*)

TUNING COIL—A coil of wire so arranged that each turn is electrically insulated from its neighbor and with a device by which contact may be made to bring any desired number of turns into the circuit so as to increase or decrease the inductance of a radio circuit so as to tune it to the desired wave length. A variable *inductance* (q.v.) used for tuning an oscillatory circuit. (See *Lengthening Coil.*)

T.Y.K. ARC—A transmitting arc used for radio telephony invented by W. Torikata, E. Yokoyama and M. Kitamura of Japan. This arc uses magnetite and brass electrodes instead of copper-carbon electrodes. A circuit diagram of the T.Y.K. system is shown in the illustration. The materials used for the electrodes are such that a high resistance film forms on their surfaces. This requires a temporary high voltage to start the discharge. This is accomplished as follows: An armature, A, is attached to one of the electrodes. The two electrodes are in contact, and a steady current is caused to flow in the circuit, through the spark induction coil B. This attracts the armature A, drawing the electrodes apart. The break of the spark-coil current at its interrupter induces a high electromotive force which, acting through the coil and the spark gap in series, breaks down the film on the gap electrodes. The power supplied to the gap is 500 volts and 0.2 ampere. A condenser of approximately .05 mfd. is used in the primary oscillating circuit.

T.Y.K. sets have been used only in small units, having a range of 30 or 40 miles.

Several unusual features appear in the circuit shown in the accompanying illustration, which gives the circuit diagram of the T.Y.K. arc.



Circuit diagram of the T. Y. K. arc.

U

ULTRA-AUDION—A name sometimes applied to the vacuum tube used in connection with *beat* reception for supplying local oscillations. In general, however, the name ultra-audion applies to a circuit for radio reception. (See *Ultra-Audion Circuit.*)

ULTRA-AUDION CIRCUIT—A type of circuit used for long wave radio reception which uses a form of regeneration, without calling for the introduction of auxiliary equipment in the circuit. A typical ultra-audion circuit is illustrated. It will be noticed that while one terminal of the secondary goes to the grid, the other terminal, which usually goes to the filament, in this case goes to the plate. Thus there is a direct plate-filament circuit which does not involve the plate and filament batteries in the usual manner.

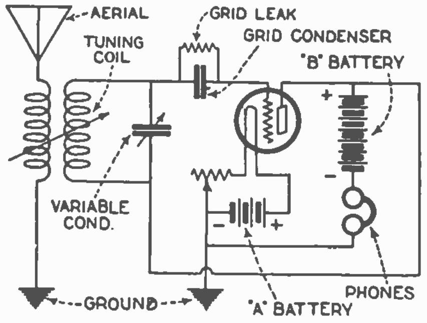


Diagram of an ultra-audion regenerative circuit.

ULTRADYNE—A modification of the *super-heterodyne circuit* (q.v.), which uses the modulation method to produce beats. In this method the incoming signal is caused to modulate the oscillations produced locally in a similar way to that in which the speech or music modulate the carrier wave of a broadcast station. It is claimed that this method is simpler than the ordinary super-heterodyne and also more sensitive to weak signals.

The circuit of the improved model L-2 Ultradyne, incorporating regeneration is shown below. The long wave intermediate transformers are accurately tuned to a wave length of 3000 meters. Referring to the diagram, it will be noted that a special form of oscillator, comprising a grid and plate coil, are used together with an oscillator tuning condenser connected across the grid coil. The first tube, which is usually the detector in the standard super-heterodyne circuit, is known as the modulator tube. (See *Super-Heterodyne Receiver.*)

UMBRELLA ANTENNA—An antenna, the conductors of which form elements of a cone with the apex at the top to which the *down lead* (q.v.) is connected.

UNDAMPED—See *Undamped Alternating Current,* also *Undamped Waves.*

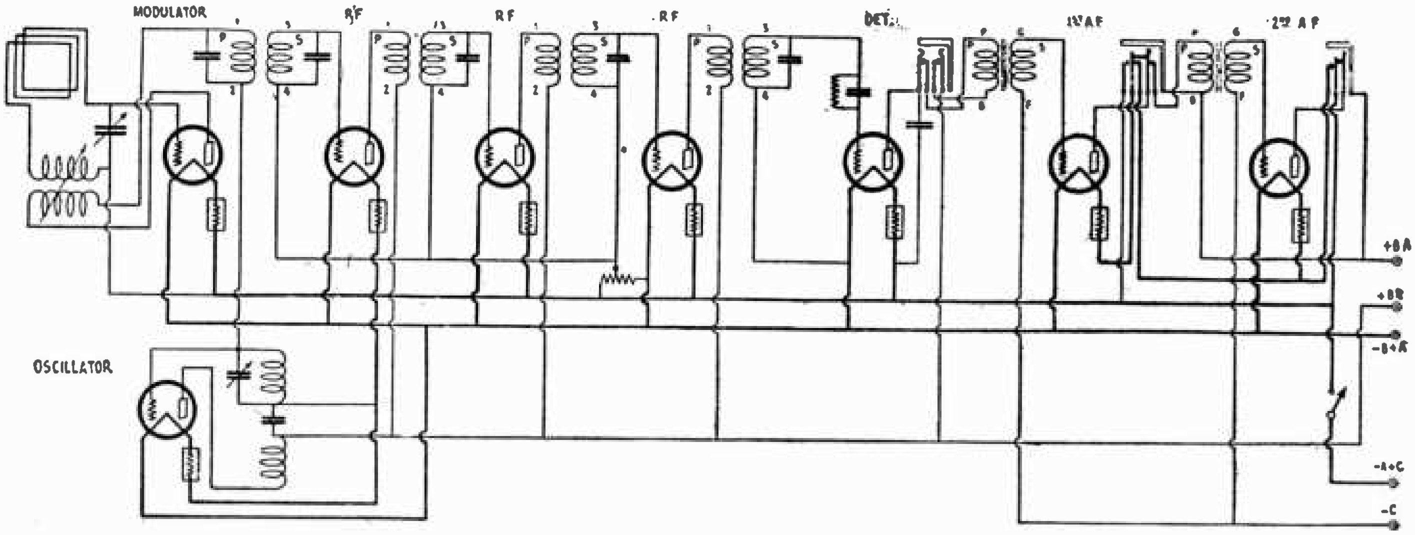
UNDAMPED ALTERNATING CURRENT—Periodic current (i.e., current passing through successive equal cycles of values) whose average value is zero.

UNDAMPED OSCILLATIONS—Oscillations which are sustained. *Undamped alternating current* (q.v.). Oscillations such as are generated by a *vacuum tube oscillator* or by an *arc generator.*

UNDAMPED WAVES—Continuous waves. Waves in which similar current cycles follow each other continuously instead of being broken up into groups. (See *Sustained Waves, Decadent Wave,* also *Damped Waves.*)

UNITS—Specified amounts of physical quantities used as a basis of measurement. (See *Practical Units.*)

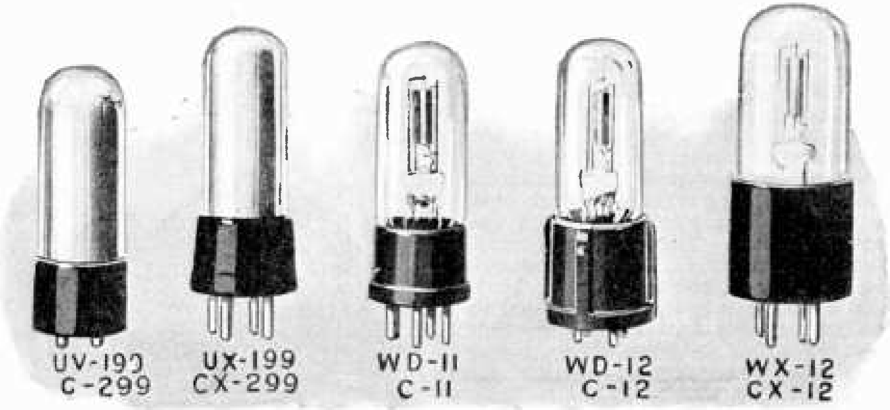
UNITS, ELECTROMAGNETIC—See *Electromagnetic Units.*



This shows the hook-up of the Ultradyne super-het. This set is not radically different from the average super-heterodyne. The heteroformers are of the tuned air core type and the filter is shown at the input side of the circuit. Aerial and ground as well as loop may be used with this set and instead of the first detector the inventor uses a tube known as the "modulator."

V

VACUUM TUBE—An evacuated bulb, or one containing a rare gas and having three elements, filament, plate and grid. (See *Three-Electrode Thermionic Tube, Triode,* also *Dynatron.*)



A group of dry-cell vacuum tubes. The first two differ only as to the type of base; both are intended to be operated from a 4½-volt "A" battery, that is, three dry-cells connected in series. The filaments draw very little current, as can be determined from the chart. The last three tubes also have identical characteristics, but are designed to fit different types of sockets. These tubes operate from a single 1½-volt dry cell and draw approximately ¼ ampere of current. The filaments are oxide-coated and very rugged.

VACUUM TUBE AMPLIFIER, THEORY OF—The vacuum tube may be used as an amplifier or magnifier because of the fact that under proper conditions, a small variation of the electromotive force applied between the filament and the grid produces a very large variation in the current flowing in the plate circuit. It is usual to use several amplifying tubes together, suitably coupling the plate of one tube to the grid of the next, thus increasing the amplification to the desired value.

VACUUM TUBE CHARACTERISTICS Performance curves of vacuum tubes. These are obtained experimentally by keeping the filament current constant and applying various known voltages between the plate and the filament and between the grid and the filament and reading the resultant currents that flow to the plate and the grid. The various values obtained are then plotted on cross-section or graph paper. Such curves are convenient for determining the operating characteristics of a particular vacuum tube under consideration. (See *Characteristic Curve.*)

VACUUM TUBE GENERATOR—The vacuum tube can be used to produce sustained oscillations without the necessity of supplying potential variations to the grid from an external source. This can be accomplished as a direct result of the amplification properties of the vacuum tube, since the energy of the output circuit is greater than the energy of the input circuit and part of this output energy may be returned to the input to produce constant reamplification.

VACUUM TUBE, POWER—A tube of special design, made for use in the last audio stage of a radio receiving set, which will handle greater current than the ordinary amplifying tube, thus resulting in more volume and at the same time clearer and more satisfactory tone reproduction. Power tubes now on the market require higher plate voltages than conventional tubes, ranging from 135 volts upwards. The amount of grid bias or "C" battery ranges from approximately 4½ volts to 45 volts, depending upon the type of power tube. Tubes suitable for developing considerable power, in radio transmission are also referred to as power tubes. By increasing the surface area and hence the filament emission or by increasing the degree of evacuation of the bulb, thus allowing a higher plate voltage, the output of the tube may be increased. A form of transmitting power tube is described under the heading *Pliotron.* The illustration below shows one of the new power tubes used for reception.

LAST AUDIO STAGE
UX-171
CX-371

A new storage-battery type power amplifier tube, for use in the last stage audio amplifier only. This tube takes the same filament voltage and filament current as the No. 112 tube but employs a "B" voltage of 180 and 40½-volt "C" battery. Special means should be provided for handling its heavy output.

VACUUM TUBE RECTIFIER—A vacuum tube designed or used to change alternating current to direct current. (See *Rectifying Tube, Kenotron,* also *Tube Rectifier.*)

VACUUM TUBE, THEORY OF OPERATION—See *Theory of Operation of Vacuum Tubes.*

CHART OF VACUUM TUBE TYPES AND CHARACTERISTICS

TYPE	USE	"A" battery volts (Supply)	Filament Terminal Volts	"A" Battery Current Amperes	"B" Battery Volts Det.	Amp.	Negative "C" Battery Volts	Voltage Amplification Factor	Output Resistance Ohms

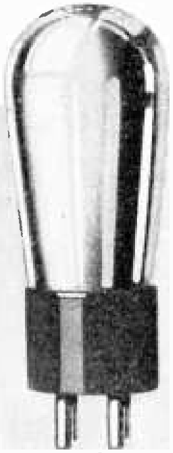
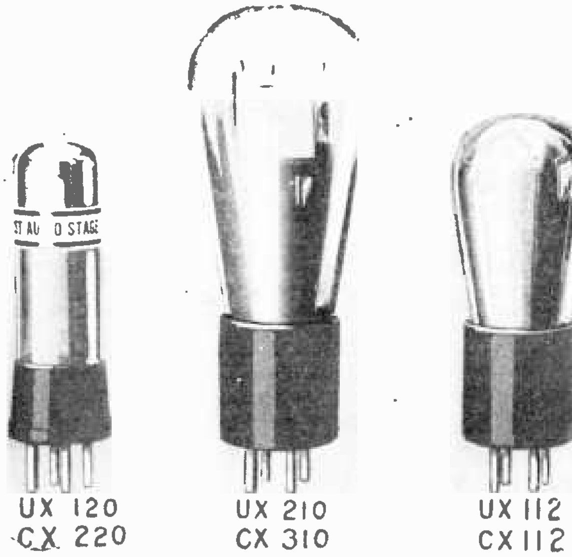
VACUUM TUBES, TYPES OF—Vacuum tubes are of various types and designs depending upon the work which they must do. They may be divided into two general classes, receiving tubes and transmitting tubes.



A new type of detector tube which has greater sensitivity than former types, due to the use of an alkaline vapor. It can be used as a detector in any type of receiving circuit.

Tubes for receiving purposes are designed either for dry cell operation or else are of the storage battery type.



These power amplifier tubes are designed for use in the last stage of an audio frequency amplifier. On the left is a dry cell tube which requires a 4½-volt "A" battery. The center tube employs exceptionally high "B" battery voltage, and is usually employed with an amplifier that operates from the house current. This tube can also be used for transmitting purposes. The right-hand tube is of the storage battery type and has a very rugged filament. It makes an excellent detector tube as well as a power amplifier.

They may be further classified as detector tubes, amplifying tubes or power tubes. There are many special types of tubes, such as *kenotrons* (q.v.), *pliotrons* (q.v.), etc.

VALENCY—The property possessed by elements in combining with or replacing other elements in a certain definite proportion. Also referred to as *valence*. (See *Electro-Chemical Equivalent.*)

VALVE—This generally refers to a vacuum tube used as a detector or rectifier. The name *valve* is used in many foreign countries to refer to the thermionic vacuum tube, as used for any purpose.

VALVE DETECTOR—See *Valve.*

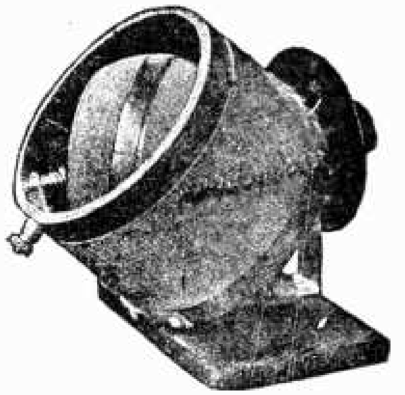
VARIABLE CONDENSER—A condenser having rotable or movable metal plates and an air dielectric. Both the stationary and rotating plates may be made of brass, copper or aluminum. Bakelite, fibre or composition are used to insulate the stationary from the movable plates. Turning the movable plates either increases or decreases the capacity of the condenser. Variable condensers are primarily used in radio for *tuning* (q.v.). They are constructed so as to have straight line frequency characteristics either by undercutting a portion of the movable plates or else by making these of a variable thickness.

VARIABLE GRID LEAK—A variable high resistance unit designed to be placed in the grid circuit of a vacuum tube used as a detector. Certain types of variable grid leaks may have their resistance varied from ¼ megohm to 10 or more megohms by merely tightening a thumb-screw. (See *Grid Leak*, also *Adjustable Grid Leak.*)

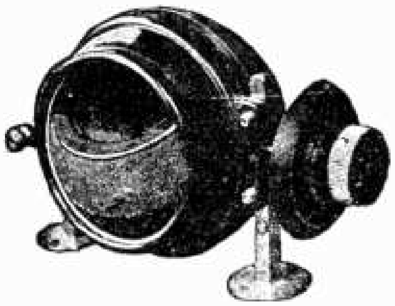
VARIABLE RATIO TRANSFORMER—A transformer in which the ratio between the primary and the secondary windings can be varied, usually by means of suitably located taps.

VARIABLE RESISTANCE—Both the *rheostat* and the potentiometer used in radio work, are variable resistances. Variable resistances are usually of high resistance wire type, with a sliding contact so that the resistance can be easily altered.

VARIO COUPLER—A tuner formerly used in radio receiving sets, having a primary and a secondary coil inductively coupled, with the secondary arranged so as to be rotable within the primary. The amount of coupling depends upon the variation of the angle between the axes of the two coils.

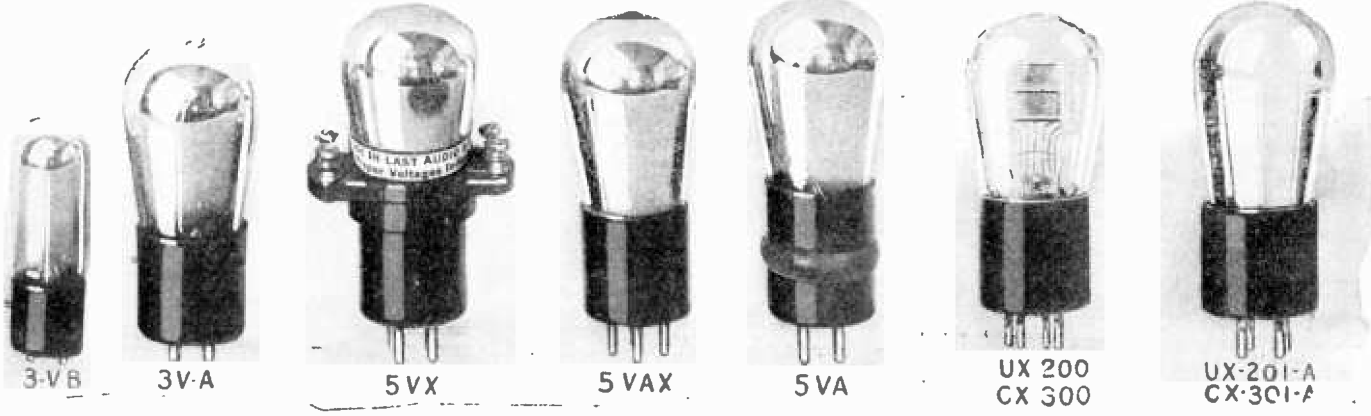


A standard form of vario coupler.



A variometer.

VARIOMETER—A tuner, similar to the vario-coupler, except that the primary and secondary coils are electrically connected.



The characteristics of these vacuum tubes are given in the vacuum tube chart on page 187. The first tube is of the dry-cell type, requiring a 4½-volt "A" battery for lighting the filament. 3V-A is a standard 5-volt tube. 5VX is a power amplifier which can be used in the last stage of any audio-frequency amplifier. There is no necessity of changing any of the wiring in the set for the addition of more "B" battery, as binding posts are included on the tube itself. 5VA has a sponge rubber ring included as a part of the base which tends to absorb all vibrations which might otherwise cause the tube to become noisy. The next type of tube is for use as a detector only. The last is the well-known 201-A type, which can be employed as a detector or an amplifier.

VECTOR—A graphical illustration used in mathematical calculations, consisting of a line with an arrow-head at one end, used to show by means of its length, direction and the angle between itself and another vector or vectors, the magnitude, direction and phase angle of alternating current quantities.

VELOCITY—The distance passed through in a certain time. Velocity is measured in feet per second, miles per hour, etc.

VIBRATION—A to and fro motion. An oscillating or swinging motion.

VITREOUS—Consisting of or pertaining to glass. (See *Resinous Electricity.*)

VOLT—The practical unit of *electromotive force* (q.v.). The volt is a measure of the electromotive force which will cause a current of one ampere to flow through a resistance of one ohm. It is equal to 10^8 absolute electromagnetic units (Abvolts).

VOLTAGE—The electrical pressure or the electromotive force between two points in an electrical circuit, measured in volts.

VOLTAGE, CONSTANT—A steady unvarying electrical pressure or electromotive force, as differentiated from a pulsating or fluctuating voltage.

VOLTAGE DROP—The fall in potential caused by the resistance of the conductor through which the current is flowing. The longer the conductor, the greater will be the voltage drop. The greater the cross-section of the conductor, the less will be the voltage drop.

VOLT-AMPERES—The product of volts as measured with a voltmeter, by the current as shown on an ammeter, in an alternating current circuit, gives the apparent power, or in other words the apparent watts. (See *Instantaneous Values.*)

VOLTMETER—An instrument for measuring voltage drop or potential difference. Most of the voltmeters used in radio work operate on the moving coil principle. (See *Galvanometer.*)

A plug-in type of voltmeter.

Panel-type of voltmeter.

VOLTMETER CALIBRATION—A method of correctly marking the voltage readings on the scale of a voltmeter or of checking up the voltmeter readings to make sure that they are accurate. The usual method of calibration is to check the voltmeter reading by comparison with a standard voltmeter. (See *Calibration.*)

V.T.—Abbreviation for *vacuum tube.*

VULCANITE — (EBONITE) — A hard black substance produced by vulcanizing rubber with about 25 per cent sulphur. It is readily polished and has excellent insulating properties.

VULCANIZED RUBBER—Pure rubber, mixed with five per cent sulphur and baked at a temperature of about 150 degrees Centigrade. Vulcanized rubber must not be allowed to come into contact with copper, which is chemically attacked by the sulphur.

W

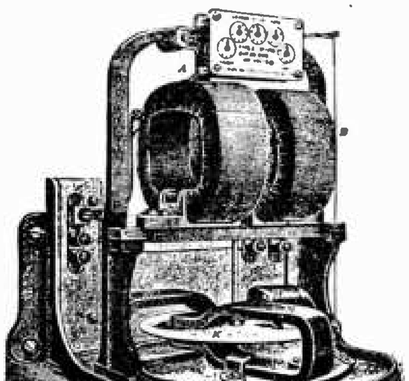
WALL TUBE—See *Partition Insulator.*

WATCHCASE RECEIVER—A telephone receiver having a shape somewhat similar to a watch. Watch case receivers are compact in construction and are the usual type used in the radio telephone *head set.*

WATT—The unit of electric power. One *Joule* (q.v.) per second. To find power in a direct current circuit, multiply voltage by amperage. The *Kilowatt* (q.v.) equals one thousand watts. Seven hundred and forty-six watts are equivalent to one electrical horsepower.

WATT HOUR—The commercial unit of electrical work. The work done in one hour by a current of one ampere flowing between two points of a conductor having a difference of potential of one volt.

WATT-HOUR METER—An integrating meter which measures energy in watt-hours or in kilowatt-hours. (See *Integrating Wattmeter.*)



A direct current watt-hour meter.

WATT, INTERNATIONAL—symbol W—The energy expended per second by an unvarying electric current of one International ampere under an electrical pressure of one International volt. IW = 1 Joule per second = 10^7 ergs per second.

WATTLESS COMPONENT—WATTLESS CURRENT—The component of an alternating current which is in quadrature with the voltage. (See *Reactive Component.*)

WATTMETER—An instrument designed to measure the power being expended in an electrical circuit. The most common form of direct current wattmeter is of the dynamometer type. This has two coils, one fixed and one movable, one coil being connected so as to exert a force proportional to the current flowing in the circuit, and the other coil exerting a force proportional to the electromotive force. The *induction* type of wattmeter is in general use for alternating current circuits. (See *Electro-Dynamometer, Dynamometer,* also *Induction Wattmeter.*)

WATT SECOND—A unit of electrical energy, representing the energy expended by one watt flowing for a second. The watt second is the same as the *Joule* (q.v.) and is usually applied to the measurement of heat developed by an electric current.

WAVE—A periodic alternation of an alternating current. As applied to an electric or electromagnetic disturbance, an electric wave is an undulatory movement of the ether, radiated from conductors carrying electrical oscillations.

WAVE ANALYSIS—A study of the wave form of an alternating current or other type of wave. The wave form of commercial alternating current used for lighting purposes approximates a *sine curve* (q.v.). A convenient instrument for the analysis and study of alternating current wave form is known as the *oscillograph* (q.v.).

WAVE ANTENNA—A horizontal antenna, the physical length of which is approximately equal to the length of signaling waves to be received, and which is so used as to be strongly directional.

WAVE DISTORTION—Alteration in the wave form of a wave after it has traversed a considerable distance. (See *Distortion.*)

WAVE FORM—Referring to an alternator, the "shape" of the curve of the current generated.

WAVE FREQUENCY—See *Frequency.*

WAVE LENGTH—symbol λ (lambda)—The distance between two successive *antinodes* (q.v.) in the same direction. In referring to the wave length of electrical oscillations in a circuit, this means the length of the waves in free space that would have a frequency corresponding to the given oscillations. Electromagnetic waves used in radio work have frequencies of from 10,000 to 3,000,000 cycles per second. Since these waves have a velocity of approximately 300,000,000 meters per second, it is possible to calculate the length of a wave by dividing the velocity by the frequency. In other words meters per second divided by cycles per second gives length of the wave in meters. Thus a wave having a frequency of 100 kilocycles (100,000 cycles) will have a wave length of 300,000,000 divided by 100,000 or 3,000 meters.

WAVE LENGTH ALLOCATIONS—In order to prevent radio transmitting stations from interfering with each other, or creating interference at a receiving station, various wave length bands have been allotted to each type of service. The following table shows the present short wave assignments and the service for which they are used:

Wave-length in Meters	*Service*
109–105	Relay broadcasting only.
105–85.7	Public toll service, Government mobile, and point-to-point communication by electric power supply utilities, and point-to-point and multiple address message service by press organizations only.
85.7 –75.0	Amateur, Army mobile, naval aircraft, and naval vessels working aircraft only.
75.0 –66.3	Public toll service, mobile Government point-to-point and point-to-point public utilities.
66.3 –60.0	Relay broadcasting only.
60.0 –54.5	Public toll service only.
54.5 –52.6	Relay broadcasting only.
52.6 –42.8	Point-to-point only.
42.8 –37.5	Amateur and Army mobile only.
37.5 –33.1	Public toll service, mobile, Government point-to-point, and point-to-point public service utilities.
33.1 –30.0	Relay broadcasting only.
30.0 –27.3	Public toll service only.
27.3 –26.3	Relay broadcasting only.
26.3 –21.4	Public service, mobile, and Government point-to-point.
21.4 –18.7	Amateur only.
18.7 –16.6	Public toll service, mobile and Government point-to-point.
16.6 – 5.35	Experimental.
5.35 – 4.69	Amateur.
4.69 – 0.7496	Experimental.
0.7496– 0.7477	Amateur.

Radio broadcast stations work within the wave length band of 200 to 545 meters at intervals of 10 kilocycles. 600 meters is reserved for distress signals. The higher wave lengths are allocated to various marine, government, university, aircraft and other uses.

WAVE LENGTH CALCULATION FOR ANTENNA—For the ordinary vertical wire grounded antenna, the fundamental wave length is slightly greater than four times the length of the wire. A constant suggested is 4.2 and applies approximately also to flat top antennae having vertical lead ins. For other calculations see *Fundamental Wave Length.*

WAVE LENGTH, FUNDAMENTAL—See *Fundamental Wave Length.*

WAVE LENGTH, NATURAL—In a loaded antenna (that is with series inductance or capacity) the natural wave length corresponds to the lowest free oscillation. (See *Natural Wave Length.*)

WAVE LENGTH OF STATIONARY S. H. M. WAVES—On a straight wire, the smallest distance between two points where the disturbance is of the same amplitude and phase; or, since consecutive loops (q.v.) are in opposite phases, the wave length is double the distance between consecutive loops or consecutive *nodes* (q.v.). (See *S.H.M.*)

WAVEMETER—A radio instrument for measuring frequency. A calibrated resonator of variable frequency, capable of easy excitation by the oscillation under test, combined with a means of indicating the attainment of resonance. The calibration may be given directly in wave lengths or frequencies or both.

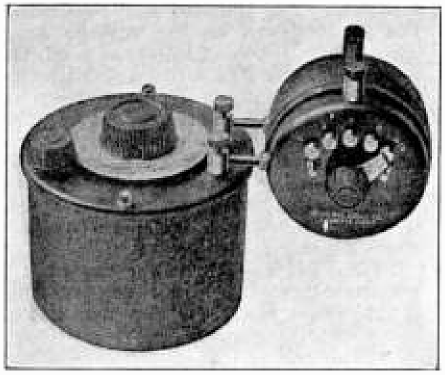


Photo by courtesy of General Radio Co.

The selectivity of the radio set may be greatly increased by the use of this wavemeter as a radio filter.

WAVEMETER CALIBRATION—Wavemeters may be calibrated by comparison with a standard wavemeter. An accurate method of calibrating a wavemeter, known as the *Three-Way Method* is shown in the accompanying diagram. In this illustration A is the standard wavemeter, B the wavemeter to be calibrated, and C is a condenser and coil of size permitting resonance with A. To calibrate, the buzzer should be put in operation, varying the capacity of the condenser C^1 until L^1C^1 is in resonance with L^2C^2 as noted in the head set. The wavemeter B should then be put in inductive relation to C and the condenser C^2 varied until the wavemeter A resonates with C. The wave length of B is now the same as A. This procedure should be carried out over the whole range of the condenser C^3.

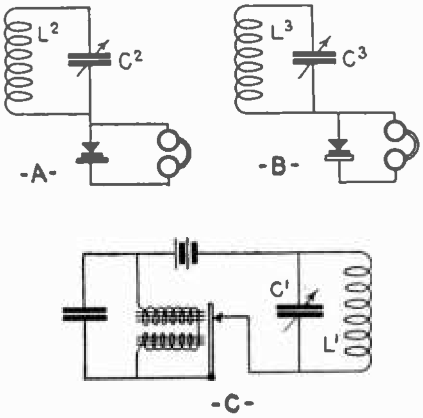

Diagram showing three-way method of wavemeter calibration.

WAVE MOTION—A disturbance of the equilibrium of a medium or body, extended or propagated from point to point with a continuous motion, each particle vibrating only on each side of its position of equilibrium, while each phase of vibration moves onward. Examples of wave motion are the propagation of electromagnetic waves, or the waves on the surface of a body of water.

WAVES, CONTINUOUS—See *Continuous Waves.*

WAVES, CONTINUOUS, KEY MODULATED—See *Continuous Waves, Key Modulated.*

WAVES, CONTINUOUS, MODULATED AT AUDIO FREQUENCY—See *Continuous Waves at Audio Frequency.*

WAVES, ELECTROMAGNETIC—Periodic electromagnetic disturbances progressive through space. (See *Wave.*)

WAVES, SUSTAINED—See *Sustained Waves*, also *Continuous Waves.*

WAVE TRAIN—A series of waves. An example of a wave train is the series of disturbances set up by each spark in a spark system of radio telegraphy.

WAVE TRAP—A device consisting of a variable condenser and coil, usually connected in the antenna circuit of a receiving set, to eliminate interference from undesired stations. (See *Filter, Filter Condenser, Acceptor*, also *Rejector.*)

WAVE-WOUND—A class of drum armature in which connections produce a "stepping forward" in a zig-zag wavy line all the time. Also called *Series* and *Two Circuit Windings.*

WEBER—The *Practical Unit* (q.v.) of magnetic flux. The engineers' unit is the "line" which is also the electromagnetic unit. 1 Weber is equal to 108 electromagnetic units (or "lines"). The Weber is produced by a current of one ampere flowing through a circuit having one henry of inductance.

WEHNELT BREAK—An *electrolytic interrupter* (q.v.).

WEIGHT—The force with which the earth attracts a body. A body varies in weight according to its distance from the centre of the earth, although its mass remains constant.

WESTON CELL—The present standard cell. It consists of mercury with a paste of mercurous and cadmium sulphates which form the cathode. The Weston cell has an anode of 12.5 per cent cadmium amalgan in an electrolyte of saturated solution of cadmium sulphate. It has a constant electromotive force of 1.0125 volts at 20 degrees Centigrade. (See *Electromotive Force*, also *Cadmium.*)

WHEATSTONE BRIDGE—An instrument for measuring resistance in which the current from a battery divides into two parallel circuits, each

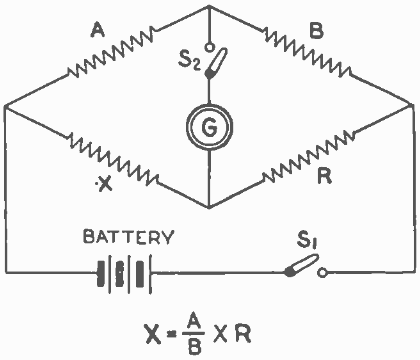

Diagram illustrating principle of the Wheatstone Bridge.

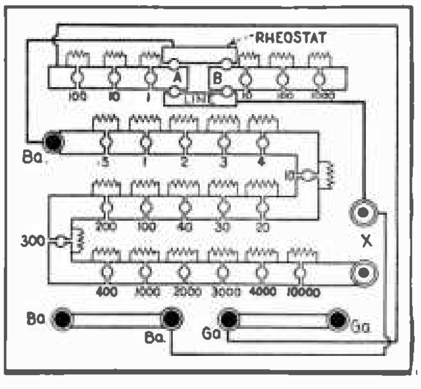


Post-Office type of Wheatstone Bridge.

divided into two "arms" capable of being adjusted so that there is no difference of potential between the dividing points on both sides. The point of zero difference of potential is indicated by the absence of deflection of a galvanometer placed across the dividing points. The ratio of the resistance of the two parts of the arms is then the same, so that if the resistance of three of the arms is known, that of the fourth arm (i.e. the resistance to be measured) can be determined.

WHEATSTONE TRANSMITTER—An apparatus for delivering telegraphic currents to a line at high speed. Control is effected by aid of a moving perforated paper tape, prepared according to a code.

WHIPPING—The binding of string or small wire round the end of a rope or multiple wire to prevent the ends from fraying out.

WIMSHURST—A type of Induction or Influence Machine consisting, in a simple form, of two discs of insulating material revolving in opposite directions. These carry a number of equal sectors which form combined inductors and carriers. There are usually two collectors and two pair of brushes. (See *Induction Machine.*)

WINDOW LEAD-IN—A form of insulator for passing an aerial *lead-in* through a window. In some cases porcelain tubes are used as window lead-in's. A common form of window lead-in consists of a flat copper conductor covered with woven cotton insulation.

WIRED WIRELESS—A method of transmitting radio messages, in which the waves are guided by wires instead of radiating freely through the ether. (See *Line Radio.*)

WIRE GAUGE—A device for measuring the diameter of a round wire in accordance with a predetermined scale. The gauge commonly used in this country is the Brown and Sharpe (B. & S.) or American gauge.

WIRELESS TELEGRAPHY—Also known as **RADIO TELEGRAPHY** (q.v.).—A system of telegraphy, utilizing electromagnetic waves set up by oscillating currents as the means of transmission. The waves generated at the transmitting station spread out from the *aerial* (q.v.) in all directions. They are intercepted by the receiving aerial, detected by a rectifying device such as a crystal or vacuum tube, amplified and delivered to a head set or loud speaker. A key is used at the transmitter to control the duration of the waves so that they will correspond to the dots and dashes of the *continental code* and these dots and dashes are reproduced in the phones at the receiving station.

WOLLASTON WIRE—Platinum wire, drawn extremely fine by the process of coating fine platinum wire with ductile material, drawing the whole down together, and (if required) removing the coating by dissolving it off.

WORK—The action of a force upon a body to overcome resistance. Work is measured by the product of the force exerted and the distance moved. Work may be measured by *ergs* (q.v.), *foot-pounds, horsepower*, etc.

WOOD'S METAL—A soft metallic alloy having a low melting point. This alloy consists of two parts of lead, one part of tin, four parts of bismuth, and one part of cadmium, all by weight. This metal has been used extensively for setting detector crystals in their cups, so as to make a good electrical contact.

X, Y, Z

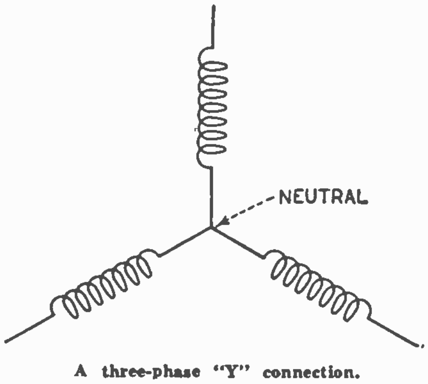
X—Symbol for *Reactance* (q.v.).

"X" RAYS—Also called *Roentgen Rays.* Electric waves of much higher frequency than light, produced by the striking of *cathode rays* upon a solid substance. These rays are not deflected by electric or magnetic fields and possess the property of penetrating solid substances which could not be penetrated by ordinary light rays. The use of the "X" Rays permit photographs to be taken of bones or other parts of the human body which could not be seen in any other way.

X'S—Disturbances of an erratic nature heard from time to time in the 'phones or loud speaker of a radio receiving set, due to storms, electric disturbances, etc. (See *Atmospherics, Natural Electric Waves, Static,* also *Strays.*)

YAGI SPARK GAP—A form of spark gap originated by H. Yagi. It is a quenched spark gap, the electrodes of which are aluminum and brass. The gap functions in an atmosphere of coal gas.

"Y" GROUPING—See *Star Grouping.*



A three-phase "Y" connection.

YOKE—A piece of soft iron used in certain forms of electromagnets to yoke two parallel cores together magnetically. The cores of the ordinary electric bell are fastened together at one end by means of a yoke.

YOKOJAMA, EITARO—Japanese radio expert. He was born in 1883 and was educated at the Engineering College of the Tokyo Imperial University. While at college, he specialized in radio. He was appointed to the Electro-technical Laboratory of the Japanese Ministry of Communications, to carry out research work in wireless telegraphy and telephony. He was one of the inventors of the T.Y.K. oscillation gaps for radio telephony, for which he received many distinctions. In 1910 he was appointed head of the Radio Section. Yokojama, who is one of the most brilliant Japanese radio experts, is a member of the Institute of Radio Engineers and of many other scientific societies.

ZEEMAN EFFECT—Doubling of the spectrum lines of light sources when placed in a strong magnetic field.

ZENNECK, J.—German wireless expert. He was born April 15th, 1871, at Wurtemberg and was educated at Tuebingen. In 1895 he was appointed assistant in the Physical Institute in Strassburg, a post he held until 1899, when he carried out a series of tests in radio telegraphy in the North Sea. In 1905 he was appointed assistant professor of physics at the Institute of Technology, Brunswick and was appointed professor at Munich in 1913. Professor Zenneck has written a number of authoritative books on wireless and also a large number of articles on electro-magnetic oscillations.

ZERO BEAT RECEPTION—The detection of continuous modulated waves using a local source of high frequency current having a frequency equal to that of the incoming wave. When this continuous voltage is impressed on the incoming modulated voltage, (both of the same frequency) the output of the detector contains a current of audio frequency similar in character to the modulated current at the transmitter.

ZERO METHOD—A method of measurement in which various adjustments are made until the current flowing through a galvanometer is reduced to zero, as in a *Wheatstone Bridge* (q.v.). (See *Null Method.*)

ZINC—A metallic element. Its chemical symbol is Zn. In color, zinc is bluish-gray. It is practically non-corrosive in the atmosphere, is capable of taking a high polish, is unaffected by water, but is soluble in nitric acid and in soda and potash solutions. Pure zinc is attacked very slowly by sulphuric acid, but this feature is one of the greatest in the application of zinc in radio work and in electrical work generally.

Zinc is one of the most important components of most dry cells. It forms the negative terminal in most "B" batteries. Zinc in rod form is used in most forms of wet cells.

ZINCITE—An oxide of zinc. Zincite crystals can be distinguished by their red color, often broken up by orange-yellow streaks. This crystal, in combination with several other crystals makes a very excellent detector for radio purposes. The *perikon detector* (q.v.) is a combination of zincite and chalcopyrites. Zincite is also used in combination with bornite, galena, copper, iron pyrites, tellurium and silicon.

ZIRCONIUM—One of the metallic elements. Its chemical symbol is Zr, and its atomic weight is 90.6. Zirconium is an iron-gray powder in one form, or it may be made to crystallize. The crystals look like antimony, are very brittle and extremely hard, being capable of scratching glass and rubies. Zirconium resembles thorium in many of its chemical properties. For the control of the vacuum in high vacuum tubes, a small quantity of thorium or zinconium is included in the tube. These metals combine with hydrogen, oxygen, nitrogen, etc., to form compounds of very low vapor pressure.

SUPPLEMENT

CLASSIFIED INDEX TO S. GERNSBACK'S RADIO ENCYCLOPEDIA

In the following index various co-related subjects have been gathered together for the convenience of the reader or student, under appropriate headings. Thus, under the heading of "Circuits," every circuit contained in the Encyclopedia is listed. Other important subjects are similarly treated. Where the reader is interested in but a single item such as, for example, "Bolitho Circuit," this can be found more conveniently by referring to the Encyclopedia itself, which, of course, is arranged in alphabetical order. All separate and unrelated headings or subjects should be looked up in this manner, that is by referring directly to the Encyclopedia, as these are not listed in the index.

K3OPS®

An electromagnetic field uses the photon as an elementary particle to transmit force. It combines:

- **A magnetic field** *force resulting from the movement of loads µT.*
- **An electric field** *force created by the attraction of repulsion loads, measured in volts per meter - V/m.*

With an energy determined according to the speed of light, the RF are by far the best medium to transmit any kind of information.

The multiplication of wireless communications systems in our environment ensures sufficient microwave leakages to harvest from the ambiant and enough energy to convert into DC electricity. Electromagnetic fields are everywhere and since they carry energy, they became the best candidate to deliver an endless source of renewable energy.

$\vec{B}$ is the magnetic induction expressed in T refered to **Nikola Tesla**, "Father of Free Energy", which is at the origin of the electromagnetism.

Using meta-materials combined with nanotechnology has deeply increased the performance and miniaturization of rectennas embedded in K3OPS system. Our products operate autonomously, offering an endless supply of green energy in a respectful and environment-friendly approach.

principles and beautiful sentences. At that point in time I would have simply been Xin, a child like any other...

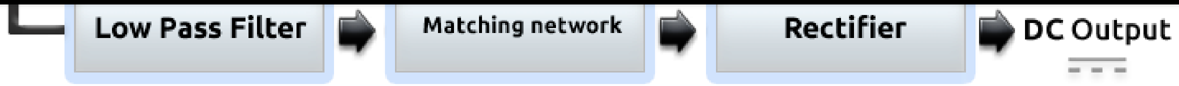
But one day I dreamed. I woke up far away, somewhere else, in another past. I decided to change my destiny and even if I was supposed to become a mathematician, I eventually decided to create, because already as a child my heart was chasing the stars.

Of the hundreds of directions shown to me after graduating, only one captured my attention: a single goal... Build the impossible for a safer world. So, over the past 3 years, our real challenge to overcome for all RF Energy Harvesting technics was to optimize electricity conversion. The massive proliferation of wireless telecommunication systems since the past two decades brought a saturation of the electromagnetic fields with a constant growth of 15% every year in our environments. As a result, this situation reversed the base problem that makes today Harvesting RF Energy a game changer. The key was the Power Management System.

We are far beyond the conversion constraint and performance by controlling "RF-interferences", by harvesting different frequencies *from near and far*, by using Metamaterials combined with nanotechnologies. We dramatically have improved power conversion efficiency and reduced the size of our Energy Harvesting systems embedded in all K3OPS' products.

Thanks to Nikola Tesla, my inspiring mentor, K3OPS' products have reached by far their objectives in terms of converting and performance, offering an endless efficient source of green energy, reliable in an environmentally friendly approach.

Xin WEI Co-Founder of K3OPS technology with Alexandre Despallieres



Low Pass Filter
Matching network
Rectifier
DC Output

The Rectenna was invented in 1964 by William C. Brown, patented in 1969. It is a rectifying antenna used to convert microwave energy into DC. A simple Rectenna consists of a dipole antenna with an RF diode connected across the dipole elements. The diode rectifies the AC current induced in the antenna to produce DC power.

1. Supplementary Figures and legends

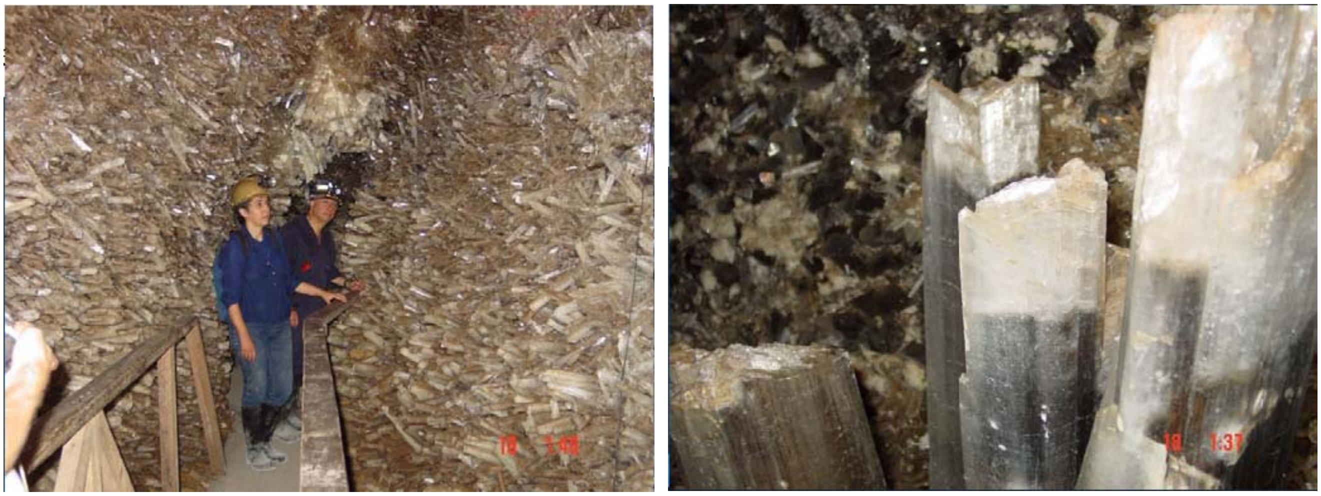

Figure DR1: *The Cueva de las Espadas* (Cave of the Swords) discovered in 1910 is located at level −120 m close to the Montaña fault (see Fig. 1). It is a long corridor (shown on the left) which walls are entirely covered by crystals from centimeter to almost a meter in size (Degoutin, 1912; Foshag, 1927). The cave is close to the natural phreatic level and this explains the light grey and black color of the crystals due to clay as well as iron and manganese oxides solid inclusions (right). These solid inclusions are in most cases aligned on growth fronts, suggesting the occurrence of episodic avalanches of strong oxidation and a growing environment from muddy waters containing colloidal clays.

2. Supplementary methods

2.1. Gypsum Crystal Habit

The habit of gypsum crystals from the Cave of the Crystals has been studied by single crystal X-ray diffraction and by laser reflection goniometry. X-ray diffraction experiments on cleavage plates were performed to get the first inputs on crystal orientation and morphology as well as the unit cell parameters required for the geometrical calculations of inter-facial and inter-edge angles. Our laboratory diffractometer, a Bruker Proteum X8 equipped with a Microstar generator, and a KappaCCD goniometer and detector was used for these X-ray diffraction studies. The unit cell parameters of the crystals investigated were a=5.684Å, b=15.189Å, c=6.282Å, β=114.10º; the face parallel to the main cleavage is, as expected, {0 1 0} and the elongation of the crystals was identified to be [0 0 1].

Interfacial angles (Fig. DR2b) were measured using a straight edge and a protractor for macroscopic forms and a simple light goniometer for microscopic faces (Fig. DR3). These studies indicate that the crystals are prisms bounded by {0 1 0} and {1 k 0} faces and caped by {-1 1 1} faces (Fig. DR2a). The {1 k 0} faces are striated and composed of alternating bundles of {1 2 0}, {1 4 0} and {1 6 0} faces making and overall orientation close to {1 4 0} (Fig. DR4 and table DR1).

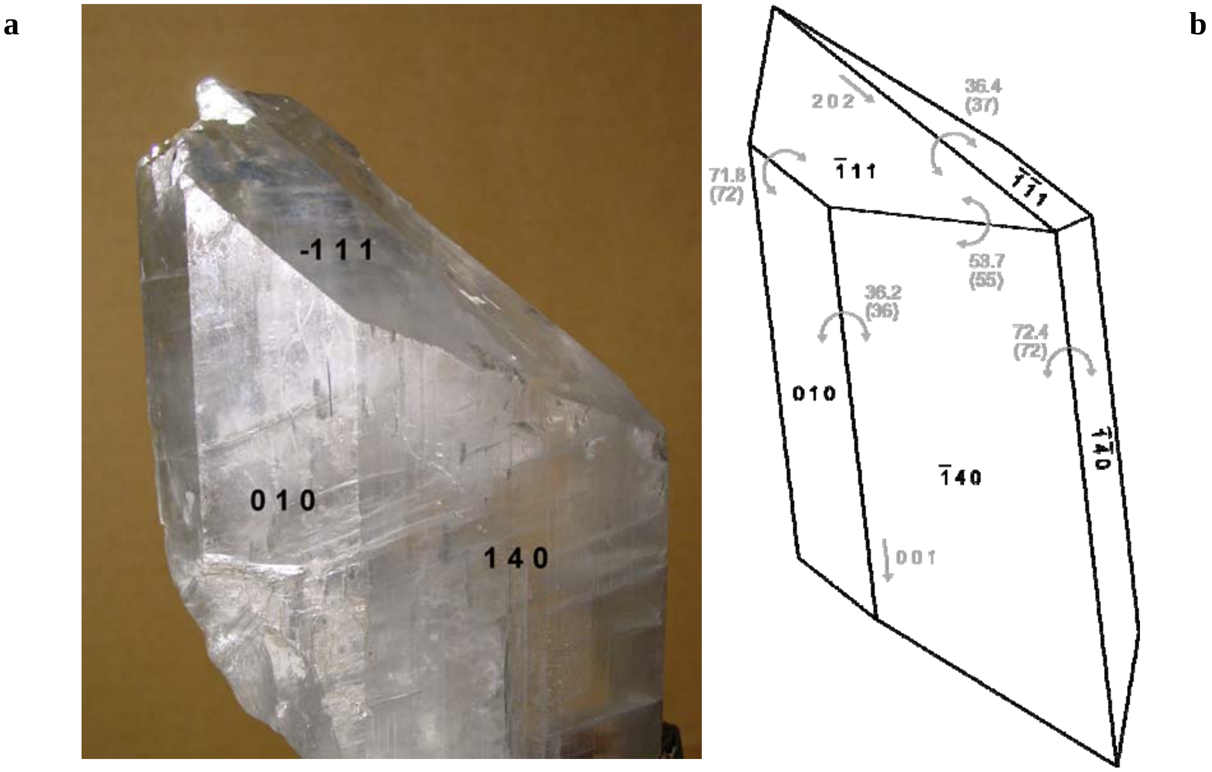

Figure DR2: a) Large blocky gypsum crystal from the *Cueva de los Cristales*. The crystal size in the vertical direction is 12 cm. b) Sketch of the crystal habit showing the indices of the faces, the main zone directions (arrows) and the main interfacial angles (curved double arrows). The numbers next to the double arrows show the values computed from the unit cell followed by the measured angles in parentheses.

Figure DR4. Structure of the {1k0} surface. a) Sketch of the face segments distribution and the corresponding angles. b-d) Scanning electron microscope views of the surface showing the variable face segments at three different magnifications..

Table DR1: Calculated and measured angles between 010 and 1k0. The measured angles can be assigned to k = 2, 4, 6

Face	Angle (calculated)	Angle (measured)
010	0.00	0
110	71.14	-
120	55.66	51
130	44.30	-
140	36.20	34
150	30.35	-
160	26.01	25

Face	Angle (calculated)	Angle (measured)
170	22.69	-

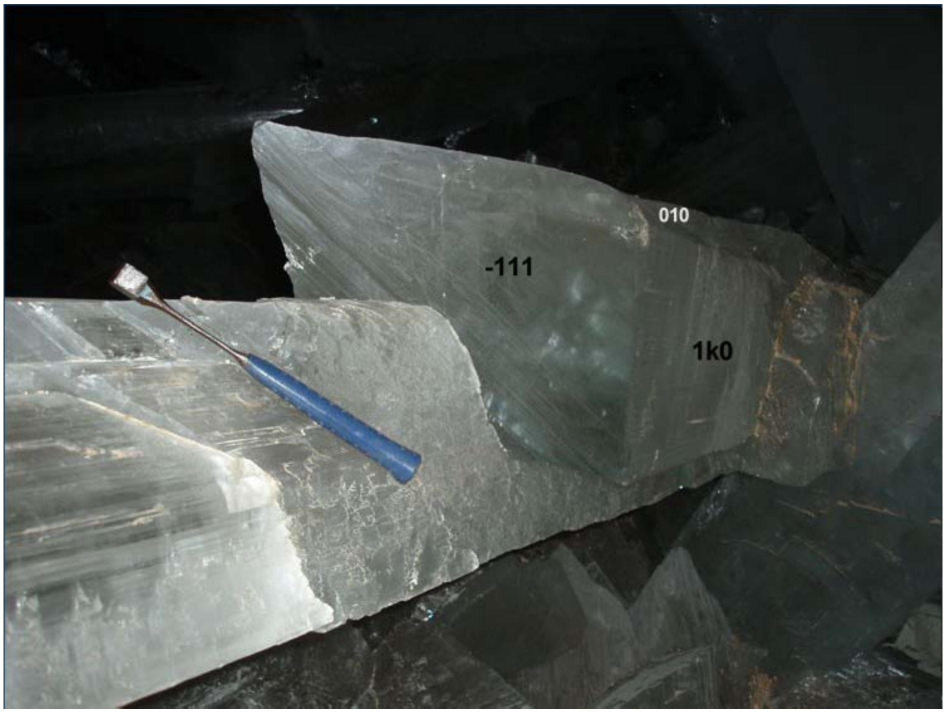

Figure DR5: Top view of a crystal beam showing the terminal faces {-111}: Notice that the large development of the prism {1k0} provokes very small pinacoidal {010} faces.

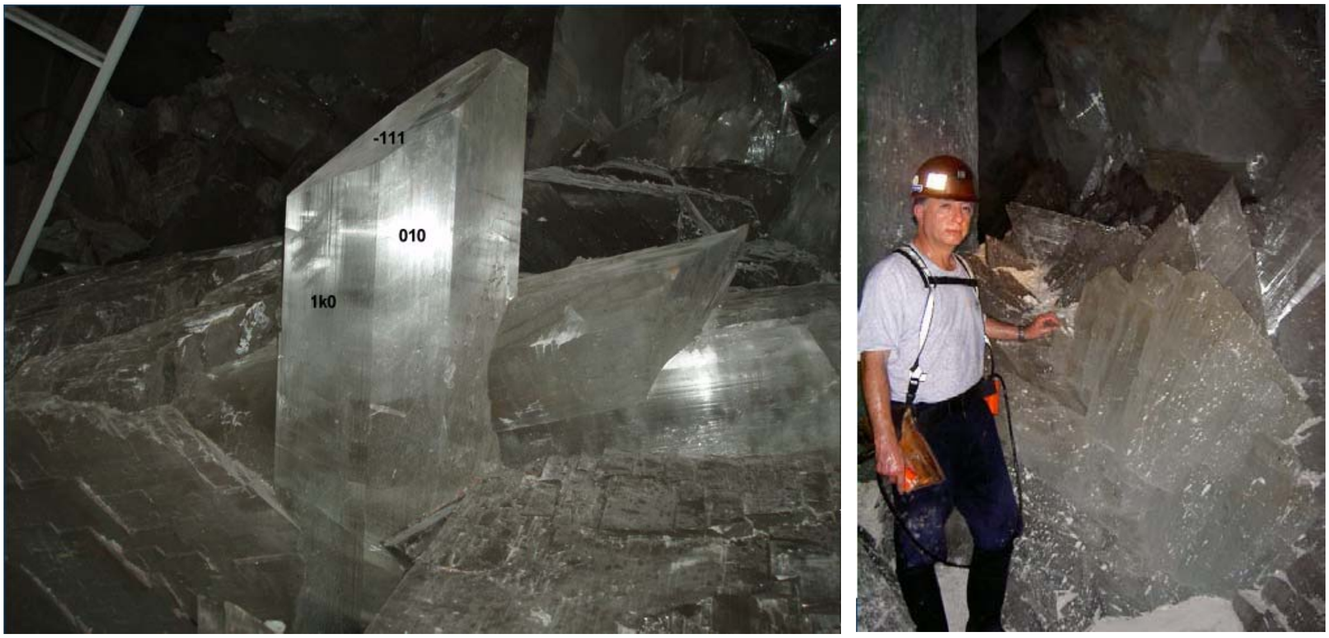

Figure DR6: Two examples of blocky crystals. The unusual blocky habit, the development of the more acute prismatic faces {140} and {160} instead of the usual {120} (Simon and Bienfait, 1965) and the alignment of the crystals with the edge [010] vertical, give them a distinctive sharktooth appearance.

2.2. Fluid inclusions

Fluid inclusion petrography and microthermometry were performed in less than 0,1m long gypsum cleavage fragment from a gypsum sample of the Cave of Crystals, where clear primary fluid inclusions related to growth bands were observed. The large fragment of the crystal from Cave of the Crystals was first sawed using an oil saw. Inclusions sizes range from 40 to 600µm and most of them display a idiomorphic shape. Microthermometry of fluid inclusions was carried out on a Linkam THMS 600 heating and freezing stage. All measurements were made using a 10× objective lens. Calibration of the stage was checked using pure CO_2 and H_2O inclusions. Although heating rates seem not to have a crucial role for regular fluid inclusions microthermometric results, as we work with large inclusions and thick gypsum slices we checked different heating rates and fragment sizes. We concluded that in our case the heating rate must be as slow as 0.1 ºC/minute near the final melting temperature, and the slices must be thinner than 1mm.

Primary fluid inclusions from gypsum growth bands were in most cases monophasic (liquid phase) at room temperature (Figure DR7). Less than 5% of them, however, also show a gas bubble. This suggests that inclusions were formed from a liquid phase at higher temperatures, but the gas phase bubble did not usually nucleate because the temperature gap to the room temperature is short. In order to increase the cooling interval, gypsum fragments were located and maintained at 2 ºC for few weeks and as expected, about 15% of inclusions showed a gas bubble after the cooling. Only those inclusions which were biphasic at room temperature were selected for cryogenic studies (33 fluid inclusions). Eutectic temperatures were not clearly observed in any run. Melting ice temperatures show a maximum at -0.1 with a dispersion of the values down to -1.1 ºC (Fig. DR10). This range of temperatures indicates a low salinity conventionally expressed in the $NaCl-H_2O$ system: 0.17 mass % NaCl with values increasing up to 1.9 mass % NaCl (Bodnar, 1993; Bakker, 2003). The dispersion of melting ice temperatures within an inclusion band is of the same order of magnitude of the variations along the whole set of samples and, therefore, no significant salinity variation with crystal growth can be established.

Heating experiments were performed in 31 fluid inclusions which were biphasic at room temperature. To avoid possible damage, the crystal fragments used in freezing experiments were discarded for heating. Homogenization took place to liquid phase, at temperatures showing a normal distribution with a maximum around 54±7 ºC (Table DR2). From the geological setting no correction due to confinement pressure is required, so this temperature range can be considered the actual temperature of crystal growth.

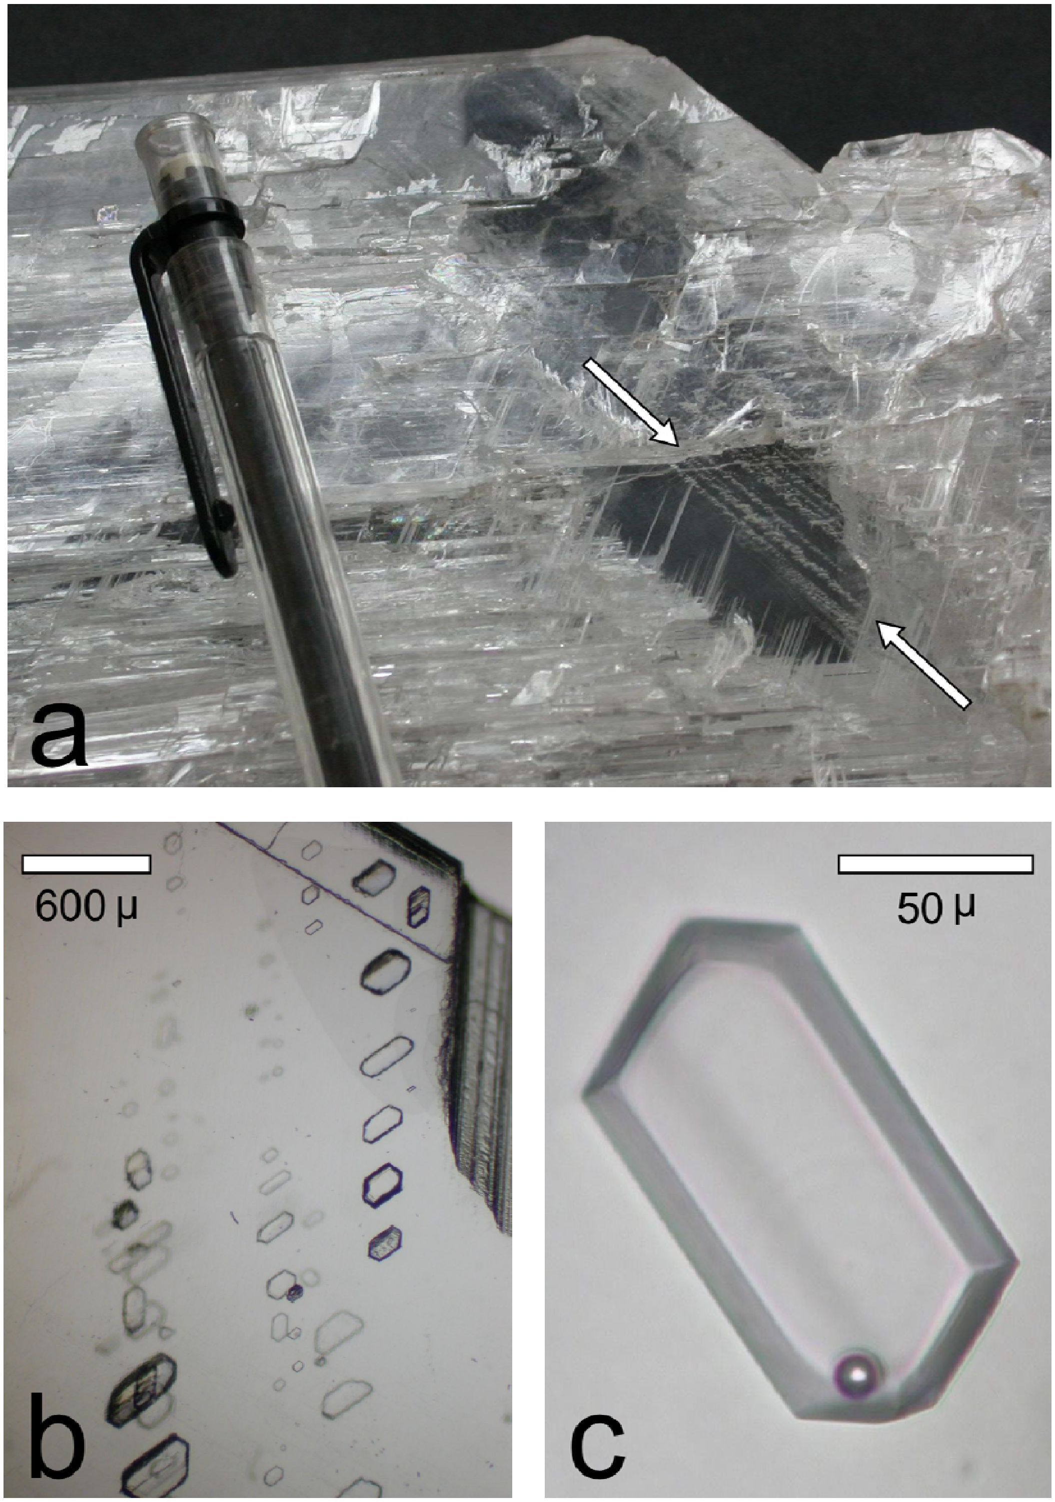

Figure DR7: a) Gypsum crystal form the Cave of Crystals showing growth bands with primary fluid inclusions (arrows). b) A detail of these inclusions along growth fronts. c) Detailed view of one of the biphasic inclusions used in the study.

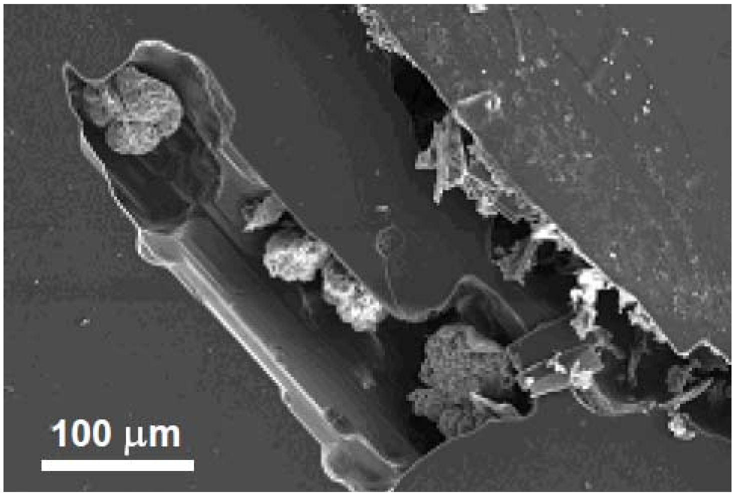

Figure DR8: Spherulitic solid inclusions trapped within fluid inclusions in gypsum crystals from the Cave of Crystals.

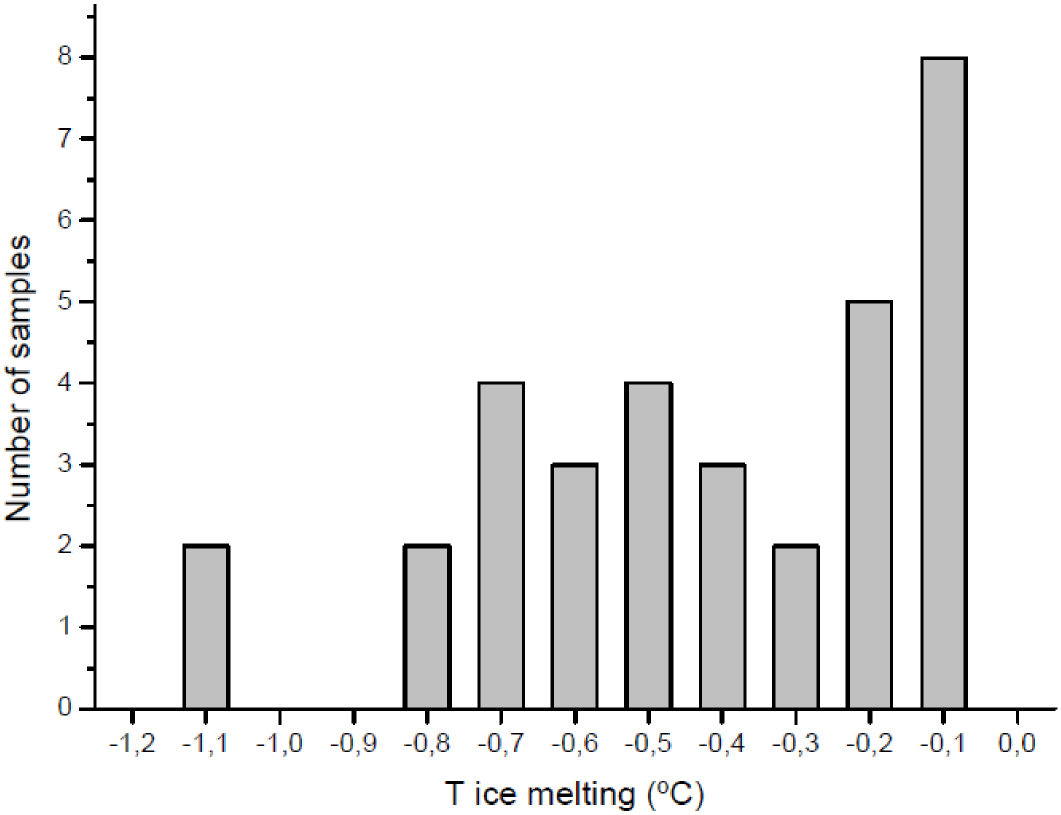

Figure DR9: a) Ice melting temperatures from 33 selected fluid inclusions which were biphasic at room temperature. The range of obtained temperatures (-0.1 ºC to -1.1 ºC, with a maximum at -0.1 ºC) indicates a low salinity of 0.31 mass % NaCl (for -0.1 ºC) up to 1.9 mass % NaCl (for -1.1 ºC).

Table DR2: Measured values of the homogenisation temperatures

54,1	53,5	54,3	50,5	52,6	52,1	54,5	54,5
54,0	52,7	48,3	56,4	60,0	58,3	61,5	57,8
52,0	52,0	51,4	46,7	46,0	46,0	38,1	49,1
51,6	56,2	54,2	52,3	53,6	56,2	48,1	

Solid inclusions have a spherulitic texture and are located within the fluid inclusions (Fig. DR8). The spherulites have a black core and a red halo under transmitted light microscopy, and SEM-EDS microanalysis shown that they are made of Mn, Fe, and Pb, and minor amounts of Si, Al, Na, Zn, and Cu. No X-ray diffraction pattern could be obtained from this spherulitic material. Similar spherulites are found in abundance in the Cave of Swords, where they produce the dark grey color of the gypsum crystals. The XRD pattern of this material shows two peaks (4.91 Å and 2.95 Å) corresponding to Mn_5O_8 compound (J17-0962 card).

2.3. Isotopic analysis

Several samples of anhydrite and gypsum from different locations in the mine were collected for stable isotope analysis. A representative sample of 0.1g of the mineral was first dissolved in 50mL of miliQ water. The dissolved sulfate was then precipitated as $BaSO_4$ by the addition of $BaCl_2 \cdot 2H_2O$ in acidic media (pH<2) to prevent $BaCO_3$ precipitation. The $\delta^{34}S$ was determined from $BaSO_4$ with an elemental analyzer coupled in continuous flow with a δC mass spectrometer. The $\delta^{18}O$ was measured in duplicate by on-line pyrolisis coupled with a δC mass spectrometer. The data were reported in the usual $\delta^{34}S$ CDT notation for the sulfur, and $\delta^{18}O$ SMOW for the oxygen. The overall reproducibility for the samples and laboratory internal standards was better than ±0.2‰ for sulfur and ±0.5‰ for oxygen.

The sulfur and oxygen isotopic composition of 17 sulfates (eight gypsum crystals, eight anhydrite crystals and one from water collected at level 530 are shown in Table DR3. Two $\delta^{34}S$ and $\delta^{18}O$ values of gypsum from Cave of the Crystals show no variation, besides the habit of the crystals (beams or blocky), with a $\delta^{34}S$ of 16.9‰ and the $\delta^{18}O$ of 17.6‰. One sample from the Cave of the Queen (sample 22) and another collected close to the Cave of the Crystals (sample 28) have similar isotopic composition. Gypsum samples from the Cave of the Swords (level 120) have slightly lower $\delta^{18}O$ values, 1‰ less than samples from the Caves of the Crystals and the Queen (level 290). The isotopic composition of the mineralizing solution is estimated to be around $\delta^{34}S$=15.3±0.2‰, with a gypsum-solution enrichment factor of 1.65‰ (value at 25°C) for sulfur (Thode and Monster, 1965), and $\delta^{18}O$=14.3‰, for a gypsum-solution enrichment factor of 3.3‰ (value at 55°C) for oxygen (Pearson and Rightmire, 1980). These values are perfectly consistent with the isotope composition of the present day water collected at level 530 (Fig. 3 and Table DR3). As seen in the same figure, the isotopic values of sulfate dissolved in the water could be explained by mixture of sulfates from the dissolution of anhydrite from different locations of the mine, those from the ore deposit area (samples 23, 24, 25 and

34) and those from upper levels in the mine (samples 4 and 21).

Table DR3: Isotopic composition of Naica samples.

sample	Mineral	location	$\delta^{34}S$	$\delta^{18}O$
9	Gyp.	Cave of the Swords	17,3	16,5
8	Gyp.	Cave of the Swords	17,6	16,7
15	Gyp.(beam)	Cave of the Crystals	17	17,4
31	Gyp.(blocky)	Cave of the Crystals	16,8	17,8
4	Anh.	close to Cave of the Crystals	16	13,7
28	Gyp.	close to Cave of the Crystals	16,3	17,8
21	Anh.	Cave of the Queen	16,7	13,0
22	Gyp.	Cave of the Queen	16,8	17,7
23a	Anh.	Ore body	14,4	16,0
24a	Anh.	Ore body	14,9	15,6
25a	Anh.	Ore body	13,8	15,7
25b	Gyp.	Ore body	17	17,9
34a	Anh.	Ore body	12,9	14,3
34b	Gyp.	Ore body	16,5	17,0
35	Anh.	level 590	13,8	14,7
36	Anh.	level 700	14,6	15,6
26	Water	level 530	14,6	14,4

2.4. Hydrochemistry

Two samples of groundwater from the levels 640 and 530 have been analyzed for major dissolved components. Cations and anions were analyzed by conventional Inducted Coupled Plasma with Atomic Emission Spectrometry (ICP-AES) and High Performance Liquid Cromatrography (HPLC), respectively, with an standard error lower than 5% in all cases. The δD and $\delta^{18}O$ values for the same two water samples were determined by H_2 and CO_2 equilibrium respectively and Isotope Ratio Mass Spectrometry (IRMS). The data were reported in the usual $\delta^{18}O$ and δD SMOW. The sample from level 530 has been also analyzed for tritium counting with a precision of ±0.31 TU (1 TU = 10^{-18} $^{3}H/^{1}H$). These data are summarized in Table DR4.

Table DR4: Chemical analyses (mg/L) of water samples from Naica mine. Legend : 290-1976, means sample collected at level 290 m in 1976. * (asterisk), measured at 20°C. Analyses 290-1976 and 430-1976 are after Dames and More (1977). The saturation index of some main minerals has been calculated with the code PHREEQC (Parkhusrt and Appelo, 2003).

	290-1976	**390-1976**	**430-1976**	**640-2002**	**530-2003**

3. Supplementary Discussion

3.2 Gypsum Nucleation

Solubility curves for gypsum and anhydrite as a function of temperature and salinity have been computed using version 2.12.1-669 (Linux) of the PREEQC software of the U.S. Geological Survey for three different pH values (6.0, 7.0 and 8.0) and three different salinity values. Calculations identified as "salinity 1" included a concentration of Na, Cl and Mg equal to the one measured in present-day waters collected in the Naica mine (100 mg/L Na, 24 mg/L Cl and 120 mg/L Mg). "salinity 2" conditions include twice this concentration and, finally, "salinity 0" calculations were made starting with pure water. In contrast with the negligible effect of pH, the salinity is a major control in the solubility of both gypsum and anhydrite. Fig. 4a of the paper shows these solubility curves.

Supersaturation values were calculated as $\sigma(T) = m_a(T)/m_g(T)$ where m_a and m_g are the equilibrium concentration of Ca in a saturated solution in equilibrium at temperature T with anhydrite and gypsum respectively as calculated by PHREEQC. This means that $\sigma(T)$ is the supersaturation with respect to gypsum of a solution obtained by equilibrium dissolution of anhydrite at temperature T. The computed supersaturation values as a function of T are shown in figure DR10.

The curves of induction time for nucleation were in turn computed from these supersaturation curves using equation

$$J = A exp - \frac{16\,\pi\gamma^3 v^2}{3k^3 T^3 ln^2 S}$$

discussed in the article. Data from three different papers have been analyzed to collect the empirical data to parameterize this equation (Lancia *et al.*, 1999; Prisciandaro *et al.*, 2001; He *et al.,* 1994). These articles show a considerable scattering in the values of activation energy, which is a critical parameter for the nucleation and can have a very large impact (several orders of magnitude) in the value of the induction time. Fortunately, owing to the extremely step slope of the induction time curve, these changes can only produce shifts of a few degrees in temperature for reasonable time values in the range "one day" to "some thousand of years". Consequently, the inherent uncertainty in these empiric data does not compromise our results and the only expected influence is a shift of (at most) 5 ºC in the lower boundary of the temperature window proposed. The parameters used for the curves shown in the article (Fig. 4b) were obtained from Lancia *et al.* (1999) because this article contains data for supersaturation values smaller than the remaining references, making more accurate the extrapolation needed for the very low supersaturation values involved in the crystallization of the Naica gypsum crystals.

3.3 Evidence of phase transition anhydrite-gypsum in Naica

Several mineral samples of gypsum, anhydrite and enclosing limestone were collected from the Caves of Crystals, Swords and Queen and from the surroundings. The mineralogy of the samples was investigated by transmitted light microscopy, Powder X-ray diffraction method (XRD), and by Scanning Electron Microscopy and microanalysis (SEM-EDS). In Figure DR11 evidence of a transformation anhydrite-gypsum at microscopic level is shown.

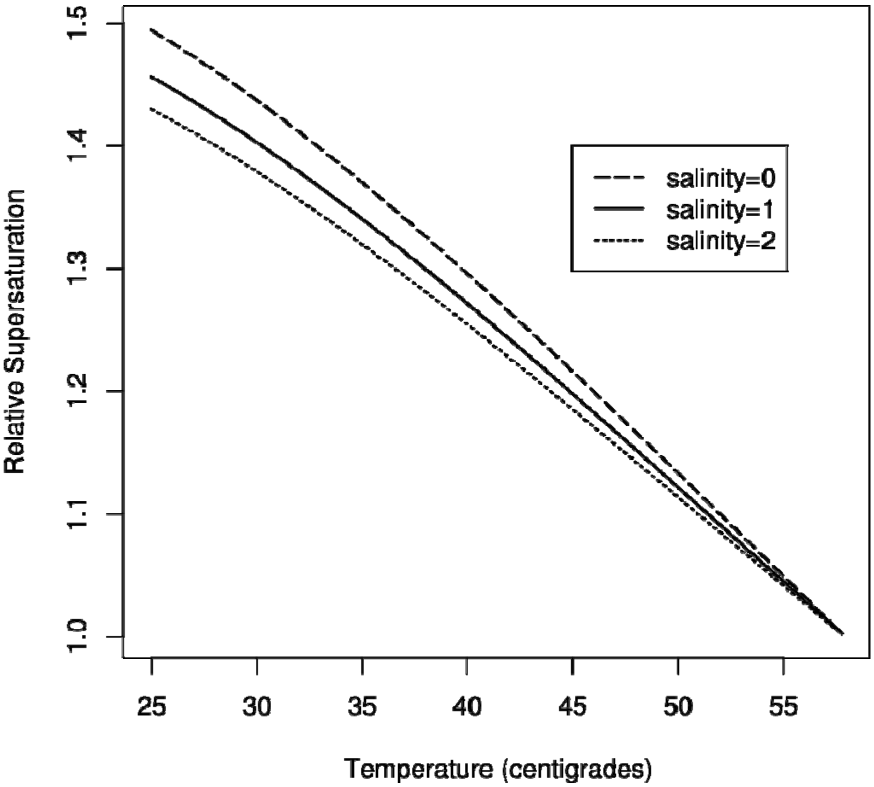

Figure DR10: Temperature dependence of supersaturation with respect to gypsum of a solution obtained by equilibrium dissolution of anhydrite.

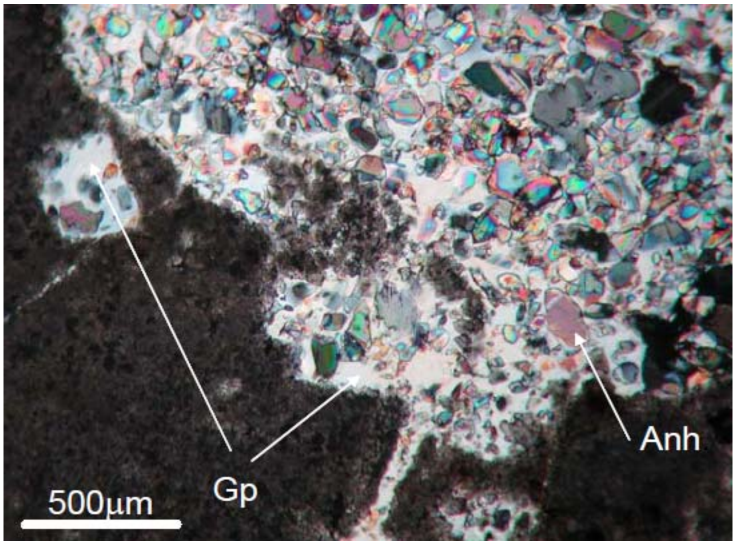

Figure DR11: Poikiloblastic gypsum crystals growing inside an anhydrite matrix. Sample collected close to the Cave of Crystals, Naica mine, level 290.

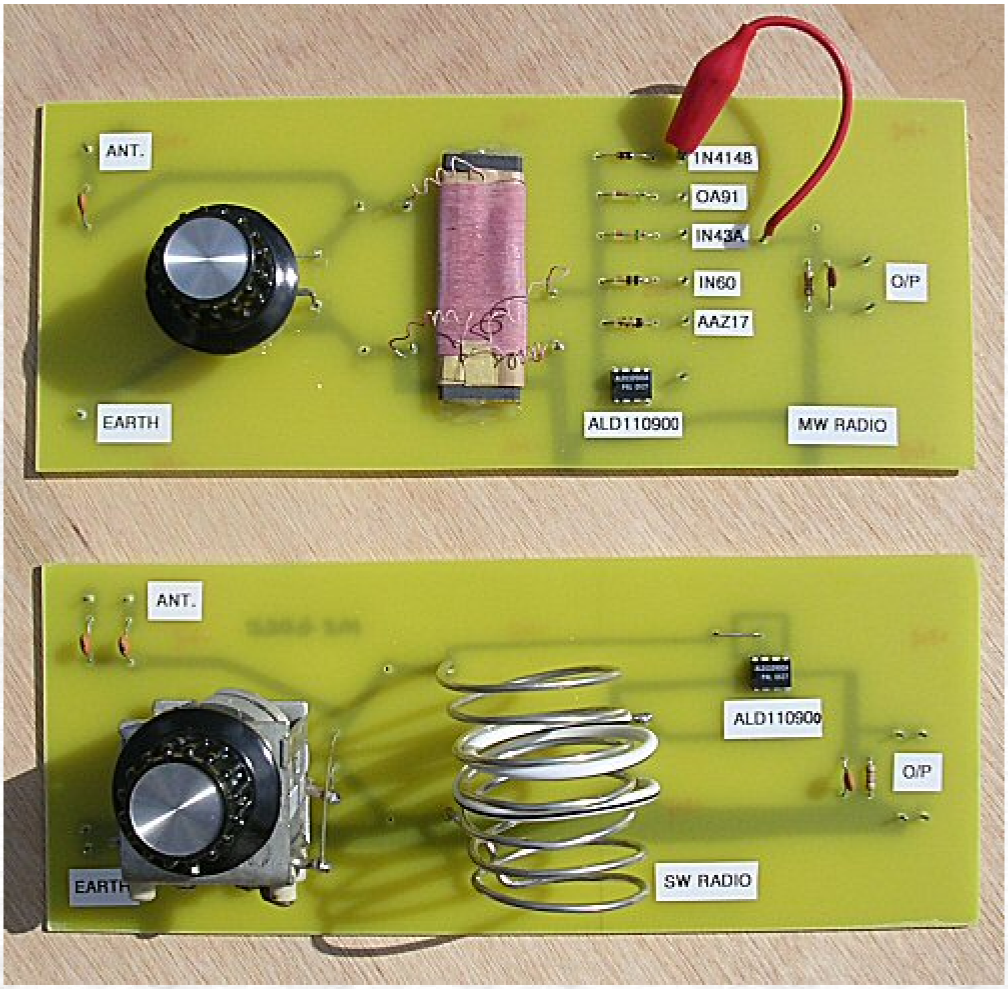
'CRYSTAL SET' RADIO'S - DIFFERENT DETECTORS



**Top: the medium wave (MW) test radio with a selection of 'detectors' (selected by the croc clip lead)
Bottom: the short wave (SW) version with a ALD110900 detector
(on each circuit board the connections are: antenna - top left, Earth - bottom left, audio output (heaphones / amp) - far right.)**

RADIO AND RADIO WAVES

The simplest 'radio' can be a piece of wire attached to the input of an amplifier. Why does this pick up radio signals? Well in principle it should not be able to pick up anything but in reality poor solder joints in the amplifier circuitry, as well as point contact effects between the ends of the anenna wire going into the input socket of the amp as well as other effects mean that you do often hear radio signals.

Radio waves are electromagnetic waves as they pass through a metal they induce small voltages into it. Any piece of metal e.g. metal fram specs, tape measures, metal window frames, a piece of wire etc. will act as an antenna and have tiny voltages induced into them. These voltages will be due to natural radio waves (from Space as well as the Sun and Earth), radio stations, satellites, mobile phones, garage door remote controls, microwave ovens .... the list goes on and on.

In the case of long, medium and short wave radio stations the amplitude of the radio wave signal is modified by the music, voice or program - we call it Amplitude modulation AM. Here the strength of the radio waves varies as the tones, loudness and pitch of the program vary. As a result the voltages induced in the metal object antennas distant from the radio wave stations also vary in accord this program information or modulation.

To actually hear the programs on the radio waves you cant actually take this tiny signal and listen to it directly (say with headphones or an amplifier). This is because the signal is a very high frequency signal out of the range of human hearing. To get the audible information - the program - 'off' the radio signal you need a device known as a 'detector'. This is usually a diode but lots of other things can act as inefficent detectors for example a mineral called galena, coke (burnt coal) ... as well as rusty screws and bad solder joints which is how the ampilfier mentioned above apparently picks up radio signals.

In the early days of radio crystals of galina were used as diodes and so these radios became known as 'crystal set radios'. They did not have any amplifiers and did not require any battery to work. They got all their power from that induced into the (of very long) antenna by the radio signal(s). The radio detector is an extremely important part of the radio and its proper function determines how well the radio works.

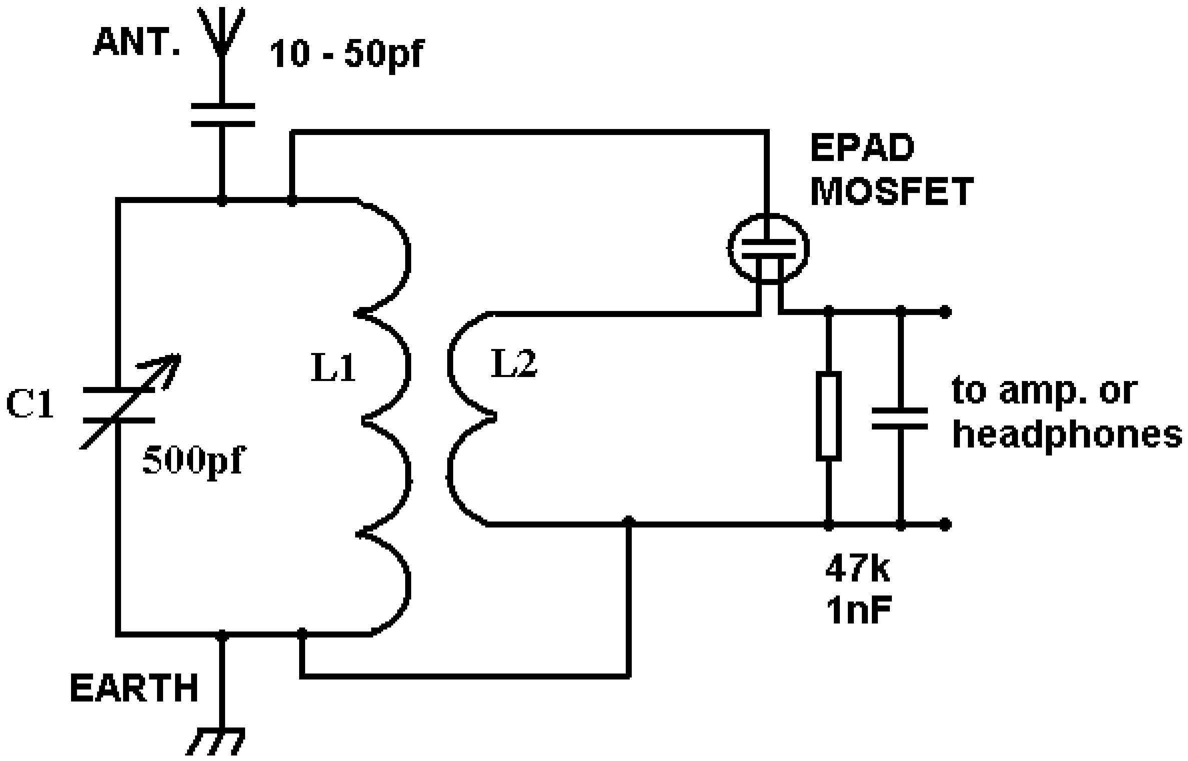
The radio signal is an AC signal. A speaker or headphones can not resonate at such high frequencies as radio waves and if you try to wire in the RF to the headphones the diaphram just averages the power. As half the time the RF is positive and half the time negative, in an AC signal, the average is zero and so you dont hear anything. The diode or detector is a device called a diode which only conducts electricity in one direction. So it only allows the positive, or negative half (one half but but not both) of the AC signal to go through (depending on which way it is wired). After the diode the average is now no longer zero its actually a changing signal dependant on the modulation of the radio wave - which is the information we want to hear. As this is at audio frequencies, and as the diaphram can move at audio frequencies, you hear the information on the detected RF signal - the music, voice or what ever.

Why should some detectors (diodes) be 'better' than others? The answer is not that some are better at 'magnifying' the signals but rather that each diode requires a certain threshold voltage in order to start conducting (one way). Signals below this level will not get passed through and a signal only slightly larger will therefore only pass through weekly (the diode unfortunatly absorbing the majority of the signal). As a result for large signals you wont expect to see much difference between different detectors but for weak signals there can be a great deal of difference. In an ideal world the diode would start to (forward) conduct at just above zero volts and this ideal detector (which does not conduct at all in reverse) would produce the greatest signal possible for the particular strength signal applied to it.

Recently I was playing around with OA91 germanium diodes for a mobile phone detector. I made a simple 10cm per side square loop and wired it directly to an LED. I was hoping that if I brought the mobile near to the loop and texted, or made a phone call, the RF should be picked up by the loop (which is almost resonant) and the LED should light - it didnt work! But putting an OA91 in series I did get it to work. So why did I need the OA91 diode when the LED is itself a diode?

It can't be due to the threshold voltage in this case as I am still using the LED and I did get it to work with the same signal! So I guess it because the capacitance of the LED is very high compared to the point-contact germanium diode. If we extend this thinking to the crystal set radio I guess the germanium diodes have very little capacitance and so dont allow any of the 'wrong' half of the AC signal through and so act as a more perfect detector. An LED would have a high capacitance and so let some of the wrong half of the AC signal through which on averaging by headphones would be nearer zero (see above) - hence less sound.

A low threshold (turn-on) voltage and a low self capacitance are crucial things in a good detector. Point contact germanium diodes having a very small area (a point of contact) have low capacitance and the germanium semiconductor-metal junction of the contact has a low turn on voltage. EPAD Mosfets also have low capacitance, high input resistance (low loading of the signal) and low turn on voltage.



MEDIUM WAVE TEST CIRCUIT (top in photo)
As a simple test circuit to compare detectors I made up a simple 'crystal set' radio from a ferrite rod coil from an old radio, tuning capacitor an array of diodes (crystals) and a simple RF filter composed of a 47k resistor and 1nF capacitor. The coil and capacitor formed the resonant circuit which was fed via a 10 - 50pf capacitor by the antenna (long wire). This capacitor helps to reduce the effect of the antennas own capacitance and inductance from modifying the resonant frequency of the tuned circuit. Ideally this should be as small a capacitance as you can get away with but too small a value will reduce the radios sensitivity ....

An earth was connected to the ground connection of the circuit. Instead of taking the antenna end of the resonant circuit to a diode detector (as many simple crystal sets do) I used a ca. 10 turn coupling coil around the coil. This was done to limit the loading on the resonant circuit by the detector. It should help keep the tuning sharp and also help to keep the overall (band) spread of tuning as large as possible.

Because of the reduction in turns (ca. 100 turns : 10 turns, i.e. 10:1) the coupling coil reduces the signal that is available to drive the detector. For example if I use a standard silicon diode (e.g. a 1N4148) which requires about 0.6V to conduct then we might need ca. 10 x 0.6 = 6V of RF to be developed in the resonant circuit! A high Q resonant circuit might do this with a long antenna coupled to it but without such a generious antenna such a set-up wont be very sensitive.

RESULTS
I tried an array of 'crystal set' type diodes to campare them. Typical rough results are shown in the table below. This was with an Earth and about 3-4m of antenna wire randomly strung near to ground level (so its a pretty bad set up really - a good test).

The EPAD MOSFET data sheets described how the gate and drain of one of the MOSFETS can be joined together to form the anode of a diode the source then forms the cathode. I tried this arangement with the ALD110900 in order to make up a 'crystal set' diode from this MOSFET but it didnt perform well.

Then I tried the alternative arrangement as described in the references above. In these articles they dont use the MOSFETS as diodes but connect the gate directly to the resonant circuit. As the input resistance is extremely high (c.a. 1E12 ohms) and the input capacitance is very low (c.a 3pf) it does not load the tuned circuit by any appreciable amount. The source and drain are then wired between the coupling coil and filter just as the usual diode detector is in a crystal set radio. In this configuration the MOSFET is working more as a gate voltage controlled resistor rather than a diode i.e 'off' for half an RF cycle and 'on' for the rest - this lets the envelope through and you hear the music or sound. One article describes the arrangement as a synronious detector. As there are two MOSFETS in one package the two are wired in parallel i.e. gate to gate, drain to drain (there is a common source) etc.

DETECTOR TYPE	AF voltage produced after filtering
1N4148 silicon	no signal
OA91 germanium	1mV
1N43A germanium	1mV
1N60 germanium	1mV
AAZ17 germanium	1.5mV
ALD110900 EPAD MOSFET wired as diode	<1mV
ALD110900 EPAD MOSFET wired as sync. detc.	10mV

Typical results of the AF voltages produced by the detector (for use by headphones or amplifier) for an Earth connection, small (ca. 3-4m antenna wire near ground level) and the prototype 'crystal set' radio.

For the simple set-up described above there was not enough signal to get the silicon diode to work at all (although a much longer wire did provide a very small signal). A simple listening test and measurement of the AF prodiced by each diode showed that their was very little difference between the various germanium diodes. The MOSFET simply wired as a diode (gate wired directly the drain) was a poor detector - better than a silicon but not nearly so good as any of the germanium diodes. Finally the EPAD MOSFET wired as a syncronious detector worked really very well apparently producing ca. 10 times the signal (in other words it has much less loss than a germanium diode) for this particular set up and station than the germanium diodes.

As the syncronious arrangement was so succesful it got me thinking about this circuit. As the gate goes straight in on the main resonant circuit where the voltages, in a good Q circuit, might well be relatively high I thought I would try a standard FET (2N3819) and MOSFET (VN10KM) instead - and they worked! (they are a lot cheaper than an EPAD MOSFET chip and easier to get). Some FETS have a larger input capacitance so it helped to put a 10pf capacitor in series to the gate (a 10M ohm from gate to earth might reduce 50Hz pick up).

They were not as good as the EPAD MOSFET (although I only tried a single device) but the arrangment was still better than a simple 'crystal set' diode. For weak signals the EPAD MOSFET should perform better as it is able to keep going while the FET and the standard MOSFET will start to trail off as the resonant circuit voltage drops below the relatively higher gate voltage required for these devices. However it was interesting to see that it seems to be possible to get a more efficent set-up for a 'crystal' radio using a standard FET or MOSFET than with the standard germanium diode detector.

By the way I recently re-tried the 1N4148 diode but wired a 1.5V AA battery with a 100k resistor across it to forward bias it - and it worked ! It seemed to work better than a OA91!

SHORT WAVE 'CRYSTAL SET RADIO (bottom in photo)

The bottom circuit shown in the photo above is my own short wave version of the 'crystal set' radio but based on the references above. It's the same circuit as the MW radio but has a reduction drive tuning capacitor and different coil. I used about 7 turns (ca. 4cm diameter) for the resonant circuit and a couple of turns of insulated wire (white) for the coupling coil. I guess the radio tunes from about 3-8 MHz - I havent tried a sig gen on it yet.

I made this in the summer months (not the best time for listening on this part of the spectrum). Using an Earth and few meters of wire for antenna I heard 2 or 3 stations from around the world during the day while at night there were at least 7 including the voice of Russia world service, Radio Thailand as well as German and French speaking stations.

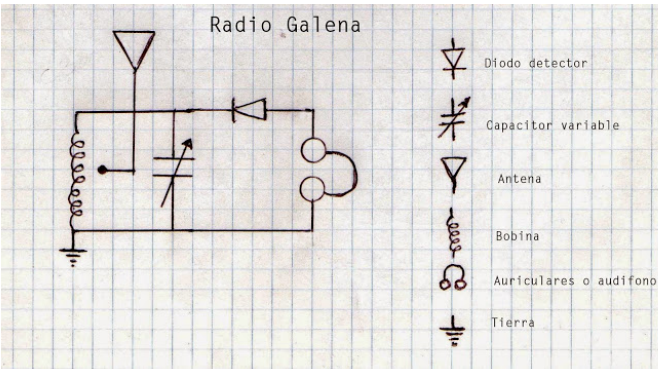
Construí tu propia radio Galena

Construcción radio Galena

Si te gustan las radio, este proyecto es muy educativo y entretenido, con la “Radio Galena” podrás recepcionar frecuencia de AM y es la base de la radio recepción, además es una radio que no requiere energía proveniente pilas, baterías ni fuente de alimentación. Ya que funciona gracias a la energía que propaga las emisoras, aparte se presta para experimentar mucho, solo busca en google “radio galena” encontraras muchísimas variantes.
Como punta pie puedes leer un poco más sobre el tema aquí http://100ciaencasa.blogspot.com.ar/2014/01/radio-sin-pilas.html y aquí http://es.wikipedia.org/wiki/Radio_a_galena

El circuito es por demás sencillo



Lista de materiales
1-Diodo de germanio aquí usamos el 1N60 (podrás usar otros siempre y cuando sea detector)
1-auricular de alta impedancia (son un tanto difícil de conseguir, pero puedes usar otro de teléfonos viejos o a la salida puedes conectarle un pequeño amplificador) (no te pierdas próximamente el proyecto Amplificador portátil de bajo coste con LM386)
1-Tandem o capacitor variable, (se lo puede comprar o conseguirse de una radio vieja)
Unos metros de cable para bobinado o cable magneto, yo recicle el

construir una radio de galena

Cinco canales de Youtube para aprender experimentos caseros

5 Experimentos Caseros... ¡Listos Para Hacer!

Experimentos caseros

bobinado de un motor quemado cuyo cable esmaltado es de .045 milímetro (casi ½ milímetro de espesor)
1-base de madera para hacer el montaje medidas 13x13 cm aprox.
1-tubo de pvc de 4 cm (1,5 pulgadas) por 9 cm de largo (se lo consigue en ferreterías es el que se usa para desagüe)
1-una varilla o alambre de unos 15 cm. aproximadamente (tips se puede usar un rayo de bicicleta)
Como siempre necesitaras estaño, soldador, alicates, algunos tornillos o clavitos, algún pegamento

EasyPDFCombine™

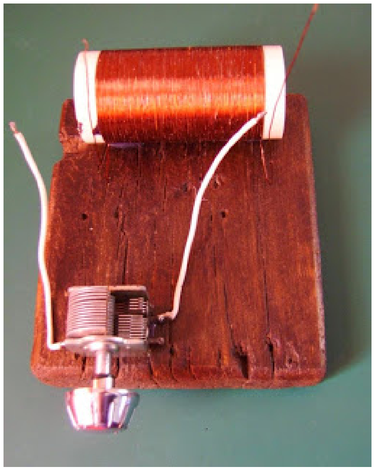
Diodo de germanio 1N60

Audífonos alta impedancia

Base madera de 13x13 cm aprox

Cable esmaltado para bobinado o cable magneto

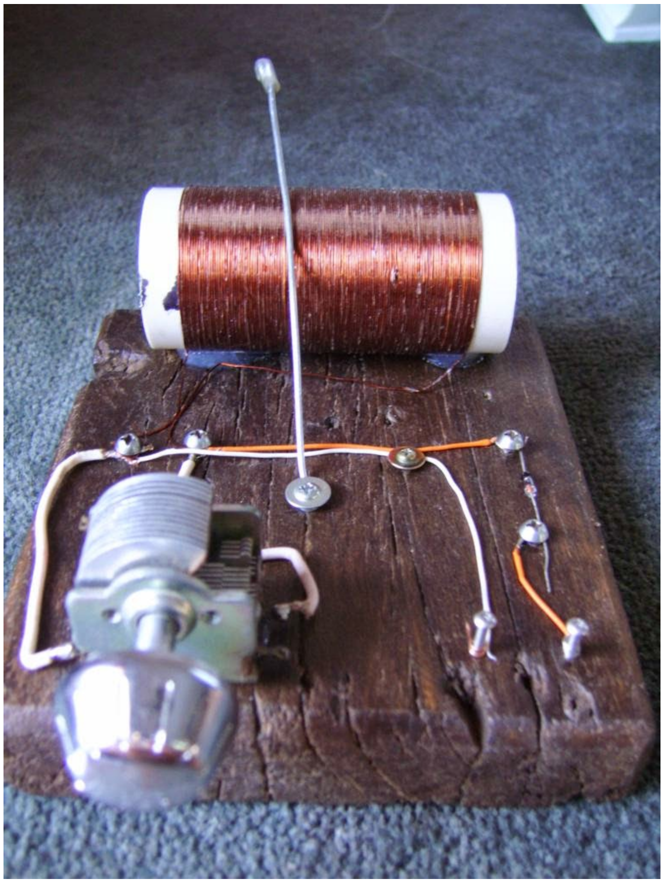
Tandem o capacitor variable y bobina montado en base.



Vallamos a la construcción
Lo primero que vamos hacer es la bobina de nuestra radio, para ello usamos el tubo de pvc fijamos en un extremo del cable esmaltado dejando un excedente de unos 10 cm. para hacer las conexiones luego, podemos usar una cinta adhesiva o como en mi caso una gotita de cianocrilato. Empezar el bobinado en el sentido que quieras (en este caso sentido de las agujas del reloj), solo ten en cuenta que las espiras estén bien prolijas y lo más juntas posibles sin que se encimen unas con otras, realizar 130 espiras y asegurar el otro extremo dejando también 10 cm. para la posterior conexión.

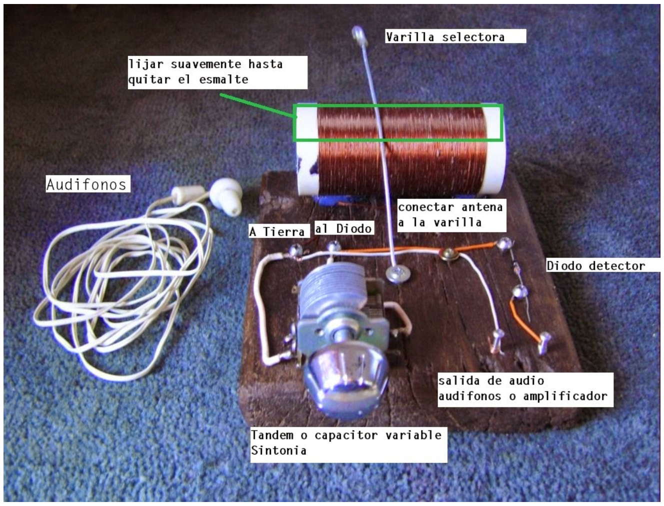
Después montamos según diagrama citado arriba, recuerda que el cable esmaltado de la bobina tienes que pelarlo ayudándote con una lija fina para sacar el esmalte sino el mismo no hace contacto ni se suelda ya que la película esmaltada es aislante.

Fotos de galena terminada



Para la recepción:
Conectamos el audífono de alta impedancia o en su defecto el mini amplificador
A tener en cuenta
vamos a lijar una sección del esmalte a lo largo de la bobina (ver figura) , la antena esta conectada a una varilla, "recepción gruesa" por así llamarlo con ella limitaremos la cantidad de espira de nuestra bobina para poder sintonizar varias estaciones de radio a modo de derivaciones, si todo funciona bien tendremos sintonía quizás algo mezclada y de no muy buena calidad, entonces hacemos el ajuste fino moviendo el tándem o capacitor variable.
Una de las cosas más importante y tener en cuenta en este tipo de radio es la antena y puesta a tierra, la antena se aconseja unos 10 metros como mínimo, pero no te asustes, puedes usar como en mi caso un alambre extendido como lo que usan para colgar la ropa y la puesta a tierra una reja que esté haciendo contacto con la tierra o cañería metálica como la de una bomba de agua vieja

Detalle de conexiones.



Varilla selectora
lijar suavemente hasta quitar el esmalte
Audifonos
conectar antena a la varilla
A Tierra
al Diodo
Diodo detector
salida de audio audifonos o amplificador
Tandem o capacitor variable Sintonia

Nota: se puede experimentar con el tamaño del núcleo de la bobina como así también la cantidad de espiras y espesor del cable esmaltado de la bobina o cable magneto, yo he realizado para este proyecto unas 5 bobinas diferentes aunque todas recepcionaban alguna emisora, pero el que mejor me resulto es el que aquí describo. También puedes experimentar con largo de antena y todo los cambios que se nos ocurran, este es un buen proyecto para la experimentación, también como detector en vez del diodo de germanio, se puede usar la piedra galena que es la que le da el nombre al modelo (un tanto difícil de conseguir), con un transistor conectando solo dos terminales, hasta como hicieron en la segunda guerra mundial con una hoja de afeitar y una punta de un lápiz, es cuestión de que investigues un poco y que experimentes. En mi caso llego a funcionar sin el capacitor variable y con recepción muy buena de las estaciones potentes.
Bueno espero te animes ya que es muy gratificante cuando sale funcionando.
Si quieres puedes mandarme o dejarme un comentario con las fotos de tu Galena.

Saludos y hasta pronto

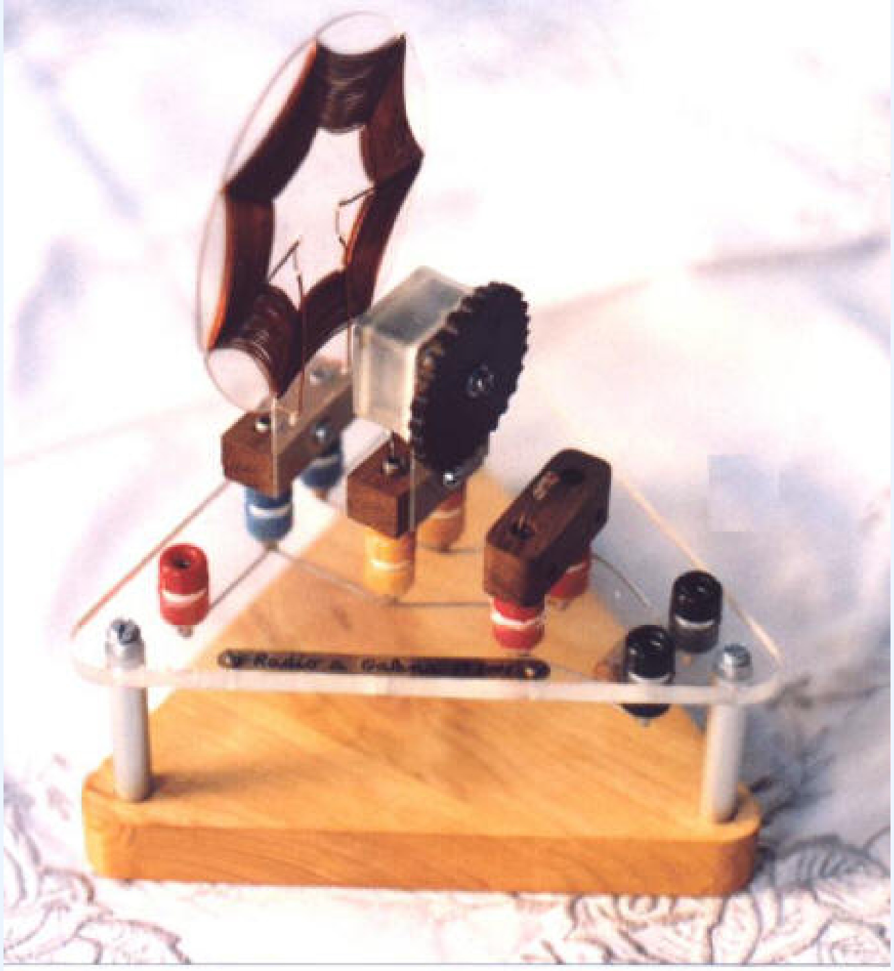
"New Age" Crystal Radio

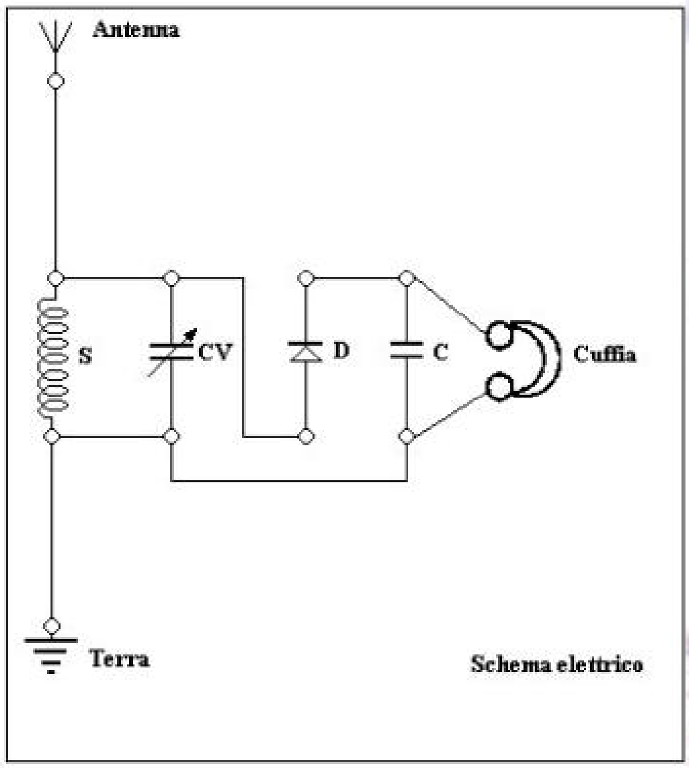
A project by Luciano Loria

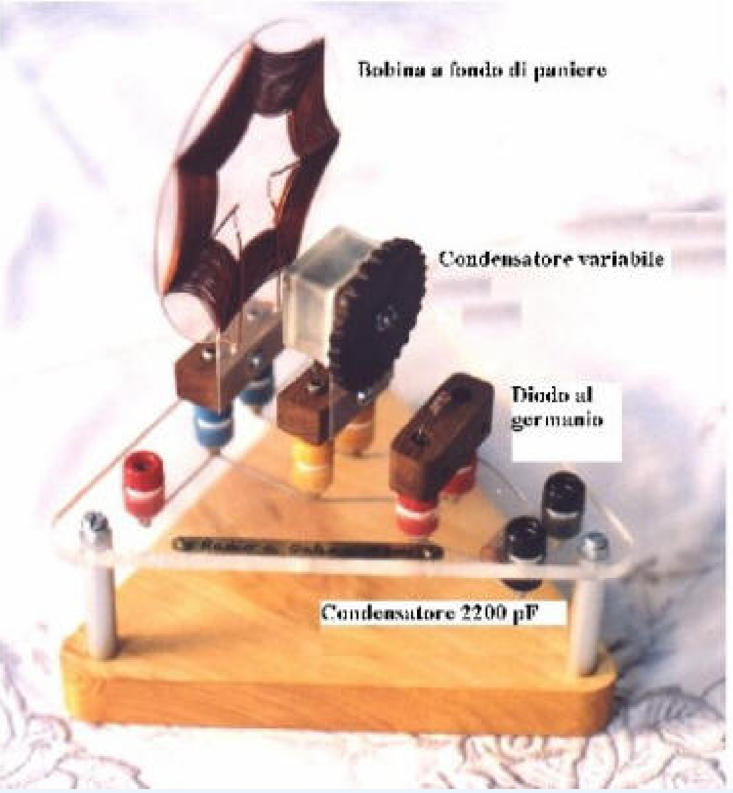


Following is proposed the construction of the most classic and simple crystal receiver, the principle scheme is, in fact, reported on all books or manuals of radio-technical and physics. In this realization the look was taken in order to expose the appliance, in the living room window, recalling, certainly, the interest of those who observe it. Clearly, the radio is fully functional: just provide adequate antenna and ground and a high impedance headset and listening to the local station is guaranteed. The construction is quite simple and affordable for anyone with good will and a minimum of simple hobbyist equipment. First of all, obtain the following material:

- 1 variable capacitor, also for recovery, transistor radio type (any capacity value);
- 1 germanium diode (any type);
- 1 capacitor of 2.2 or 3.3 or 4.7 nF;
- 10 4 mm diameter bushings of various colors;
- 6 bananas diameter 4 mm;
- 1 wooden strip 10 x 10 mm, length 8-10 cm approximately;

- 1 wooden cutout, 2 cm thick, from 15-20 x 15-20 cm on the side;
- 1 cutout of plexiglass, thickness 4-5 mm, from 15-20 x 15-20 cm on the side;
- 1 aluminum or brass tube, diameter 6-8 mm, length about 15 cm;
- 3 wood screws 3mm diameter, about 45-60 mm long;
- 1 piece of wire for connections in tinned or silvered copper with a diameter of about 0.8-1 mm.
- For the basket-shaped coil see separate **description** .





Construction:

Cut out from the wood and plexiglass an equilateral triangle of about 15 cm on each side and smooth the edges; on the plexiglass triangle, about 3 cm from the vertex, three 3 mm diameter holes for the passage of the screws and 10 8 mm holes to fix the bushes. From the diagram and from the photo it is easy to establish the position of these holes, the interaxis between the bushings where they will be inserted: the coil, the variable capacitor, the diode and the bonnet, is 19 mm (standard pitch of the normal plugs and sockets 10 A). Fit the bushings in their place and, following the diagram, make the few connections with the tinned or silver wire, the only element that will be mounted in a fixed position is the capacitor from 2.2-4.7 nF, to be welded directly on the headphone output bushings. Divide the aluminum or brass tube into three parts, making pieces of about 4 cm; connect the top plate in plexiglass with the wooden base using the wood screws, using the three tubes as spacers. Then, using the wooden strip, make the wooden spikes, 19 mm pitch, of support for coil, CV and diode; the bananas will provide the necessary brass thorns. Fix the coil and the variable capacitor to their supports by means of screws and connect the terminals to the plugs. The diode must be fixed directly without any other precautions. Insert in their place, the tuning coil, the variable capacitor, the germanium diode; connect antenna and ground,

Construction and Operation of a Simple Homemade Radio Receiving Outfit

The 1922 Bureau of Standards publication, *Construction and Operation of a Simple Homemade Radio Receiving Outfit* [1], is perhaps the best-known of a series of publications on radio intended for the general public at a time when the embryonic radio industry in the U.S. was undergoing exponential growth.

While there were a number of earlier experiments with radio broadcasts to the general public, most historians consider the late fall of 1920 to be the beginning of radio broadcasting for entertainment purposes. Pittsburgh, PA, station KDKA, owned by Westinghouse, received its license from the Department of Commerce just in time to broadcast the Harding-Cox presidential election returns. In today's world where instant global communications are commonplace, it is difficult to appreciate the excitement that this event generated.

News of the new development spread rapidly, and interest in radio soared. By the end of 1921, new broadcasting stations were springing up all over the country. Radios were selling faster than companies could manufacture them. The demand for information on this new technology was almost insatiable. The Radio Section of the Bureau of Standards provided measurement know-how to the burgeoning radio industry as well as general information on the new technology to the public. Letters to the Bureau seeking information on radio technology began as a trickle, and then soon became a flood. Answering them became a burden.

Circular 120, published in April 1922, began: "Frequent inquiries are received at the Bureau of Standards for information regarding the construction of a simple receiving set which any person can construct in the home from materials which can be easily secured. This publication has been prepared to meet these inquiries." The circular also noted that the Bureau was cooperating with the Bureau of Markets and Crop Estimates of the Department of Agriculture. In the early days of radio, broadcasts to farmers of crop price reports were an important public service.

In 1921 factory-made radios were very expensive. Many of them cost more than $2000 in today's dollars, and less affluent families could not afford to have one. When the Bureau published this circular (which sold for only five cents) on how to build a simple crystal radio at home, it was an instant success. Thousands of orders

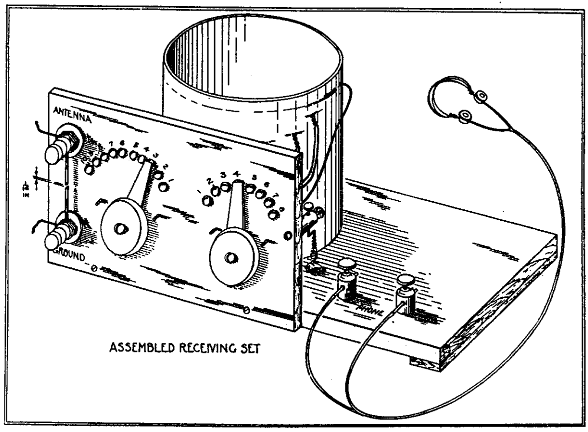

Fig 1. The crystal radio described in Circular 120.

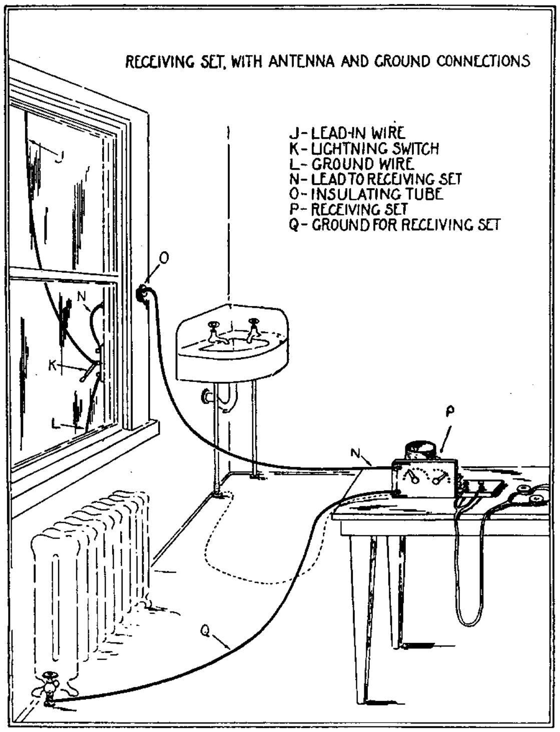

Fig. 2. Diagram showing the antenna and ground connections to the radio.

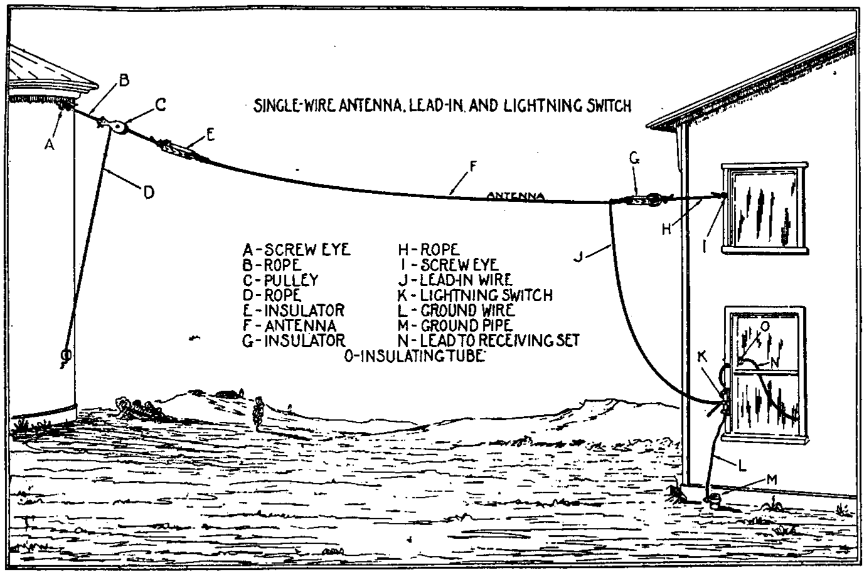

Fig. 3. Details of the outdoor antenna recommended for use with the crystal radio.

flowed in from every state. The circular showed how almost any family having a family member handy with simple tools could make a radio. The circular states "Satisfactory results have been obtained from sets constructed according to these instructions by persons having no previous experience with radio." The authors stated that the cost of the materials for the radio and associated headphones and antenna system should not exceed $10.

Newspapers around the country urged readers interested in radio to order a copy, and in many cases they reprinted the entire article. Even today, antique radio collectors searching attics and basements often come across dusty home-built crystal radio sets that were obviously constructed using the Bureau's plans. No doubt the remarkably rapid growth of the radio industry in the U.S. during the 1920s (analogous to the growth in Internet-related businesses today) was aided considerably by information provided to the public by the Bureau, such as this circular and the other items noted in the bibliography [2-6].

Circular 120 proved such a success that the Bureau published a number of other circulars on radio technology intended for the general public, as noted in the bibliography. All were popular. In some cases, commercial radio manufacturers copied the circuits proposed by the Bureau. During the same era, other radio publications of the Bureau captured public attention as well, though perhaps in smaller quantities than Circular 120. *Radio Instruments and Measurements* [7], Circular 74, published first in 1918 with a second edition published in 1924, became a best seller in the post-WW I era. Its principal authors were most likely J. H. Dellinger, J. M. Miller, F. W. Grover, and G.C. Southworth. The authors of Circular 120 are not stated, but some of those same individuals likely contributed to it. J. Howard Dellinger's story is particularly interesting. He came to the Bureau in 1907 as a laboratory assistant at $900 per year, and retired as Chief of the Central Radio Propagation Laboratory in 1948. He headed the Radio Section for much of its existence. Appendix D of Reference [9] is a biography of Dellinger.

The Principles Underlying Radio Communication [8], Signal Corps Radio Communication Pamphlet No. 40, published in 1919 and issued in a revised edition in 1922, is another interesting example of a popular radio book. Written by the Bureau of Standards for training Army Signal Corps officers, it was an expanded and updated version of Circular 74, noted above, but was also widely used by college students and others studying radio. In spite of the "pamphlet" designation, it was actually a 600-page book. Thomas Edison said ". . . This is the greatest book on this subject that I have ever read, and I want to congratulate you and your Bureau on its production."

While the general public was interested in radio information for the lay person, the fledgling radio industry needed in-depth technical assistance from the Bureau, which it got. The Bureau helped radio manufacturers make better measurements for quantities such as resistance, capacitance, voltage, and frequency. Results of Bureau research on antennas and radio wave propagation, direction finders, vacuum tube characteristics, and testing were eagerly utilized by major companies such as General Electric, Westinghouse, Western Electric, and RCA, as well as by a myriad of small radio companies no longer in existence. At the same time that the Bureau was providing information to people constructing radios on their kitchen tables, Radio Section staff members were presenting technical papers on radio at conferences and in journals such as the *Proceedings of the Institute of Radio Engineers.* A good example of the latter is the classic work by John Miller, who discovered and explained "the Miller effect"—a feedback effect in triode vacuum tubes that limited their ability to amplify at radio frequencies [9].

Circular 120 described in detail not only the crystal radio itself but also how to construct an antenna and ground system. To minimize the cost, the circular suggested winding the tuning coil on a discarded cylindrical oatmeal box. For years afterwards, home experimenters used oatmeal boxes as coil forms for homemade radios. The crystal radio did not require batteries, but it did require the user to purchase a commercially made set of headphones (or telephone receivers as they were called in those days), since that accessory was not suitable for home construction.

One can just imagine the thrill of a farm family that had never heard a radio broadcast before trying the new set for the first time, and one of the family members crying out, "Come listen! I am hearing something!" The electronics revolution was underway and the Bureau played a significant part in accelerating the new technology.

Prepared by Brian Belanger.

PUBLISHER'S NOTE

Some of the circuits in this book have been adapted from H. Ness's *Handbook of Tested Transistor Circuits* (Babani Press), and the tables of transistor characteristics are based on data from Electrovalue Ltd., to which grateful acknowledgement is made.

1 RADIO MADE EASY!

Everyone knows what a radio is, but many people find it difficult to understand how a radio receiver works. Reading technical books on the subject is not always a help. The language of radio, and the understanding of technicalities, can prove difficult or even impossible without some previous background knowledge of the subject. So we will start right from scratch—in plain language!

The 'sending' of sound is easy to understand. When someone speaks he (or she) sends out a sort of pressure wave from the mouth. This travels through the air at approximately 335 metres per second, or 1,100 feet per second (the speed of sound). When a sound wave reaches the ear of a listener (anyone who happens to be in the way of it), the pressure wave will set parts in the ear vibrating, the 'signal' being transmitted to the brain and 'received' as an impression of sound—Fig. 1.1.

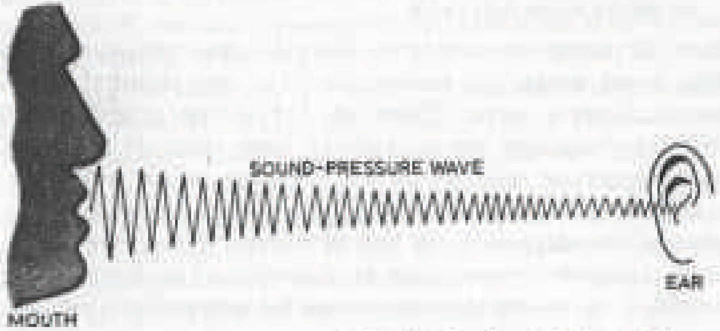

Fig. 1.1 Speech is transmitted directly through the air by sound-pressure waves.

Sound-pressure waves have another characteristic: their strength decreases quite rapidly with distance. Doubling the distance between 'sender' and 'receiver' would result in the level of sound received being reduced by one *quarter* (not one half).

The only effective way to increase 'distance of sending' or *range* is to increase the strength of the original sound, by shouting, for instance, although this will not greatly increase the range. (Remember that the strength of the sound-pressure waves decrease in proportion to distance *times* distance, or (distance)^2.) The other method is to increase the strength of the original sound by using a megaphone or public-address system. Both are devices which boost sound, known as *amplifiers*. A simple megaphone is a mechanical amplifier, while a public-address system is an electronic sound amplifier, based on a *microphone*, an *amplifier circuit*, and a *loudspeaker*–Fig. 1.2.

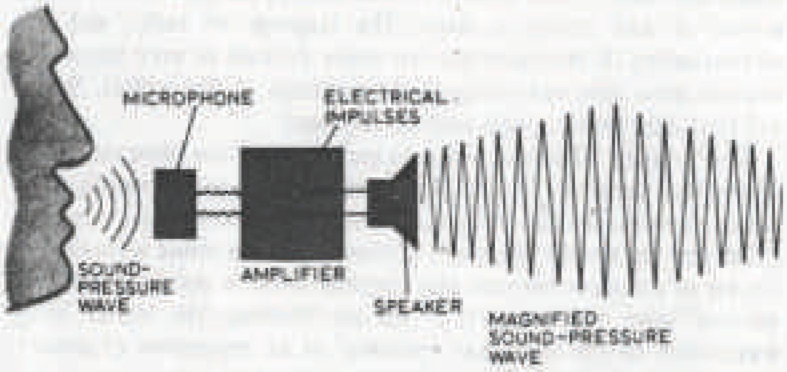

Fig. 1.2 To extend the range of sound transmitted, some form of amplifying device can be used.

Here the microphone acts rather like the human ear, being vibrated by the sound waves, but turning this effect into electrical impulses rather than nerve pulses. These are fed to the amplifier, which considerably magnifies the strength of these electrical signals. The stronger signals are then fed to a loudspeaker, which works like a microphone in reverse. It is fed with electrical impulses to set a diaphragm vibrating, which in turn generates a sound-wave 'output'. Because the incoming signal (into the microphone) has been magnified or amplified, the sound wave issuing from the loudspeaker is very much stronger than the original 'input' sound.

Such a system is still limited in range. Words spoken into a public-address system may be heard, under favourable conditions, as far away as, perhaps, one mile–but certainly not much further. Also, wind blowing in opposition to the sound will considerably reduce the range. So to increase range still further, some other method of transmitting the sound must be used–Fig. 1.3.

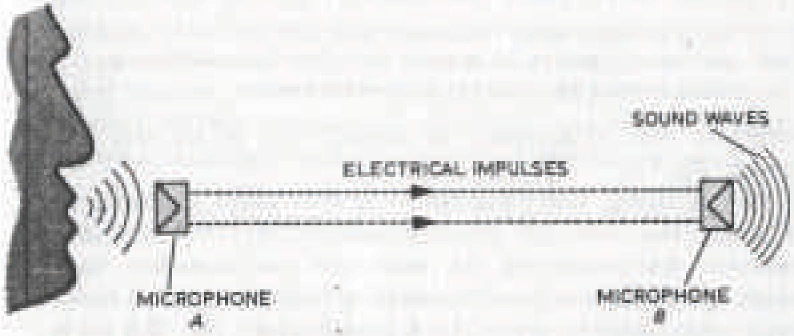

Fig. 1.3 To transmit sound over longer distance, wires are used to connect two microphones. In a simple system, the microphones can also work as speakers. In the usual telephone system, a separate microphone and speaker (earpiece) are used at each end.

Again the original sound is directed into a microphone, which is connected by two wires to another microphone. Each microphone can act either as a microphone or speaker. Microphone *A* turns sound into electrical impulses, which are transmitted along wires to microphone *B* which is vibrated to turn these impulses into the original sound; in other words, it is working as a speaker. If sound is now introduced into microphone *B*, electrical impulses will be transmitted along the wires back to *A*, which now acts as a speaker.

The particular advantage of a 'wire' system is that once the sound is turned into electrical impulses, these impulses can be transmitted over quite long distances without greatly diminishing in power. There will be a reduction in power with increasing length of wire, because all wires or conductors of electricity offer some *resistance* to the passage of electric currents. The greater the wire length, the greater the resistance, and thus the greater the loss of electrical energy. This will show up in the 'received' sound, being much weaker than the original.

There are ways of compensating for this; for example, the inclusion of a battery in the circuit, to produce a more 'responsive' microphone circuit (i.e. make the electrical impulses, generated by the microphone,

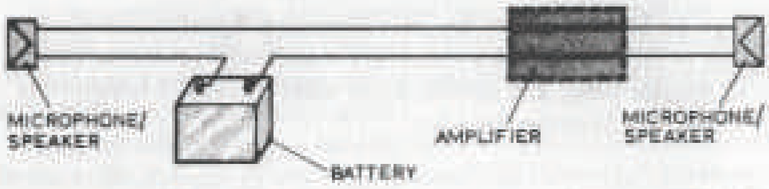

Fig. 1.4 Better sound transmission over wires is given by added power (via a battery). An amplifier can also be introduced into the circuit to boost the strength of the electrical impulses.

stronger). Also, if necessary, an amplifier can be included in the circuit – Fig. 1.4.

Before leaving this particular set-up it is worth explaining that, although two wires are shown connecting the two microphone/speakers, the system will also work with *one* wire. But, since a single-wire connection cannot complete a 'loop' for electrical currents, some other 'common' connection is needed at each end. This can be a connection to *earth*, and provides the 'return path' for the circuit – Fig. 1.5. There are disadvantages in such a system used for telephonic communication (which we have been describing), but the use of earth as a 'common' connection is very useful in radio work, as will be seen later. The earth may be 'real' – i.e. a connection to a physical earth; or 'virtual' – i.e. connection to a common line in the radio circuit with no external earth connection.

Telephonic transmission is possible over very long distances, but it does need interconnecting wires and one or more 'switching centres' in order to be able to connect one 'sender' to more than one 'receiver', or alternative 'receivers'.

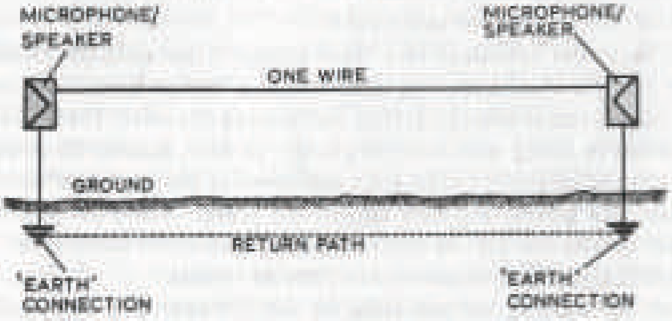

Fig. 1.5 Simple telephone systems can operate over a single wire with 'earth return'.

Radio is wire-less transmission (hence the original name, *wireless*): electrical impulses generated in a microphone are sent directly through the air – and *any number* of receivers can *tune in* to the same signal at the same time. The 'sender' becomes a *broadcast station*, each of the listeners using a radio receiver to hear the broadcast signals.

But electrical impulses, generated by sound waves reaching a microphone, cannot be sent directly. In the absence of connecting wires in the microphone, nothing will happen. The trick is to turn the electrical impulses generated in the microphone into a type of electrical signal which *will* travel through the atmosphere (and even into space); involving turning the electrical impulses into *radio-frequency waves*.

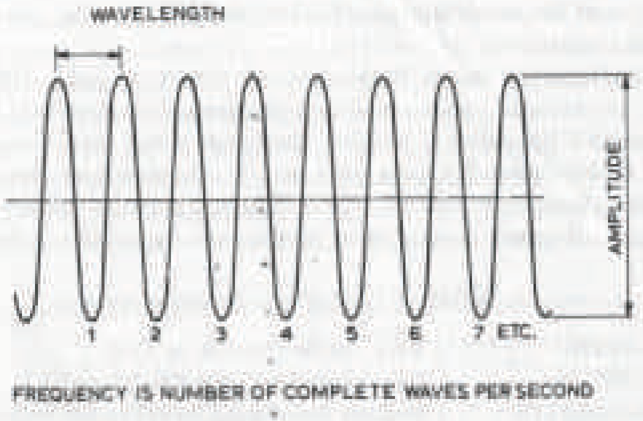

Fig. 1.6 A waveform is defined by its wavelength – or now, preferably frequency – and amplitude. Amplitude is a measure of the 'power' or strength of the wave.

A wave is simply a way of expressing, in physical form, a transmission involving energy. (A simple wave is shown in Fig. 1.6.) The characteristics of the wave are defined by its *wavelength*, or distance from crest to crest, and by its *amplitude* or 'swing' on either side of the centre-line along which the wave is moving.

Instead of wavelength, however, it is more convenient to speak of *frequency*, the number of complete waveforms produced per second. Wavelength, frequency and the *speed* of the wave are simply related as follows:

$$\text{wavelength} = \frac{\text{wave speed}}{\text{frequency}}$$

Wavelength (where used) is normally quoted in *metres*; frequency is now quoted in *Hertz* (abbreviated Hz).

All the sound and electrical waves we have considered so far have been at *audio* (or 'hearing') frequency (abbreviation AF). The original sound waves (which are an audio frequency) are converted directly into electrical waves, and back again into sound waves, all at the same frequency. The complete range of audio frequencies is from about 30 Hz (a very low, deep note) to around 16,000 Hz. The ear cannot respond to frequencies outside this range, so they are not heard. Neither, as we have noted, are any of these audio-frequency waves directly transmissible through the air over any distance, mainly because their *amplitude* decreases rapidly with increasing distance. *Amplitude* is a measure of the power or 'strength' of the wave (think of sea waves for a simple comparison).

Radio-frequency waves travel with the *speed of light*, 300,000 metres per second. Because of their high speed, their amplitude is far less modified by distance. Another distinction is that radio-frequency waves (abbreviation RF) are sent out in all directions from the source–a characteristic of all electro-magnetic radiation (unless constrained or 'beamed' in a position or direction by suitable reflecting devices).

The various radio waves are divided into categories, namely:

10–30 kHz	Very low frequencies, or VLF.
30–300 kHz	Low frequencies, or LF (long wave).
300–3,000 kHz	Medium frequencies, or MF (medium wave).
3–30 MHz	High frequencies, or HF (short wave).
30–300 MHz	Very high frequencies, or VHF.
300–3,000 MHz	Ultra-high frequencies, or UHF.
3,000–30,000 MHz	Super-high frequency, or SHF.

The LF range corresponds to the 'long wavelength' band; the MF range covers the 'medium wavelength'; and the HF covers the 'short waveband'.

An immediate problem arises. Radio waves (RF) cannot be heard, so how can they be made to transmit sound? The answer is surprisingly simple: the radio-broadcast station transmits an RF signal corresponding to the particular RF frequency allotted to it–Fig. 1.7. This is called the 'carrier', and since it will normally be well above 30,000 Hz it cannot be heard (except possibly some side-effects in the form of a little 'noise').

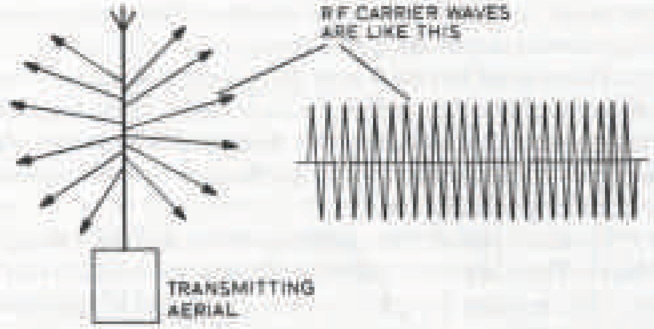

Fig. 1.7 Form of a steady RF carrier wave which is transmitted at a specific frequency.

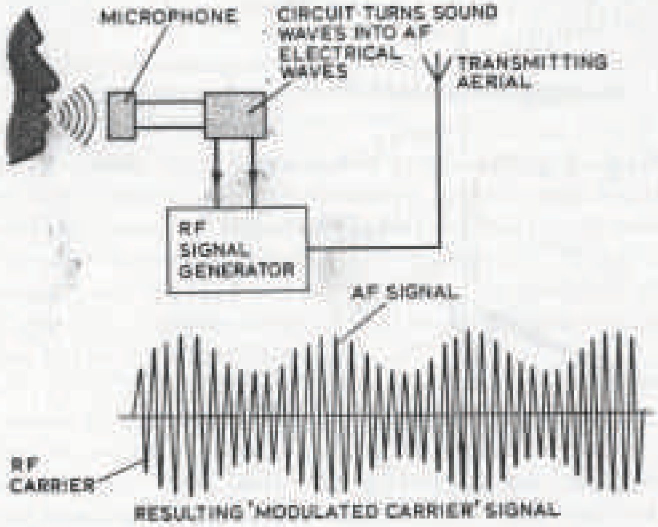
To transmit sound–speech or music–a microphone is used to turn sound waves into audio-frequency (AF) electrical waves, just as in the previous systems described. Alternatively, these AF electrical waves can be obtained direct from a disc or tape recording, etc.

This 'sound' signal is superimposed on the carrier wave being transmitted. Instead of having a constant waveform (constant amplitude, as in Fig. 1.7), the combination of the AF ('sound' wave) with the carrier results in a wave something like that shown in Fig. 1.8. The 'top'



MICROPHONE
CIRCUIT TURNS SOUND WAVES INTO AF ELECTRICAL WAVES
TRANSMITTING AERIAL
RF SIGNAL GENERATOR
AF SIGNAL
RF CARRIER
RESULTING 'MODULATED CARRIER' SIGNAL

Fig. 1.8 The effect of superimposing an audio-frequency (AF) signal on the RF carrier is a modulated carrier-wave transmission.

and 'bottom' of the carrier wave now assume the form of the 'sound' wave, which is thus carried along with the carrier.

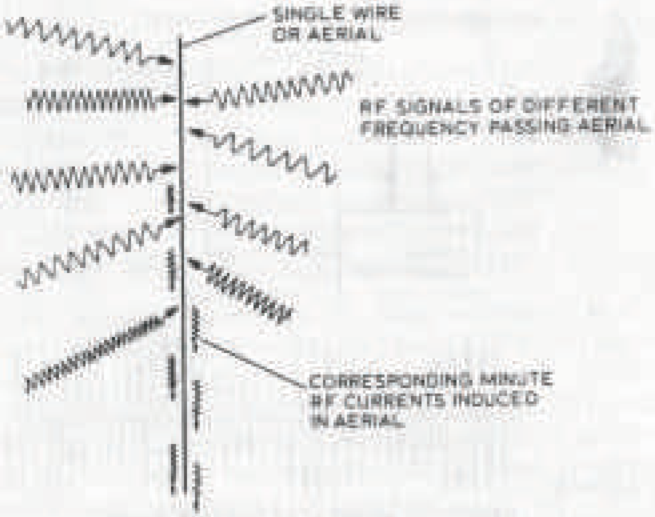
This combination is known as a *modulated wave*. The 'sound' or AF wave has modified the form of the RF carrier wave, or modulated it. It is also easy to see that what has actually been modified or modulated is the *amplitude* of the carrier wave; so this form of radio transmission is called *amplitude-modulation* or AM.

This is the only type of radio transmission we shall be dealing with in this book. There are others, notably *frequency modulation* or FM, used for VHF working (which is outside the scope of reception by simple radio receivers).

No problems, therefore, in getting AF signals 'on the air'. In fact, the air is literally full of such signals almost every hour of the day, radiated from different broadcast-transmitting stations.

The next step is to be able to pick them out of the air, so to speak; and, in particular, to pick out or *tune in* to the one particular station we are trying to listen to.

A single length of wire will 'pick up' virtually all AM signals present. This is because each signal represents varying amounts of electrical energy passing across the wire when, by a phenomenon known as



SINGLE WIRE OR AERIAL
RF SIGNALS OF DIFFERENT FREQUENCY PASSING AERIAL
CORRESPONDING MINUTE RF CURRENTS INDUCED IN AERIAL

Fig. 1.9 A simple wire aerial is a very weak 'receiver' of radio signals (by a process known as induction).

induction, a part of that varying energy will appear in the wire as an *induced current*. This current will vary with the same *frequency*, and duplicate the same *modulation*, as the original signals—Fig. 1.9.

The single length of wire, or *aerial* as it can now be called, is thus probably being affected by dozens of different RF signals, each inducing its own 'current image' in the wire; all these currents will be extremely minute—far too small to measure. So the aerial is only the starting point for a practical receiver; another example of 'electronic trickery' is required, namely a *tuned circuit* connected to the bottom of the aerial—Fig. 1.10.

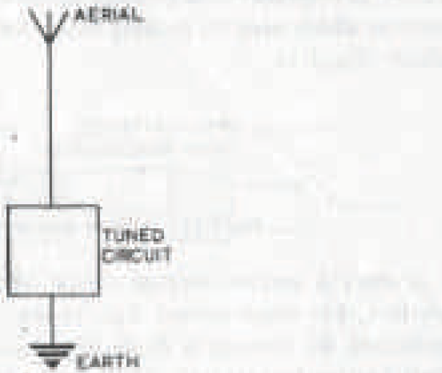


Fig. 1.10 The addition of a tuned circuit to an aerial produces amplification of signals induced in the aerial at one frequency only (the resonant frequency of the tuned circuit).

A tuned circuit normally comprises a *coil* (which is far more efficient than a straight wire for picking up induced currents), and a *capacitor* (which acts as a stop or a break in a circuit for direct current, d.c., but passes alternating current (a.c).

A capacitor also has the important property, when combined with a coil, of generating a greatly magnified induced current at the particular frequency known as *resonant frequency*.

This is a very important factor in the behaviour of a *tuned circuit*. Radio signals at that frequency, present in the aerial, will be greatly magnified or amplified, while other signals at different radio frequencies will not. Thus, apart from picking up and magnifying a particular broadcast frequency, the tuned circuit virtually rejects all the other signal currents present in the aerial because they are so minute.

Since the resonant frequency of the tuned circuit depends on the value of the capacitor and coil *inductance*, a suitable combination of values can be calculated to give maximum response (i.e. 'resonate') at any particular broadcast frequency. However, this would largely restrict the scope of the receiver; therefore, one of the tuned-circuit components is made *variable* in value, which means that the tuned circuit can now be adjusted to *tune in* to a whole range of separate broadcast frequencies.

One more step is needed to complete a basic receiver. The tuned circuit, when adjusted for resonance, is picking up the original carrier plus sound signals, or modulated RF signals. As this signal cannot be fed directly to a speaker (not being at audio frequency) it is fed through a *detector*, which need be nothing more than a simple component called a *diode*–Fig. 1.11.

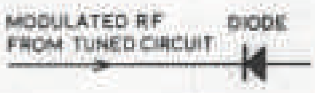

Fig. 1.11 A diode acts as a detector.

A *diode* is another stop-go device, which passes a.c. or d.c. in one direction, but stops current flow in the other. The effect of passing modulated RF through a diode is to 'chop off' the 'bottom' of the signal, leaving two separate components; one being the 'top half' of the original carrier, the other a varying d.c. component, following exactly the variations of the original AF signal used to modulate the carrier–Fig. 1.12.

The output from a diode detector can, in fact, be fed direct to a suitable speaker, which will respond to the varying d.c. signal, turning this into audible sound in a similar way as telephonic transmission–Fig. 1.13. The RF signal 'top half' present will not affect the speaker,

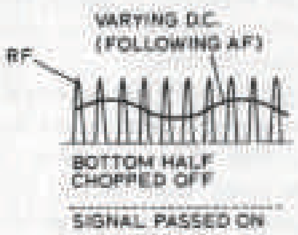

Fig. 1.12 The form of the signal passed by a diode detector–a mixture of 'chopped' RF and a d.c. component varying in AF

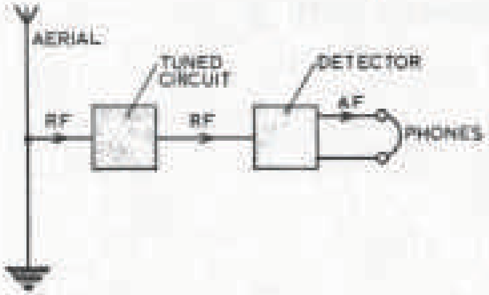

Fig. 1.13 The basic stages which make up a simple receiver.

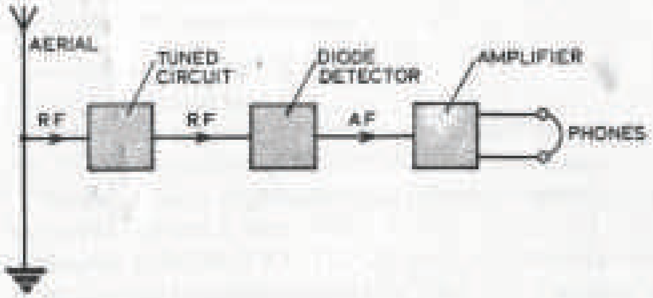

Fig. 1.14 More output power can be obtained from a receiver by interposing one (or more) stage(s) of amplification after detection.

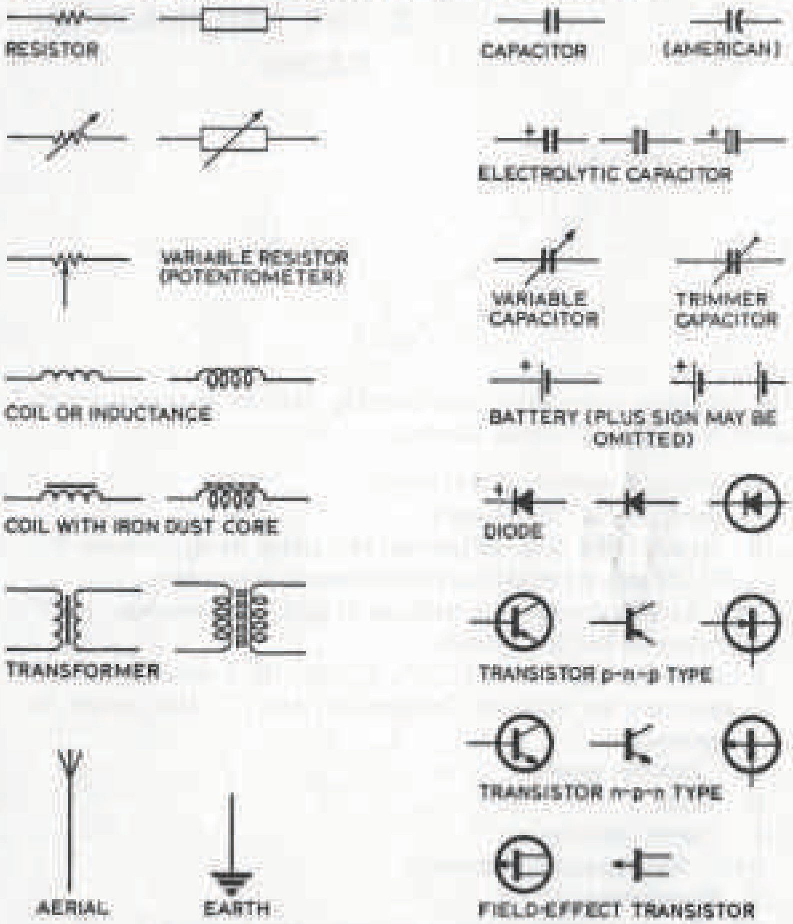
although it may be desirable to introduce some further components to smooth out possible interference with the sound signal required.

Such a basic circuit relies only on the *tuned circuit* for the amount of amplification produced–and thus the volume of sound heard in the speaker. Surprisingly, this can be all that is necessary to hear a limited number of stations quite clearly on a simple crystal set, using an earpiece as a speaker. To produce better volume, however, it is a relatively straightforward matter to introduce one or more stages of *amplification* after the detector–Fig. 1.14.

2 THE LANGUAGE OF RADIO

The following abbreviations are normally used to designate *components*, particularly on circuit drawings.

A Aerial; or current value in amps.
E Earth; or potential (e.m.f.).
R Resistor (the different resistors in a circuit being numbered R1, R2, R3 etc., for individual identification); or resistance.
VR Variable resistor or potentiometer (although sometimes the 'V' is dropped and just R used).
C Capacitor (numbered C1, C2, C3 etc., in a circuit). Variable capacitors are normally designated C, *not* VC. Also symbol for capacitance.
CT Trimmer capacitor.
D Diode.
L Coil (or inductance).
RFC Radio-frequency choke.
T Transformer.
TR Transistor, although there are alternatives used, e.g. Tr, VT and T; also sometimes Q. If T is used for transistors, then TR is used for transformers.
FET Field-effect transistor.
I Current.
IC Integrated circuit (module).
PC Printed circuit or printed-circuit board (PC board).
S or SW Switch.
J Jack.
V Voltage or e.m.f.
Z Impedance.



RESISTOR
CAPACITOR

Fig. 2.1 Standard symbols used in circuit diagrams with alternatives in most cases. These cover the symbols most likely to be found on British, European and American circuit diagrams.

Components on circuit diagrams are also designated, and easily identified, by symbols, and here again there are some variations to be found—see Fig. 2.1.

Basic quantities are measured in units as follows:

Resistance	in ohms (Ω).
Capacitance	in farads (F).
Inductance	in henrys (H).

Impedance	in ohms.
Potential difference or e.m.f.	in volts (V).
Current	in amperes (amps).
Power	in watts (W).

Numerical values of these units are often too large or too small to be expressed conveniently, when the following *prefixes* are used (representing multiples or sub-multiples).

Prefix	Symbol	Factor by which unit is multiplied	Example
mega	M	1,000,000	10 MHz (10 megahertz) = 10,000,000 Hz
kilo	k	1,000	10 kΩ = 10,000 ohms
milli	m	1/1000 or 0.001	2 mA (2 milliamps) = 0.002 amps
micro	μ	1/1,000,000 or 0.000001	6 μV (6 microvolts) = 0.000006 volts
nano	n	0.000000001	not widely used as a prefix in basic electronics
pico	p	0.000000000001	220 pF (220 picofarads) = 0.000000000220 farads

*Note: the unit name is often omitted when the inference is obvious. Thus for a 10-kΩ resistor, the value would be quoted as 10 k.

As a simple guide, mega (M) and kilo (k) are most usually found describing high values of *radio frequency* and *resistors*.

Milli (m), and to a lesser extent micro (μ), are most commonly associated with very low values of *current* or *voltage*, and practical values of *inductances*.

Practical values of *capacitors* are invariably quoted in microfarads (μF) or picofarads (pF).

Note: components are described in detail in Chapter 11.

3 CRYSTAL SETS

The simplest type of radio receiver consists of an aerial, a tuned circuit and a detector–plus headphones to listen to the signals received by the tuned circuit. It is generally called a *crystal set* because it works on the same principle as the very earliest radio sets, using a lead-galena crystal and a 'cat's whisker' as a detector. The only real difference is that the crystal and cat's whisker have been replaced by the much more efficient point-contact *diode*.

A simple *tuned circuit* can be made by winding a coil of wire of specific diameter and length (number of turns) to match the capacitance range of a variable capacitor. The combination of coil (inductance) and capacitance can then be adjusted by turning the variable capacitor spindle to be resonant, or tune in to various broadcast frequencies. The signal which is tuned in is then passed to the diode which blocks the RF content, and rectifies and passes on the AF content to the headphones, which transform these signals into audible sounds.

The tuned circuit can be combined with the aerial by winding the coil on a *ferrite rod*. This increases the inductance of the coil (reducing the length of wire required), whilst the rod itself also acts as an aerial to pick up the radio signals. This is the type of aerial employed in most domestic radio receivers. However, with very simple sets working with very weak signals, an external aerial may also be required.

The performance of all simple, low-powered receivers is, in fact, very much dependent on the efficiency of the aerial and tuned circuit, which can be regarded as the critical part of the system. Performance can perhaps be improved by experimenting with different aerial/tuned-circuit systems, and by the addition of further circuitry, as explained in later chapters.

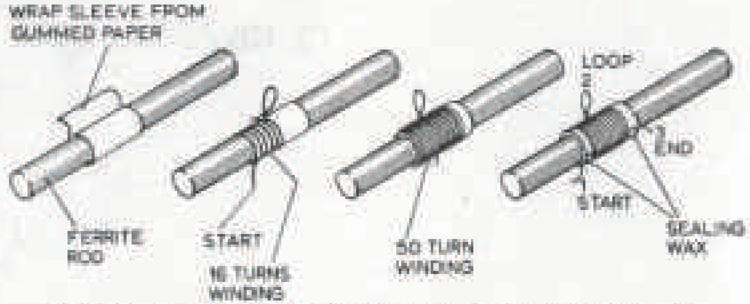

Fig. 3.1 Aerial tuning coil wound from 38-s.w.g. wire on a $\frac{3}{8}$-in. diameter ferrite rod.

Fig. 3.1 details the construction of a suitable coil for a tuned circuit, matched to a ferrite rod of $\frac{3}{8}$ in. diameter and about 4 in. long (see Chapter 4 for alternative coil windings on different rod sizes). If a rod is purchased longer than 4 in., it can be used as it is, or cut down by marking around with a file and then breaking off the surplus length.

Cut seven 1-in. lengths of gumstrip. Moisten one and wrap around the rod gummed side up. Now add about another half a dozen wrappings of similar length over the first, this time with gummed side *down* to form a reasonably rigid tube. Make sure that the paper tube is a *sliding* fit on the ferrite rod and leave to dry thoroughly (preferably removed from the rod so that it cannot become stuck to it).

When the paper tube is quite dry it should be rigid, when the coil windings can be applied. The wire to be used is 38-s.w.g. enamelled copper wire, the number 38 referring to the actual diameter of the wire according to the standard wire gauge (s.w.g.).*

Starting about $\frac{1}{4}$ in. in from one end of the paper tube, wind the wire carefully round the tube, with each turn tight against the one before it, until sixteen full turns have been completed. Then make a loop in the wire, as shown, and carry on winding, with succeeding turns touching, until fifty turns in all have been completed. The two loose ends of the coil (the start and finish) can be secured with a dab of sealing wax whilst the projecting loop can be twisted together (e.g. by putting a pencil through the loop and twisting up). Cut off the loop, leaving about $\frac{1}{2}$ in. protruding from the main coil, bare the wire ends and solder together. This forms point 2 on the coil; the start is point 1, and the end point 3—see Fig. 3.1. It will be easy to remember these

---

* American wire gauge (AWG) is about two sizes smaller than the British standard wire gauge (s.w.g.). For example, 38 s.w.g. is approximately the same as 36 AWG.

without marking since the loop or tapping point (2) comes much closer one end (1) than the other (3).

Cut a panel of *Paxolin sheet* to about the size shown in Fig. 3.2, using a hacksaw.* On this secure a *tag strip*, as shown, and drill a hole to mount a miniature or small-size 500 pF *variable capacitor*.

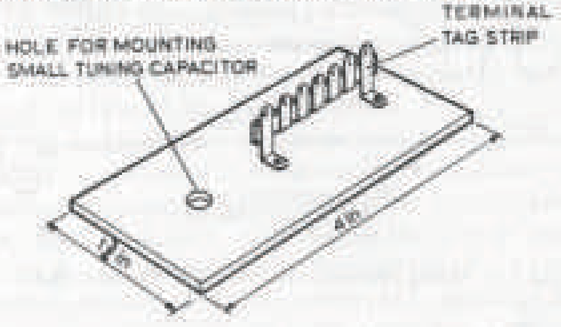

Fig. 3.2 Paxolin panel and tag strip for crystal set circuits.

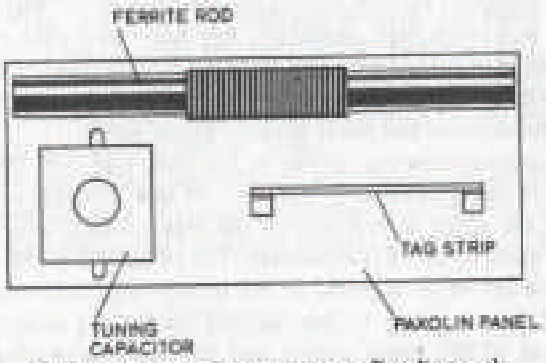

Fig. 3.3 Layout of components on Paxolin panel.

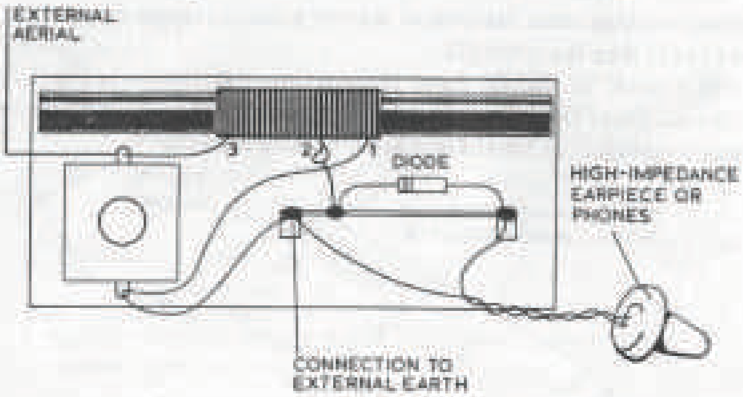
The aerial coil is then mounted on the panel as shown in Fig. 3.3, gluing the coil on to the Paxolin with two or three dabs of sealing wax, or some other suitable adhesive. *Note:* the ferrite rod must be free to slide in the paper tube for 'tuning' adjustments.

Virtually any miniature germanium or silicon diode will be suitable for the detector. Recommended types, which are readily available, are 1N34 and 1N914.

Earphones must be of *high-impedance* type, which need not be expensive to buy, and the higher the impedance the better the reception.

---

* A phenolic or fiberglass sheet may also be used.



EXTERNAL AERIAL
3
2
1
DIODE
HIGH-IMPEDANCE EARPIECE OR PHONES
CONNECTION TO EXTERNAL EARTH

Fig. 3.4 Wiring connections to complete the crystal set.

Alternatively a deaf-aid type earpiece can be used; this will not give the same volume or quality of reproduction as headphones, but is a less expensive component. This should preferably be of the *high-impedance magnetic* type, with high sensitivity. Any high-impedance earpiece will suffice, but if of crystal type will require a resistor, connected across it, to complete the circuit. This will reduce the amount of current flowing through the earpiece and lower the strength of signal.

Wiring connections are shown in Fig. 3.4. End 3 of the aerial coil (the end of the 50-turn coil) connects to one terminal of the tuning capacitor, the aerial or 'hot' end of the tuned circuit, and the point to which an external aerial is connected. The other end of the coil (end 1) connects to the other terminal of the tuning capacitor, from which an additional wire is taken to the first tag on the tag strip. This is the 'earthy' end of the tuned circuit, and the point to which an external earth is connected. Leave plenty of slack wire between the coil and tuning capacitor.

The other connections are then as follows:

(i) Tapping point of the coil wire bared and connected to the second tag.
(ii) The diode also soldered to this same tag, and to any other free tag.
(iii) Headphone (or earpiece) leads to the 'earthing' tag, and to the 'free' tag to which the above diode has been connected. All connections should be made with *soldered* joints.

The wiring-up can be checked against the *circuit diagram* shown in Fig. 3.5 (ignoring the components shown with broken lines). The set should now be 'working'.

In areas of strong signal strength, no external aerial or earth connections should be necessary. Performance will, however, be improved in any area by attaching an aerial wire (which can be any thin wire, e.g. using the same wire as for the coil winding), of up to 160 feet. The longer the aerial the better the reception, provided it is led away from the receiver to as *high* a point as possible.

An earth connection may further improve aerial performance; by this we mean a connection to some conductor positively in contact with the ground (preferably buried), an excellent example being a metal water-pipe. Thus, if an earth connection is found to be necessary (or you want to try one to see how performance is affected), connect a wire from the 'earthing' tag on the receiver to a convenient water-pipe.

This question of obtaining a *good* aerial and earth is a most important one in areas of poor signal strength. Linking up to a television aerial is often a good plan, since TV aerials are also usually mounted as high as possible. If bare wire is used, it is also important that the upper (free) end of the aerial is not made fast to something which could produce an earth connection (e.g. a damp tree), or at least is suitably insulated from such a support. String is not an efficient insulator; that, too, can conduct when wet.

Quite good results are often obtained by using the springs of a bed as an aerial, in which case an earth connection is usually not necessary. Sometimes, too, when other attempts to yield a good signal strength in

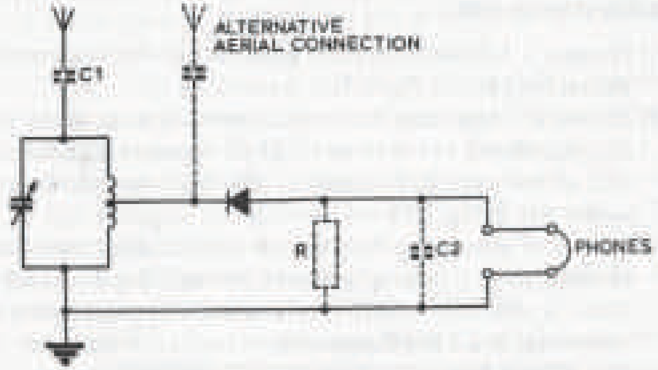


Fig. 3.5 *Circuit 1.* Circuit diagram of basic crystal set.

the aerial have failed, connecting the *aerial* side of the tuning coil to a *good earth* (a water-pipe) can produce better results, the normal earth connection being left off.

Tuning

The receiver is adjusted as follows. Turn the tuning capacitor to fully close the vanes, then open about half a turn on the spindle or knob. (If you are using a trimmer as a tuning capacitor, screw right down and then open half a turn.)

The tuning coil should now be slid up and down the ferrite rod (the coil leads were left a fairly long time to give the necessary freedom of movement) until BBC Radio 3 is heard.*

It may be necessary to slightly alter the adjustment of the variable condenser to tune in to this programme. Also, because of the ferrite-rod aerial the set will be directional, that is, the signal strength received will depend to some extent on the direction in which the aerial rod is pointing, so position the set to pick up the maximum volume.

Having established the best position of the tuning coil on the rod to receive BBC Radio 3, fix permanently with a dab of sealing wax. You should then find it possible to tune in to further stations by altering the setting of the variable capacitor–e.g. typically Radio 4 in about the middle of the capacitor travel and Radio 1 towards the other end.

Any reception you get will almost certainly be very weak and (unless you live close to a broadcast station) you can really feel satisfied if you get any station at all at audible strength. But it is surprising how, sometimes, even quite distant stations can be heard. Also you can often improve the reception and listening strength by quite simple modifications. Try these in order:

(i) Connect a 1,000-pF capacitor across the headphone (earpiece) connections (C2 in Fig. 3.5).

(ii) Instead of connecting the external aerial directly to the tuned circuit, connect one lead to a 220-pF capacitor, and the other end of the capacitor circuit to the 'hot' end of the tuned circuit (C1 in Fig. 3.5).

(iii) Instead of connecting the external aerial to the tuned circuit, connect to the tapping point of the coil (tag to which the diode is also connected). Try a direct connection, and also connecting in a 220-pF capacitor.

---

* Tune to an AM broadcast station near the lower end of the dial—close to 550 kHz.

(iv) Try connecting a 1.2-k resistor (or higher value) across the phone connection (R in Fig. 3.5). You may be using the wrong type of phones or earpiece, which do not provide a proper load or complete the circuit.

If there is a complete lack of response, check for faulty wiring-up. A more likely cause, however, is lack of an external aerial or earth connection in an area where these are strictly necessary for adequate reception; or an inefficient aerial (too short) or poor earth connection (bad electrical contact to a good earth point, or connection to a bad earth point).

Another possible cause of apparent failure may be too much outside noise entering the ear so that it is impossible to detect the very weak radio signal as it is being tuned in. Headphones are better than a single deaf-aid type of earpiece in this respect but, in any case, a really quiet room is virtually essential for initial setting up and tuning adjustments. Also, if your adjustment of the tuning control is too coarse, you may completely miss the setting for the station you are looking for, without realizing it.

Reception will also tend to vary with weather conditions. Some days it may be so poor that what was normally a strong station is hardly heard at all. The simple basic receiver has many limitations but, since it costs very little to construct and nothing at all to operate, this must be regarded as inevitable.

Providing you can hear something–even if too weak a signal to distinguish properly–you can certainly improve the performance of your basic set by further experimentation with tuned circuits (see Chapter 4) and/or the addition of amplification to the circuit. You can also try other types of basic crystal set, as described in the following projects.

Circuit 2 (Fig. 3.6) is identical to *Circuit 1* except that, instead of a diode, a transistor is used as a detector. Only two of the transistor leads are connected–the emitter (*e*) connection to the tapping part of the coil, and the base (*b*) to the 'earthy' end of the circuit. The collector lead of the transistor is ignored (bend it out of the way so that it cannot accidentally short out the other leads).

You can try almost any type of low-cost AF transistor; recommended types are OC42 2N370, 2N2925, 2N5088.

With the addition of two more components, Circuit 2 can be modified to work the transistor both as a detector and an amplifier, to give stronger signals through the headphones. Using the same transistor type

as above (or near-equivalent) resistor R should be 15 k and capacitor C3 1 μF or higher.

This time a battery is also required to supply power for the transistor to work as an amplifier. This can be from 1.5 V up to 9 V. Remember the rules for polarity of connection: those shown in Fig. 3.7 are for a p-n-p transistor; an n-p-n transistor would need the battery connected the opposite way round. Battery polarity also affects the connections of capacitor C3 (if an electrolytic or polarized type).

Experiment further by trying the effect of using additional capacitors in the circuit, e.g. C1, 220 pF; C2, 0.001 μF (try other values as well); C4, 0.001 μF (try other values as well).

CRYSTAL EARPIECE

Fig. 3.8 *Circuit 4.* Double diode crystal set.

This circuit incorporates 'voltage doubling' to improve the signal volume and should give better performance than a single diode circuit. L and C1 are the usual tuned circuit, but an unusual feature is that the *aerial* is connected to the coil tapping point. Any type of germanium diodes can be used (they should preferably be the same), making sure to connect them the right way round. A high-impedance *crystal* earpiece must be used in this circuit.

Capacitor values are: C2, 220 pF (this capacitor can be omitted–try with and without in the circuit); C3 and C4, 1,000 pF.

The optimum tapping point for the aerial connection to the coil L is best found by trial and error (see Chapter 4 on 'Tuned Circuits'), but the set should work at a nominal one-third tapping point from the 'earthy' end.

This set can also be tried with conventional tuned-circuit coupling–i.e. aerial to the top of the coil L, and diode D2 connection to the tapping point on the coil.

4 MORE ABOUT TUNED CIRCUITS

The basic combination of a coil of certain *inductance* connected in parallel with a *variable capacitor* is the form of tuned circuit used in most radio receivers, from simple crystal sets upwards. The *tuning range* of such a circuit is determined by the respective values of inductance and capacitance used. At the same time, the *resistance* of the coil can have a significant effect on the *selectivity* of the circuit, so that a particular broadcast frequency is tuned into sharply, with other nearby frequencies rejected.

In the simple tuned circuit used for the crystal set of Chapter 3, the aerial is connected to the upper or 'hot' end of the coil, the other end of the coil being earthed; the diode is connected to a tapping point on the coil. Performance may well be improved by adjusting both the aerial-connecting point and the diode-connecting point, as shown in Fig. 4.1.

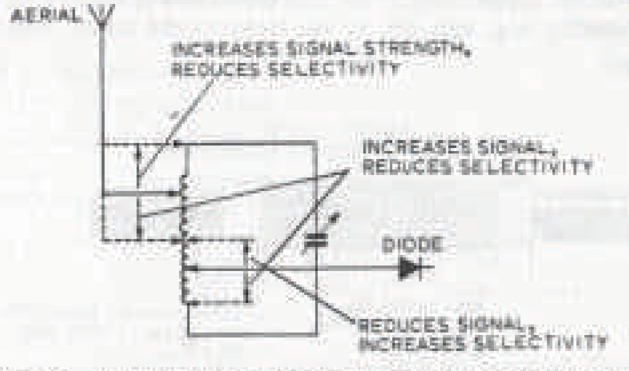

Fig. 4.1 The effect of varying the tapping points on the aerial coil.

Connecting the aerial to the 'hot' end should give the loudest signal, but the *selectivity* of the circuit may be poor because of the coil *resistance* involved in the actual circuit to earth. Connecting the aerial to a tapping point lower down the coil (towards the 'earthy' end) should improve selectivity, but reduce signal strength. Experimentation will produce the optimum aerial-connecting point. There will also be an optimum tapping point for the diode.

Finding optimum tapping points for the aerial and diode connections is a bit tricky on a close-wound coil since each tapping point tried has to be bared by scraping off the enamel insulation, with the risk of producing shorted turns. The same *effect* can be provided by removing, or adding, turns at each end of the coil, using the original tapping point for the diode connection–e.g. see Fig. 4.2. Unless the *total* number of turns on the coil remain the same, however, the inductance of the complete coil will be altered, and thus the tuning range of the tuned circuit (see later). Then the *diode* tapping point will be shifted.

For this type of experiment an air-cored coil of relatively large diameter is easier to use, wound on a card or paper tube to which two $\frac{1}{4}$ in.^{2} lengths of hardwood or balsa strip have been cemented. The windings can be bared by scraping or sandpapering over this raised section, and individual wires carefully separated to avoid shorting–Fig. 4.3. Optimum tapping points can be established by pushing bared ends on the aerial- and diode-connecting wires into the raised section of the coil, soldering in place very carefully once they have been found. This should not result in shorting out more than a few turns at these points; which will not greatly modify the coil inductance if allowed for in the initial winding (e.g. add five or six turns to the design number of windings).

SCRAPE OFF ENAMEL TO TRY DIFFERENT TAPPING POINTS
DIODE TAP
COIL WINDING OF ENAMEL-LED WIRE

Fig. 4.3 Construction of an air-cored aerial coil.

In air-cored coils, the inductance can be calculated with reasonable accuracy from the diameter and number of turns (see also Fig. 4.4):

$$\text{L, inductance, microhenries} = \frac{R^2 \times N^2}{9R + 10l}$$

where R = coil radius in inches,
l = coil length in inches,
N = number of turns.

The more usual form of this formula is:

$$N = \sqrt{\left(\frac{(9R + 10l) \times L}{R^2}\right)}$$

(A worked-out example using this formula is given later.) This is based on the turns of the coil being close-wound, in enamelled copper wire.

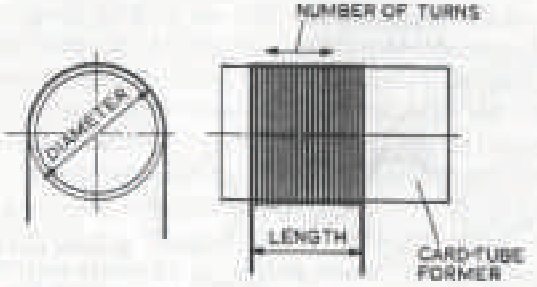

Fig. 4.4 Air-cored coil design parameters.

The actual diameter of the wire is not significant, provided the coil diameter is reasonably large (e.g. greater than 1 inch). The formula is not valid for smaller-diameter air-cored coils, or for coils wound on a ferrite rod.

The typical tuning capacitor has a rating of (about) 50 pF up to 350 pF or 500 pF. The relationship between tuning or *resonant frequency* and inductance and capacitance is:

$$\text{resonant frequency } (f) = \frac{1}{6.28\sqrt{(LC)}} \times 10^6 = \frac{0.16}{\sqrt{(LC)}} \times 10^6$$

where L = inductance in microhenries (μH),
C = capacitance in picofarads (pF).

This is more conveniently written as a solution for the *product* of inductance and capacitance required, i.e.

$$LC = \frac{0.025}{f^2} \times 10^{12}$$

For the medium waveband the range of frequencies to be covered is 500 to 1,500 kHz.* Thus, to encompass this range, the products of LC required are:

at 500 kHz

$$LC = \frac{0.025}{(500)^2} \times 10^{12}$$

$$= 0.001 \times 10^8 \text{ (approx.)}$$

---

* In the U.S.A. the AM broadcast band is from 540 to 1600 kHz.

at 1,500 kHz

$$LC = \frac{0.025}{(1{,}500)^2} \times 10^{12}$$

$$= 0.0001 \times 10^8 \text{ (approx.)}$$

At one end of the capacitor tuning range where $C = 50$ pF, inductance L required is:

$$\frac{0.001 \times 10^8}{\cancel{50}\ 500}$$

$$= 200\ \mu\text{H}$$

At the other end of the capacitor tuning range where $C = 500$ pF, inductance L required is:

$$\frac{0.0001 \times 10^8}{\cancel{500}\ 50}$$

$$= 200\ \mu\text{H}$$

Using a 1-in. coil diameter (0.5-in. radius) and a coil length of 1.5 in.

$$N = \sqrt{\left(\frac{(4.5 + 15) \times 200}{0.5^2}\right)}$$

$$= \sqrt{15{,}600}$$

$$= 125$$

In other words, a 125-turn air-cored coil of this size should be about right for covering the medium waveband, matching a 50–500 pF variable capacitor. Tapping point (or diode connection) would nominally be one-third of the coil length from the 'earthy' end.

Air-cored coils can also be designed in this way for long-wave coverage (more turns); or short-wave reception (less turns), which is not likely to be so good because of the low efficiency of the coils. Also, at higher frequencies the resistance of the *capacitor* is also significant, and so simple calculation of coil size is no longer valid.

The efficiency of a tuning coil can be expressed in terms of the magnification of the original signal received, when tuned to resonance, and decreases with increasing coil resistance. The magnification produced in a resonant circuit is referred to as the 'Q'; a high-Q coil is thus desirable for maximum performance and selectivity, and is essentially a low-resistance one. For this reason larger diameter air-cored coils, using thicker wire, are more effective than smaller diameter coils wound from thinner wire (since wire resistance increases with decreasing diameter).

Equally, the inductance of a wound coil can be increased by winding it over a magnetic-iron core, such as a ferrite rod. Much smaller diameter coils can be used, requiring less turns, to produce the inductance required—both reducing the length of wire and its resistance.

Because the actual inductance produced is dependent on the size and characteristics of the core material, windings for ferrite-rod aerials cannot be calculated, and are based on empirical results, or optimum windings established by trial and error.

Common sizes of ferrite rod available are:

¼-in. diameter	length 3½ in.
5/16-in. diameter	lengths 4, 5, 6 and 8 in.
⅜-in. diameter	lengths 4, 5, 6, 8 and 10 in.

Fig. 4.6 Medium-wave winding for a ferrite slab.

A long length enables maximum adjustment of coil position (a way of 'trimming' the aerial) and, also, additional coils to be incorporated on the same rod, if the circuit needs them (e.g. for multi-waveband coils). But it is the diameter which really determines the winding specification.

Recommendations for medium-wave coil windings for these three standard ferrite-rod diameters are given in Fig. 4.5, all windings being enamelled copper wire. Normal tapping points are one-third from the 'earthy' end. It is a simple matter to experiment with different windings—e.g. adding more turns to extend the *wavelength* upwards (i.e. lower frequencies), or reducing the number of turns to extend the *wavelength* coverage downwards (i.e. for higher-frequency transmissions).

Ferrite-core material is also available in slab form, which is often easier to accommodate in a small receiver case. A typical ferrite-slab size is 2¾ in. long by ¾ in. wide, with a thickness of ⅛ in. or less. A typical winding specification is shown in Fig. 4.6.

Generally, the long waveband should be covered by *doubling* the number of turns used for the medium waveband. *Reducing* the number of turns shifts the coverage out of the medium waveband down into the trawler band (80 m) and 'top-band' (160 m). For short-wave coverage very few turns indeed will be needed—perhaps less than half a dozen—and the optimum number can only be determined by careful experiment.

Separate coils for the various wavebands to be covered can be accommodated on the same ferrite rod and connected to a common tuning capacitor via a waveband switch—Fig. 4.7. This is the usual

Fig. 4.9 'Loose' inductive coupling with separate coupling coil.

procedure with an elaborate receiver circuit and domestic radios, but is seldom satisfactory with the simpler circuits because of the tuned-circuit characteristics (i.e. the need for meticulous adjustment to get optimum results for any single waveband coverage).

All the coil constructions so far described are based on single windings (covering a specific waveband) with a tapping point for the output (diode connection in the case of simple receivers). The alternative form is to provide *inductive coupling* for the output in the form of an overwinding, which can comprise five or more turns of the same gauge wire used for the main winding–Fig. 4.8. The optimum number of turns for the overwinding depends on the degree of coupling required, which in turn is influenced by the characteristics of the following circuit. The position of the coupling coil can also affect the performance, although usually it is best positioned over the 'earthy' end

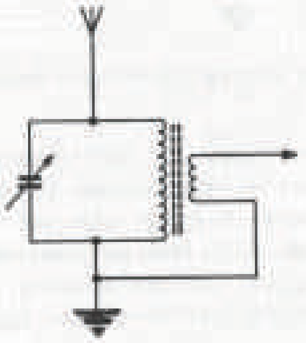

Fig. 4.10 Transformer coupling between tuned circuit and next stage of receiver.

of the main coil. Both number of turns and coupling-coil position are subjects for experimental adjustment to obtain optimum results.

Sometimes a coupling coil is wound on the ferrite rod, separate from the aerial coil, providing a 'loose' coupling–Fig. 4.9. Regenerative receivers often make use of this form of coupling for introducing 'feedback' into the front of the circuit (see Chapter 9).

Inductive coupling is also called *transformer* coupling, since the principle of passing current generated in one coil into another coil is the same. With transformer coupling (Fig. 4.10) the aerial coil has no tapping point, and is an alternative to direct coupling, where the next stage of the circuit is connected directly to a tapping point on the coil.

There is a third method of coupling which may be used between stages in a radio circuit–*capacity coupling*. Here, connection between the stages (e.g. to the tapping point on the aerial coil) is made through a capacitor, which isolates the two stages as far as d.c. flow is concerned (only a.c. will pass through the capacitor)–Fig. 4.11.

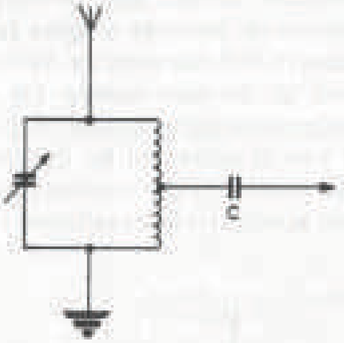

Fig. 4.11 Capacity coupling between tuned circuit and next stage of receiver.

Again the optimum value for the capacitor depends on the characteristics of the circuits being coupled. To couple an aerial coil to the next stage in a receiver, optimum values can vary from 200 pF to 10 μF. In general, though, a high value gives best results.

Direct, transformer, and capacity coupling are alternatives for connecting any two stages in receivers–not just the tuned circuit to the next stage.

5 AMPLIFIERS

It is a characteristic of a transistor that it works as an *amplifier* of signals. In the most widely used mode of connection of transistors for such duties with input and output circuits both connected to the emitter (common-emitter mode), the degree of amplification or current gain is called the 'beta' (β) of the transistor. This is given as h_{FE} (or static forward current ratio) in transistor characteristics data (see also Chapter 7).

A basic transistor amplifier circuit is very simple–and is identical for a p-n-p or n-p-n transistor, except for the battery polarity–see Fig. 5.1. Virtually any low-power AF transistor can be used in this circuit. The *bias resistor* (R) must have a value providing a collector current not exceeding the maximum specified rating for the transistor used, the actual current flowing in the collector circuit also being influenced by the voltage of the battery.

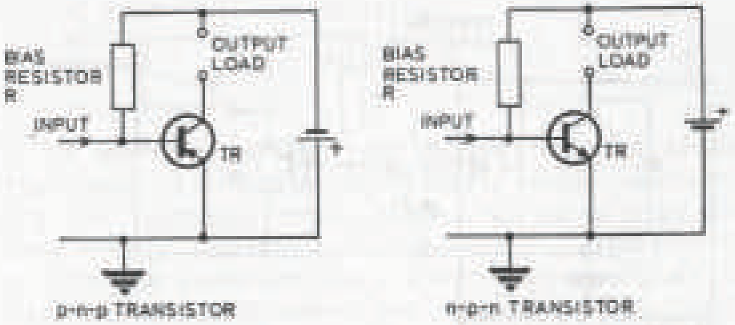

Fig. 5.1 Basic amplifier circuits with simple current biasing via a single resistor.

Knowing the transistor characteristics, a suitable value for R can be calculated as follows:

$$R = \text{gain} \times \frac{\text{battery voltage}}{\text{collector current}}$$
$$= h_{FE} \times \frac{\text{battery voltage}}{I_c}$$

where I_c is equal to, or preferably less than, the specification figure for I_c max.

Assuming that an OC72 transistor is being used, and the battery voltage is 9 V, specified figures are:

$$I_c \text{ max} = 250 \text{ mA}$$
$$h_{FE} = 30 \text{ to } 90$$

Taking the maximum gain, and 2.5 mA as a 'safe' working figure for the collector current:

$$R = 90 \times \frac{9}{0.0025}$$
$$= 324\text{k}\Omega$$

A suitable (preferred-value) resistor would thus be 330k.

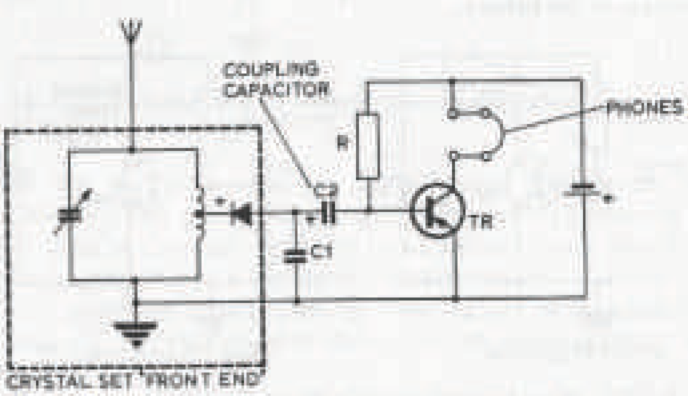

Fig. 5.2 *Circuit 5.* Crystal set with single stage of amplification. Any ~~RF~~ transistor can be used for TR.
AF

Fig. 5.2 shows the complete circuit for a simple AF amplifier of this type, coupled to the 'front end' of a basic crystal set. The detector (output) is coupled to the amplifier via capacitor C2, a suitable value for which would be 10 μF or higher (e.g. 20, 25, 30, 40 or 50 μF); capacitor C1 (0.001 μF) may not be necessary. The output load in the collector circuit is formed by high-impedance phones.

Note that the *polarity* of the battery used to power this circuit is important (as far as the transistor connection is concerned); also the connections to the *diode* and C2 (which will normally need to be an electrolytic type to provide the high-capacity value required). With an n-p-n transistor the battery polarity would be reversed; and also the diode and electrolytic capacitor connections.

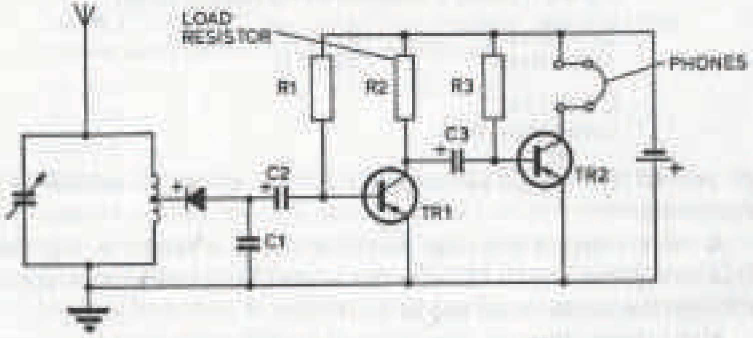

Fig. 5.3 *Circuit 6.* Crystal set with two stages of amplification. Component values matching OC71, OC72 or near equivalent for TR1 and TR2:

R1, 470 k	C1, 0.001 μF
R2, 4.7 k	C2, 8 or 10 μF
R3, 470 k	C3, 8 or 10 μF

Battery voltage 6 to 9 V.

The same type of circuit can be used to provide additional amplification, if required, simply by adding another amplifier stage (Fig. 5.3). The second amplifier stage can be identical to the first or based on a higher-power transistor taking the higher output present and providing even greater gain. The load in the output (collector) of the first amplifier stage is provided by a resistor (R2) (which should be about the same value as the phone resistance, 3.3 to 4.7 k), and the two stages coupled by a capacitor (C3). Value of R3 depends on the second transistor used, and may be anything from 47 Ω to 470 kΩ; capacitors

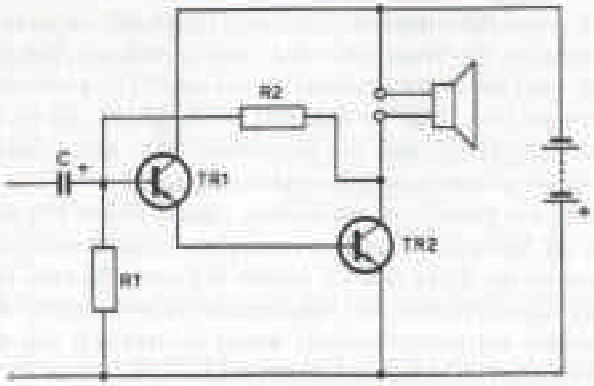

Fig. 5.4 *Circuit 7.* Amplifier for loudspeaker output

TR1, OC72 R1, 6.8 k
TR2, AD140 R2, 33 k
C, 8 or 10 μF
Loudspeaker, 80 Ω

C2 and C3 can be 10 μF or larger (20 μF up to 50 or 100 μF), electrolytic.

A more compact two-stage amplifier circuit is shown in Fig. 5.4. This may prove capable of operating a small 80 Ω loudspeaker direct, although the current drain will be quite high.

Alternatively, three or four stages of amplification using low-power transistors, following a basic 'front end' crystal set, should provide enough power to drive a small loudspeaker at the final output, through a suitable step-down transformer, to provide an impedance match (see Chapter 6).

Simple amplifier circuits of this type have the important limitation that performance of the transistor(s) will tend to vary with temperature. There is also the possibility of 'thermal runaway' developing, which can destroy the transistor(s), because as the external temperature increases the collector current also tends to increase, which in turn causes a further increase in junction temperature, so the effect is cumulative and goes from bad to worse, even to the point of ruining the transistor completely. It is possible to overcome this trouble by arranging for the circuit to be self-biasing or d.c. stabilized so that a constant operating collector current is provided, regardless of transistor type or temperature variations. In other words, the working point of the collector circuit is stabilized.

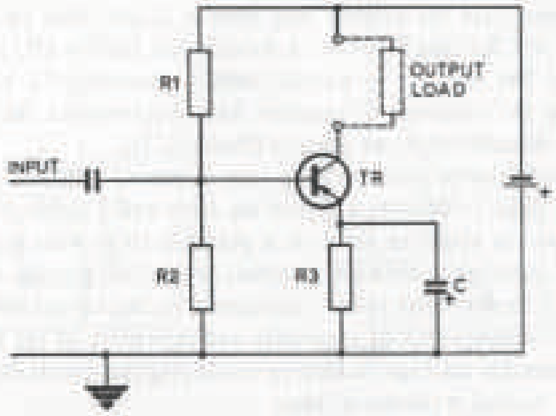

Fig. 5.5 Stabilized bias circuit for transistor amplifier stage. Typical values for low/medium-power transistors

R1, 22 k C, 8 or 10 μF
R2, 10 k
R3, 1 k

A further advantage of a stabilized circuit is that it makes the performance of the amplifier less dependent on the characteristics of individual transistors, which can differ appreciably even for the same type. Capacity coupling between stages should be used since this makes each stage independent as regards working, rather than inter-dependent.

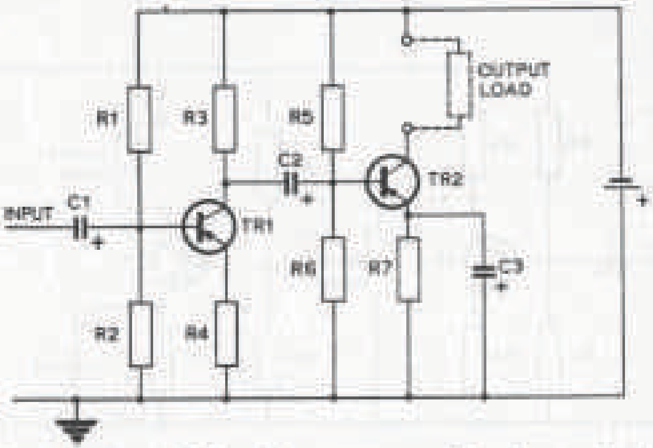

Fig. 5.6 *Circuit 8.* Practical two-stage amplifier using two low/medium-power AF transistors. (See Chapter 7 for determination of matching component values.)

To achieve this the original bias resistor is split into two separate values R1 and R2 (see Fig. 5.5). A further bias resistor (R3) is applied directly to the emitter, in parallel with a capacitor (C) to act as a by-pass for AF currents. (Transistor bias requirements, and data on transistor characteristics, are given in Chapter 7.)

A receiver design incorporating two stages of amplification with stabilized circuits following a crystal set front end is shown in Fig. 5.6. This, in fact, is about as far as it is practical to go with such a basic circuit as, although additional complete stages will provide more gain and greater final output power, deficiency in the circuit will also be aggravated–notably lack of sensitivity and selectivity in the front end. Such deficiencies are best tackled by modifying the circuit design from the simple 'crystal set detector' basis.

The amplifier stage(s) also provides a convenient point to insert a *volume control* into the receiver circuit. This takes the form of a potentiometer which can replace one of the bias resistors, or be placed in series with the flow of the current after the first stage of amplification–Fig. 5.7. This will introduce minimum distortion over the volume control range.

On low-power receivers which give satisfactory reception without an external aerial, a volume control can be an unnecessary refinement. Since the ferrite aerial has directional characteristics, merely turning the set one way and the other will produce changes in signal strength.

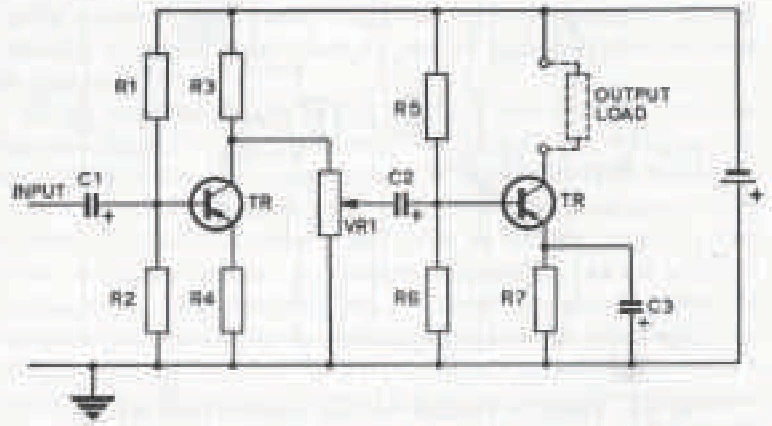

Fig. 5.7 *Circuit 9.* Two-stage amplifier with volume control.

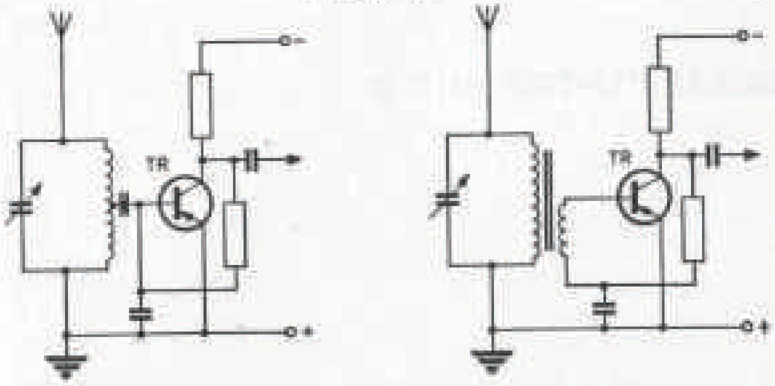

Fig. 5.8 Basic pre-amplifier circuits. The transistor (TR) must be an RF type; p-n-p transistors shown in these diagrams. If n-p-n transistors are used, the battery polarity must be reversed.

Pre-amplifiers

A pre-amplifier is designed to amplify signals between the tuned circuit and detector stages. The main difference is that the transistor(s) selected must be an RF type since it is handling RF signals at this stage. Otherwise the basic circuit is similar to that of an AF amplifier–see Fig. 5.8.

6 THE OUTPUT STAGE

By a suitable choice of transistors, the amplifier stages can be used to power a loudspeaker direct, using a minimum of components. A typical circuit of this type was shown in Fig. 5.4, using a high-gain AF transistor for TR1, and a power transistor for TR2. The main disadvantage of such a set-up is the relatively high current drawn by the circuit.

Single transistor outputs work with 'Class A' operation, which means that the values of bias and signal voltage applied to the transistor ensure that collector current always flows. Fig. 6.1 shows a basic Class A output circuit incorporating transformer coupling to a loudspeaker.

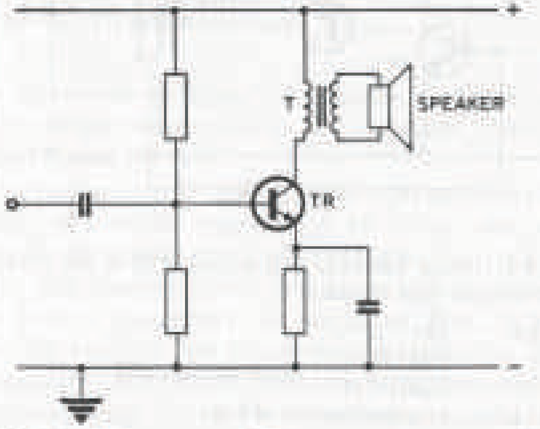

Fig. 6.1 Basic Class A output. TR is output transistor working as an amplifier. Loudspeaker impedance is matched to output load requirements via the step-down transformer T.

A more economic way of producing satisfactory output power is to employ a single transistor *driver* working a complementary pair of transistors (an n-p-n and a p-n-p selected with matched characteristics) in push–pull configuration. The output power obtained from a pair of transistors in push–pull is considerably more than double the power obtained from a single transistor of the same type. With 'Class B' operation the transistors are biased to nearly cut-off, so that only a marginal current flows under 'quiet' conditions. Push–pull outputs may, however, also be designed for 'Class AB' operation, with rather higher current drains.

Basically, distortion is lowest with Class A operation, whilst Class B operation provides the lowest current drain but introduces the possibility of crossover distortion being present, which can be overcome by applying a slight forward bias to each transistor. Class AB offers a compromise between the two.

T2, output transformer

Two types of basic push–pull output circuits are shown in Figs. 6.2 and 6.3, one with direct coupling and the other using transformer coupling, both interstage (between driver and push–pull input) and to the loudspeaker. The coupling transformer can provide additional amplification; an output transformer, on the other hand, is invariably a step-down type to adjust the loudspeaker impedance to the required output impedance. Both types of circuits have their advantages and disadvantages, although for simpler receivers all-transistor circuits are usually preferred.

Much also depends on the requirements of the receiver. Thus to operate a small loudspeaker successfully an *audio power output* of 5 mW or better is required (higher still for larger speakers, of course). At the other extreme, about 10 μW represents, for most people, the threshold of audibility in high-impedance phones; and 0.1 mW a normal minimum for comfortable listening and ready identification of sounds in headphones. For easy listening with high-impedance phones, an audio output power of up to 0.5 mW is desirable. Higher signal levels will tend to 'swamp' headphones but can, of course, be reduced by fitting a volume control.

Typical characteristics of headphones, earpieces and loudspeakers are:

Headphones

High-impedance type, d.c. resistance 2,000–4,000 Ω; typical impedance 10,000 Ω (at 1 kHz).

Low-impedance type, (i) d.c. resistance 15 Ω, typical impedance 80 Ω (at 1 kHz); (ii) d.c. resistance 80 Ω, typical impedance 120 Ω (at 1 kHz).

Earpieces

High-impedance type, d.c. resistance 2,000 Ω; typical impedance 7,500 Ω (at 1 kHz).

Low-impedance type, (i) d.c. resistance 4 Ω, typical impedance 15 Ω (at 1 kHz); (ii) d.c. resistance 14 Ω, typical impedance 60 Ω (at 1 kHz); (iii) d.c. resistance 60 Ω, typical impedance 250 Ω (at 1 kHz).

Loudspeakers

Typical d.c. resistance 3 Ω; typical impedance 8–16 Ω.

It will be obvious from a study of these figures that low-impedance phones, a low-impedance earpiece, or a loudspeaker will be a mis-match

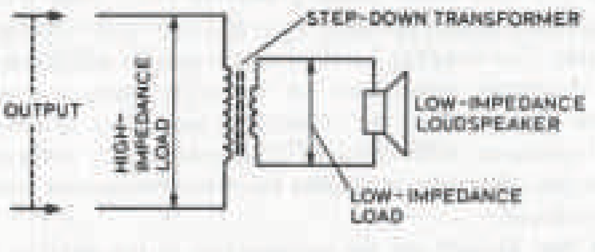

Fig. 6.4 Load balancing via output transformer.

for coupling to an output requiring a *high-impedance load* (as in the case of most of the simple all-transistor output circuits).

To employ low-impedance phones, earpiece or a loudspeaker with an output requiring a high-impedance load, a matching step-down transformer (output transformer) must be used. The primary of the transformer then provides the required output load, indirectly coupled to the secondary to which is connected the low-impedance phones or speaker—Fig. 6.4.

The turns ratio required from the transformer is easily calculated as:

$$\sqrt{\left(\frac{\text{output load impedance required in ohms}}{\text{phone or speaker impedance in ohms}}\right)}$$

Some typical transformer ratios and their suitability for matching are:

Ratio	Listening device	Equivalent output load impedance (Ω)
41:1	8-Ω Speaker	15,000
35:1	4-Ω earpiece	5,000
30:1	8-Ω Speaker	7,000
18:1	14-Ω earpiece	5,000
14:1	15-Ω earpiece	2,000
9:1	60-Ω earpiece	5,000
5:1	80-Ω headphones	2,000

For other required output load impedances, the turns ratio can be calculated from the formula.

Tone controls

The output voltage after amplification will only be a faithful reproduction of the original input if the amplifier produces the same gain for all signals, whatever their frequency and complexity. This is seldom the case with simple circuitry, so that the balance of the original sound or speech is upset and distortion results. If the gain is inadequate at low frequencies, the sound reproduced will tend to be tinny or harsh; conversely, if the gain is inadequate at the higher frequencies the sound is subject to booming.

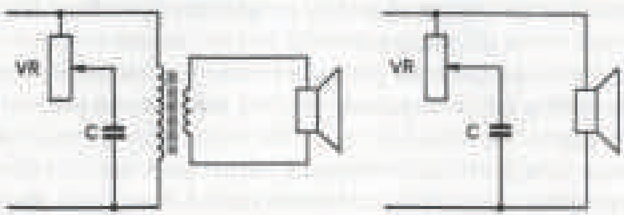

Fig. 6.5 Simple tone controls.

An adequate measure of tone control can be realized by connecting a variable resistance (potentiometer) and fixed capacitor in series across the primary terminals of the output transformer; or directly across the speaker, as shown in Fig. 6.5.

This, in effect, forms another tuned circuit, the resonant frequency of which can be altered by adjusting the setting of the potentiometer to favour or raise the treble or bass in the output signal by, effectively, additional amplification. The tone control on a domestic receiver is usually of this form—the knob controlling a potentiometer connected in series with a fixed capacitor across the output transformer. Typical values used are: potentiometer, 0–5 k; fixed capacitor, 0.1 μF.

7 TRANSISTORS, BIAS AND STABILIZATION

The two conventional bias arrangements for transistors are shown in Figs. 7.1 and 7.2, both having advantages and disadvantages. Current bias is the simpler of the two, since it requires only one resistor which determines the values of the base current I_B and the operating or emitter current I_E, viz:

$$I_B = \frac{V_S - V_{BE}}{R}$$

$$I_E = \frac{V_S - V_{BE}}{R}(1 + h_{FE})$$

V_{BE}, the base-emitter voltage, is of the order of 0.1 to 0.2 V for germanium transistors, 0.6 to 0.7 V for silicon transistors. In normal practice there will be negligible change in current with variations of V_{BE}, but will be dependent on the spreads of h_{FE} (the small signal

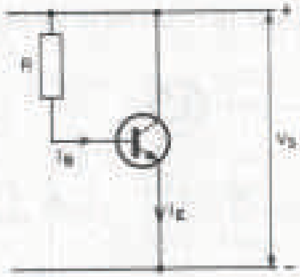

Fig. 7.1 Simple current bias circuit.

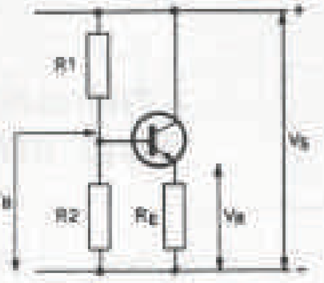

Fig. 7.2 Conventional voltage bias circuit.

forward current ratio of the transistor). Thus simple current biasing is most suitable for transistors which have only narrow h_{FE} spreads.

Voltage biasing with emitter feedback yields the following voltage relationships (see also Fig. 7.2):

$$V_B = \frac{R2 \, . \, V_S}{R1 + R2}$$

$$V_E = \frac{R2 \, . \, V_S}{R1 + R2} - V_{BE}$$

The emitter current is therefore:

$$I_E = \frac{R2 \, . \, V_S}{R_E(R1 + R2)} - \frac{V_{BE}}{R_E}$$

For the effect of spreads to be negligible the voltage V_E must be large compared with changes in V_{BE}. Also, R_E must be large if changes in emitter current I_E, due to variations in the supply voltage V_S, are to

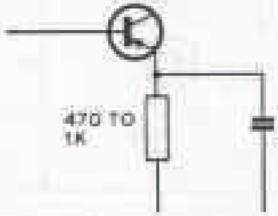

Fig. 7.3 Stabilization, with common component values used.

be kept small. In practical circuits a voltage drop (V_E) of 1 V with germanium transistors and 3 V with silicon transistors is aimed at.

The collector-to-base leakage current is a major factor contributing to the shift in operating point of a transistor, since this is highly sensitive to temperature. Thus bias stabilization is normally desirable with germanium transistors, the usual arrangement being as shown in Fig. 7.3. Silicon transistors have negligible leakage current, even over their full working temperature range, and stabilization is not necessary, except in some cases where other characteristics developed in the particular circuit may make it a prudent addition.

Working characteristics of a number of readily available transistors are summarized in the following tables. Data on other types are available from the manufacturers; also in many suppliers' catalogues.

8 TRF RECEIVERS

The tuned radio frequency (TRF) receiver is based on 'double tuning'–one before and one immediately after the pre-amplifier or RF amplifier, as shown in the block diagram of Fig. 8.1. The two tuned circuits are literally identical and, in fact, are usually 'ganged' together, using twin variable condensers and adjusted by a single control knob (although the respective circuits are wired to the separate electrical parts of the two-part condenser–see Fig. 8.2).

To provide *complete* matching of these two tuned circuits, the two separate variable condensers are individually adjusted with the aid of smaller 'trimming' capacitors mounted in parallel with them. Similarly, the inductances of the two tuning coils completing the respective tuned circuits can be matched for identical performance by winding on coil formers with iron-dust cores. In this manner small differences in the actual wiring up of the two tuned circuits, and in effective component values, can be balanced out for optimum performance. This, in fact, is a necessary process in setting up or *aligning* the complete receiver for best performance, and can be done quite satisfactorily on a trial-and-error basis.

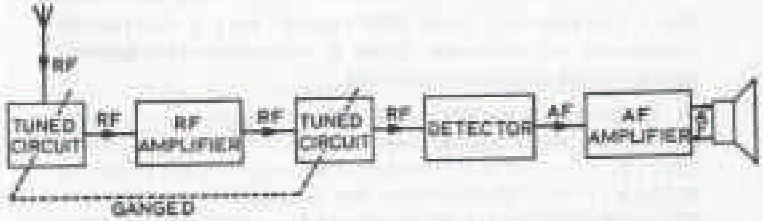

Fig. 8.1 Block diagram of a tuned radio frequency (TRF) receiver.

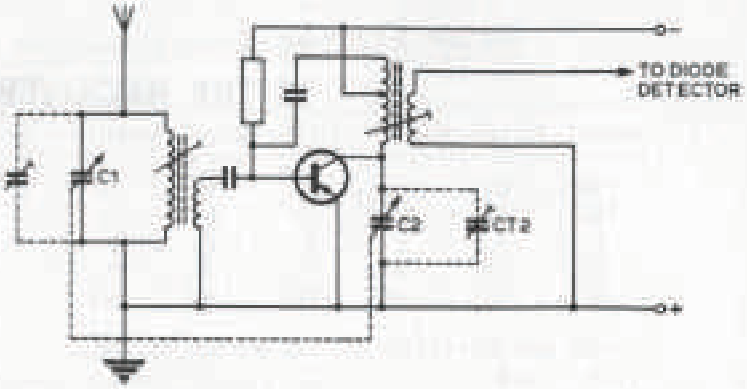

Fig. 8.2 Double-tuned circuit with RF amplifier – the 'front end' of a TRF receiver.

A simple one-transistor TRF receiver circuit is shown in Fig. 8.3. Alignment difficulties are minimized by employing a proprietary coil L1, L2, L3 for TRF working, eliminating the need for ganged tuning capacitors with separate trimmers. It is an interesting circuit to experiment with and compare the performance against that obtained from a basic crystal set with one stage of amplification added. It should be superior, but like the crystal set will require an efficient external aerial and good earth connections before satisfactory listening volume is obtained in most areas.

D, any crystal diode

L3, L4 can be wound exactly as L1, L2, except that the 50-turn winding has a centre tap. A short length of ferrite rod should be used for the core, L3, L4 being wound on a paper sleeve so that the rod can be slid in and out for adjustment purposes.

Important. Coil L3, L4 will need screening from L1, L2 and associated components. This can be done with thin aluminium sheet, suitably fitted around L3, L4.

Performance can be improved by using a higher power transistor for amplification, and/or adding a further stage or two of amplification. This follows along the same lines as for other receivers—see Chapter 5.

A rather more elaborate TRF circuit, but again using low-power transistors, is shown in Fig. 8.4. This uses a standard ferrite rod aerial with inductive coupling (see Chapter 4), and a ganged tuning capacitor for C1, C4.

9 REGENERATIVE AND REFLEX RECEIVERS

In the crystal set, and similar simple receivers, a weak RF signal in the aerial is fed directly to the detector, and the extracted AF signal amplified to the required level to operate headphones or a loudspeaker. However, no amount of AF amplification *after* detection is effective if the original RF strength is too small.

An obvious method of improving this state of affairs would be to amplify the RF signal picked up by the aerial and tuned circuit *before* passing to the detector. This is quite a practical arrangement, the immediate advantages being an improvement in both *sensitivity* and *selectivity*, and also *quality* of reproduction. Improved sensitivity means that weaker (more distant) stations can now be received at greater volume; better selectivity means that sharper tuning can be obtained, a necessity to eliminate interference from adjacent stations now more readily picked up.

Quality is improved because there is less demand for AF amplification, while the output power can readily be boosted to operate a loudspeaker without putting any particularly high demands on either the efficiency of the aerial system or the AF amplifier stages.

An elementary circuit of this type is shown in Fig. 9.1, using a single transistor as a pre-amplifier, followed by a diode detector. This is easy to build and should work quite well in most areas, although still almost certainly requiring a good external aerial and earth connections for the best results, and must be used with an *inductively coupled* tuned circuit.

There is, however, a method of considerably improving the performance of this set by incorporating *regeneration*. This is done by taking part of the amplified signal and feeding it back into the tuned

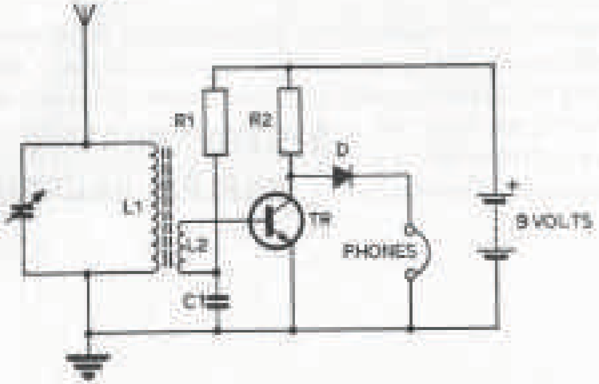

Fig. 9.1 *Circuit 14.* Single-transistor receiver with pre-amplifier.

D, any crystal diode

circuit, where it will be amplified again, resulting in a further improvement in selectivity and sensitivity. Care should be taken that not too much signal is fed back, causing the circuit to become unstable and oscillate or 'squeal'.

This modification is shown in Fig. 9.2. One length of insulated wire

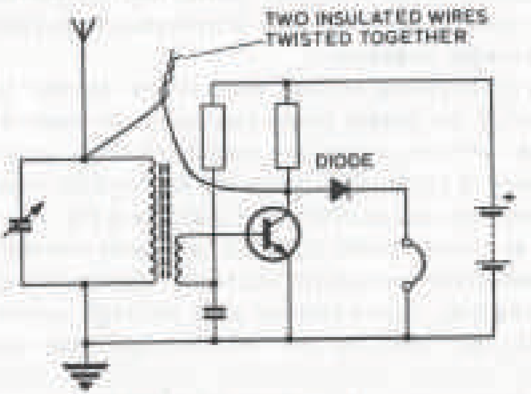

Fig. 9.2 *Circuit 15.* The design of Fig. 9.1 converted to regenerative working. The twisted wires can be replaced by a 10-pF or 20-pF trimmer capacitor.

is connected to the front end of the diode, another to the top end of the tuned circuit. The free ends of these two wires are then twisted together over a length of about half an inch.

This, in effect, provides a capacitive coupling for the feedback signal where the actual amount of feedback can be varied by twisting the wires more tightly together, or untwisting part of their length. The optimum amount of 'twist' can be determined by experiment, when the final performance should be considerably better than that of the original circuit. However, the *position* of the twisted wire coupling relative to other components is critical; any slight disturbance can considerably modify the performance or cause the receiver to oscillate.

For a more stable arrangement, a 10-pF or 20-pF trimmer capacitor can be used instead of twisted wires to provide the feedback coupling, adjusted for optimum results.

If the set does not work with 'regeneration', or the results are poorer than the original circuit, then the feedback is probably 'negative' rather

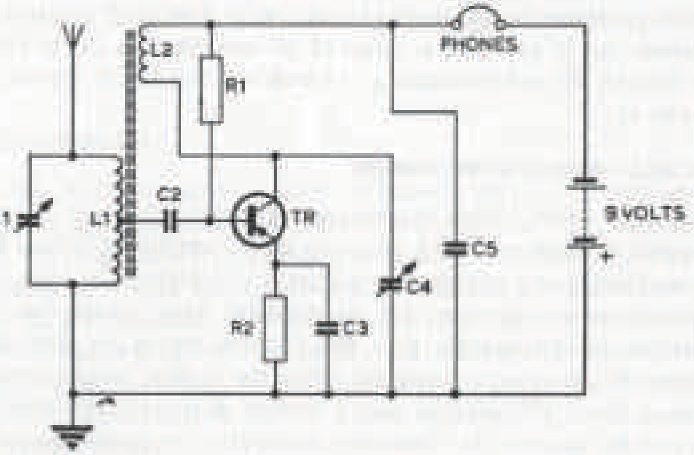

Fig. 9.3 *Circuit 16.* Simple regenerative receiver with inductively coupled feedback

C5, 10 μF
R1, 1 M to 4.7 M (find best value by experiment)
R2, 3.3 k

than 'positive'. Reversal of the coupling-coil connections should correct this.

An even better arrangement is to use *inductive* rather than capacitive coupling for the feedback, which can be done by winding a feedback coil on the same ferrite rod as the aerial coil. A suitable feedback coil is made by winding 8 turns of 38-s.w.g. wire on a similar paper sleeve to the tuning coil, so that the finished coil can be slid up and down the ferrite rod. The degree of coupling can then be adjusted by sliding this feedback coil up and down the rod to arrive at a position which gives optimum results.

The circuit is also modified somewhat, as shown in Fig. 9.3, to include a variable capacitor connected to the transistor collector to control the amount of reaction or regenerative feedback. If the set does not oscillate with this variable capacitor adjusted to *minimum* capacity (i.e. vanes fully closed) then the feedback coil must be reversed on the ferrite rod (alternatively reverse the coil connections to the rest of the circuit).

This particular circuit can also be used as the 'front end' of a receiver to which one or two further stages of AF amplification can be added (see Chapter 5); and terminating in a push–pull output if desired (see Chapter 6).

The super-regenerative receiver

The limit to which ordinary regenerative amplification can be carried is the point at which oscillation starts, so the RF amplification (and thus the sensitivity) of a regenerative receiver is limited by this factor. The super-regenerative receiver is a development which overcomes this limitation by introducing into the detector circuit an alternating voltage, of a frequency somewhat above the audible range (typically between 20 to 100 kHz), in such a manner as to vary the operating point of the detector. In effect, this interruption or *quench* frequency switches the detector (originally adjusted to be near the point of oscillation) in and out of operation. The time taken for the RF oscillations to build up to their peak will be proportional to the original modulated signal (i.e. the RF signal picked up by the aerial), and by arranging for these to be quenched before they can reach their peak, extremely high amplification is possible–equivalent to a gain of over one million in a single stage in certain cases.

On this basis, the circuit is ideal for increasing the sensitivity of a receiver in a relatively simple manner. However, both the design requirements and adjustment are somewhat critical, but more advanced and detailed treatment of these is beyond the scope of this book. The super-regenerative receiver, too, is not particularly suited for the reception of normal broadcast frequencies. The circuit requires a ratio of signal frequency to quench frequency of the order of 1,000:1 or greater, which means that for a broadcast signal of 500 kHz the quench frequency must be of the order of 500–1,500 Hz, or in the audio band. A further limitation is that, as they are continually oscillating, they will cause interference on other receivers in the neighbourhood–although this effect can be minimized by suitable circuit design.

A further variation, which is even less suitable for lower radio frequencies but again is capable of giving excellent results with very high frequencies, is the self-quenching super-regenerative receiver. In this case, as the name implies, the super-regenerative detector supplies its own quench frequency. The frequency of these quench oscillations depends on the feedback and the 'time constant' of the circuit, the time between each burst of oscillation varying as the input signal varies. The action of the oscillations is said to be a blocking or 'squegging' effect.

Reflex receivers

A reflex circuit works on a rather different principle. Here the *audio frequency* signal following the detector is fed back into a pre-amplifier stage, the complete circuit shown in block diagram form in Fig. 9.4 also providing RF and AF amplification. It looks a more complicated circuit involving a considerable number of components but, in fact, a *single* transistor can be made to perform the work of RF and AF amplifier.

Fig. 9.5 shows a basic single-transistor reflex circuit which is fairly non-critical and should be easy to operate satisfactorily; this is actually a three-stage circuit.

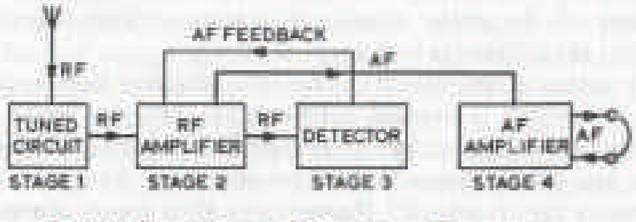

Fig. 9.4 Block diagram of a four-stage reflex receiver.

R, 1 M
TR, 2N2926

A rather more conventional design is shown in Fig. 9.6; the 'front end' of this circuit comprises the tuned circuit feeding an RF amplifier stage. In this type of circuit the tuning coil must be inductively coupled. The output from the RF amplifier employs what is known as *choke capacitance* coupling, a radio-frequency choke coil (RFC) being used to ensure an adequate load impedance for RF currents without having a d.c. voltage drop (*i.e.* offering high resistance to RF but low resistance to d.c.). The use of this choke coil also means that the gain of the amplifier varies with the frequency of the input, because the reactance of the choke varies with frequency. This effect is not desirable, but is tolerable in this type of circuit.

The output of amplified RF is fed from this stage into the detector stage. A feedback is arranged as follows: the AF signal passed by the detector, plus a little residual RF appearing at this point, is passed back to the base of the transistor in the previous stage, the AF being little affected by the capacitor C7. However, any RF is heavily attenuated or reduced, thus the transistor is made to perform the additional function of an AF amplifier. By choosing a suitable value for C7 a low reactance to RF is assured, but a high reactance to AF. For example, a 0.01 µF capacitor has a reactance of 30 Ω at 500 kHz, increasing to 3,000 Ω at 5 kHz. If 5 kHz represents the *upper* limit of AF signals likely to be encountered, reactance will become proportionately higher at lower audio frequencies. Conversely, for radio frequencies above 500 kHz the reactance will decrease proportionately.

L1 and L2, RFC (choke coils) (see text)

Specification for the RFC is 1 or 1.5 millihenries (mH). A suitable coil can be made by winding on a standard ¼-in. diameter coil former, using 38-s.w.g. enamelled wire. Cut two ¾-in. diameter cheeks from thin Paxolin or similar insulating material to fit together on the coil former, spacing them ⅛ in. apart–Fig. 9.7. The space between the cheeks is then completely filled with a winding of 38-s.w.g. insulated wire, winding on one layer with turns adjacent, then a second layer over the top, and so on until the coil has built up to the same diameter as the cheeks. The coil windings can be held with a wrapping of cellulose tape and the ends

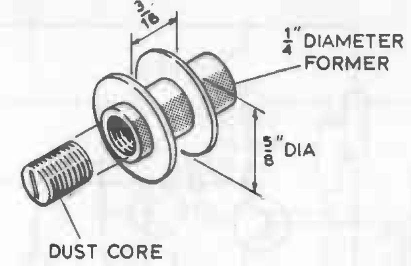

Fig. 9.7 Coil former for winding the RFC coils.

should be secured to one of the cheeks with sealing wax or something similar. The provision of an iron-dust core to fit the centre of the coil core enables the inductance of the completed coil to be varied by screwing in and out, thus taking up any differences introduced in the actual winding; in other words, the dust core forms a trimming adjustment.

All the other components used are familiar, standard types. High-impedance headphones, or a high-impedance magnetic type earpiece must be used with this circuit.

The same circuit can be modified for regenerative working as well (regenerative-reflex receiver), simply by connecting a 10-pF trimmer

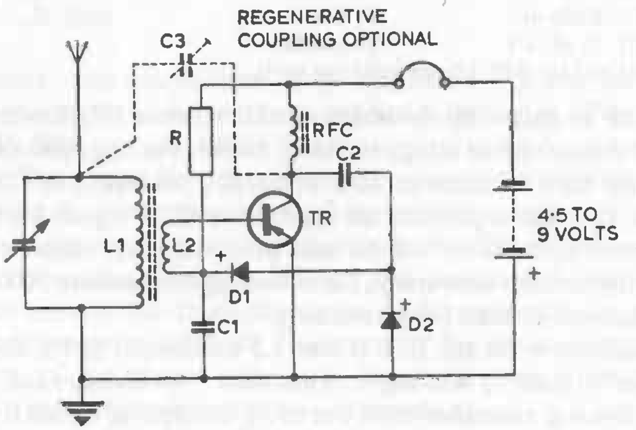

Fig. 9.8 *Circuit 19.* Single-transistor reflex receiver using two diodes.

capacitor between the collector of the transistor and the 'hot' end of the tuned circuit. This capacitor is adjusted to give optimum regenerative coupling.

In areas where radio reception is generally good, either circuit (reflex or regenerative-reflex) if assembled correctly should give good listening strength without the use of an external aerial.

It is possible to simplify the single-transistor three-stage reflex receiver by using two diodes in the circuit instead of one. A typical circuit of this type is shown in Fig. 9.8. Again the circuit may be converted to regenerative-reflex working by connecting a 10-pF or

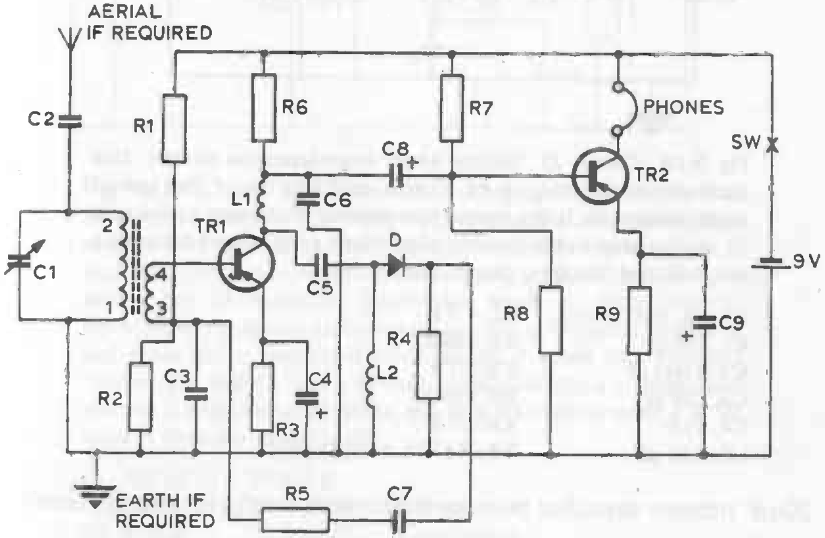

Fig. 9.9 *Circuit 20.* Four-stage reflex receiver. This is an extended version of the design given in Fig. 9.6–the same basic circuit with the addition of an AF amplifier stage. Using low-power transistors, output power is matched to high-impedance phones.

The output from the reflex stage may be fed directly into headphones (three-stage circuit); or may be followed by a stage of normal AF amplification (four-stage circuit–see Fig. 9.9); or further stages of amplification (five-stage circuit), etc, all the additional stages being AF amplifier stages.

As with the simpler circuits, however, there is a practical limit to the number of amplification stages which can usefully be added. The basic three-stage circuit (with no AF amplifier) should give audible headphone reception on a number of different stations; the four-stage circuit should give good headphone reception with local stations very loud; or equally be capable of giving good volume with a loudspeaker, depending on choice of transistors for the amplifier stages.

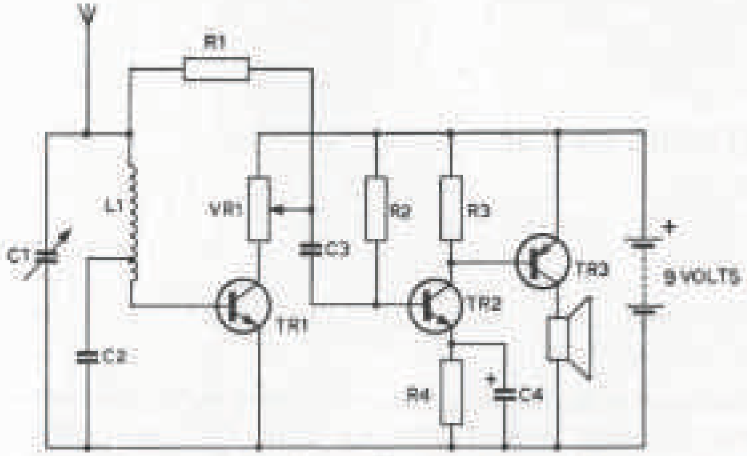

Fig. 9.11 *Circuit 22.* Three-transistor regenerative receiver with loudspeaker output. This design of regenerative receiver employs resistive feedback rather than capacity feedback. The advantage is that the regeneration, once adjusted, should remain at an optimum setting for all broadcast frequencies tuned in. With capacity regeneration, optimum adjustment is usually to a specific frequency and needs to be readjusted when the set is tuned to a different station. The coil (L1) is a 90-turn winding of 32-s.w.g. enamelled wire on a $\frac{3}{8}$-in. diameter ferrite rod with the tapping point 8 to 10 turns in from the 'earthy' end.

10 SUPERHETS

The superheterodyne or *superhet* receiver works on a more complicated principle than other types and involves more stages and more components. The RF signal from the tuned circuit is combined with another HF signal generated by a *local oscillator* in the receiver itself in a *mixer* or *convertor* stage. This stage then has an output which is a 'beat' frequency, equal to the *difference* between the two signals, this 'difference' frequency being called the *intermediate frequency* (IF).

The IF output from the mixer is then amplified (in one or more stages) before being passed to the second detector stage, where the modulated IF is converted to AF and subjected to further stages of amplification. The second HF signal is generated within the receiver itself by the HF or local oscillator, applied to the mixer. A block

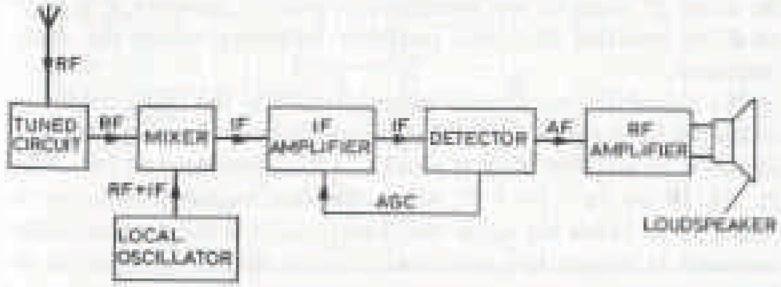

Fig. 10.1 Block diagram of a superhet circuit. Feedback of a proportion of the signal after detection is usually necessary to reduce gain on strong signals and prevent distortion through overloading. This is known as automatic gain control (AGC).

diagram is shown in Fig. 10.1, where it will be noticed that RF amplification can again be applied after the tuned circuit, if required.

The principal advantages offered by the superhet are that the gain and selectivity obtained from the IF amplifier do not depend on the frequency of the signal as they do with 'straight' receivers. Also the IF can be made lower than the signal frequency, resulting in higher stage gain and a narrower response curve. Again, too, since the IF amplifier is dealing with a constant frequency it can dispense with variable capacitors, reducing the risk of unwanted feedback and generally making the receiver less critical in design. The main disadvantages are the higher cost of such a circuit and the necessity of achieving proper alignment.

Most commercial domestic receivers are of the superhet type because of the superior performance offered and, although rather more complex, the type is equally suited to amateur construction.

The usual IF employed is between 450 and 475 kHz (455 kHz is more or less standard in this country) and the IF amplifier is tuned to the specific IF employed; this IF amplifier thus employs one or more stages of RF amplification with fixed tuning. A little thought will show that to 'feed' the IF amplifier correctly it will be necessary to vary the local oscillator in step with the tuned circuit. Thus if the receiver is designed to tune over a range of from, say, 800 kHz to 1,800 kHz and the IF is 470 kHz, then the oscillator frequency must range from 800 + 470 = 1,270 kHz to 1,800 + 470 = 2,270 kHz. Equally, to produce the same IF response the local oscillator could be set to 800 – 470 = 330 kHz to 1,800 – 470 = 1,330 kHz. The result would be the same as far as the IF amplifier was concerned; in practice, however, it is more usual to establish the local oscillator frequency above the signal frequency.

The converter thus actually receives two RFs: the signal frequency which can be designated Fs and the local oscillator frequency Fo. The following IF amplifier stage is tuned to a fixed frequency of Fo – Fs = Fi, the IF (or Fs – Fo = Fi, where the local oscillator frequency is chosen to be below the signal frequency); and it is the purpose of the converter to supply this particular IF as its output by a process of frequency conversion.

In fact, any oscillator HF will cause IF response at two signal frequencies, one equal to Fo – Fs and the other equal to Fo + Fs. One will be the real signal required, e.g. the correct value of Fs for the station selected, whilst the other is an undesirable *image* signal.

To clarify this by a numerical example, suppose the desired signal frequency is 800 kHz and the IF 450 kHz with the local oscillator set above the input signal frequency. To produce the necessary IF output at 800 kHz signal input the local oscillator will have to be set for 800 + 450 = 1,250 kHz. Exactly the same IF output will be produced, however, if a 1,250 + 450 = 1,700 kHz input signal is received, since the result of mixing will again be a frequency of 1,700 – 450 = 1,250 kHz. An essential feature of satisfactory working, therefore, is good *selectivity* in order to reduce the response to image signals to negligible effects.

The signal-to-image ratio, or image ratio as it is usually called, depends on the selectivity of the RF tuned circuits preceding the mixer or converter. At the same time the higher the IF the higher the image ratio, since raising the IF increases the frequency separation between signal and image and places the latter farther away from the peak of the resonance curves of the signal-frequency circuits.

The less experienced amateur–and certainly the beginner–is usually reluctant to tackle superhet construction because of the many complexities and large number of components involved, particularly in alignment, to get the circuit working satisfactorily. Probably the best approach, until experience is gained with superhet behaviour, is to build from kits, which include pre-aligned IF transformers. However, it is

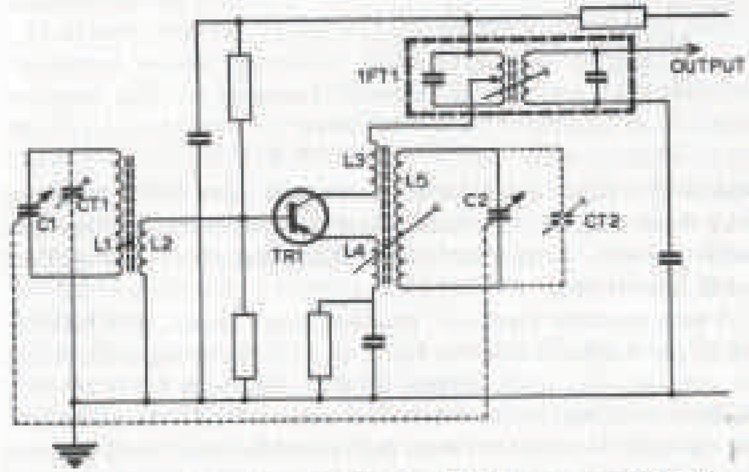

Fig. 10.2 Typical superhet 'front end', featuring conventional tuned circuit, local oscillator and mixer, and also one stage of IF amplification.

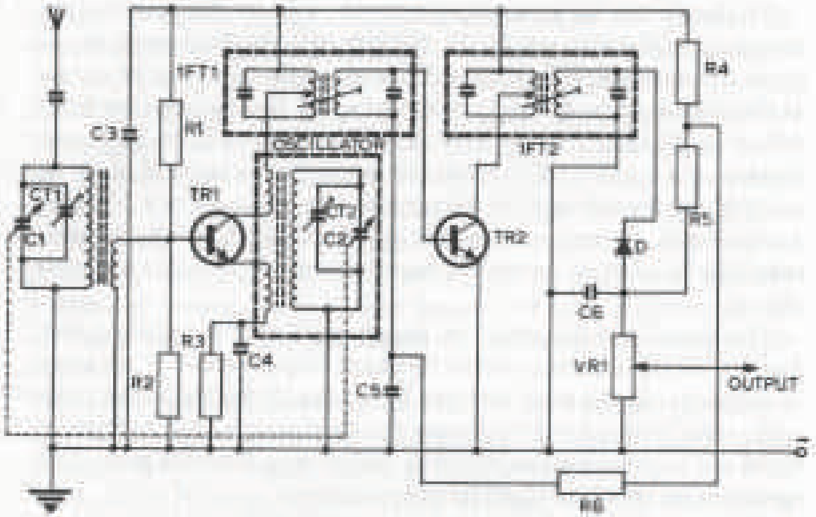

Fig. 10.3 *Circuit 23.* Complete superhet circuit up to output stage–i.e. to be followed by any suitable output circuit. This design uses n-p-n transistors.

possible to produce a working superhet circuit based on two transistors and a diode detector, with suitably selected components for the critical circuit elements–notably the ganged tuning capacitors, local oscillator and IF transformers.

A basic superhet 'front end' including tuned circuit, local oscillator and IF transformer is shown in Fig. 10.2. L1 is the tuning coil and L2 is the coupling coil (each wound on a ferrite rod); L5 is the local oscillator coil, inductively coupled to transistor TR1 via L3 and L4. The resonant frequencies of these two circuits are tuned simultaneously by the twin-ganged variable capacitors C1 and C2. In a practical circuit each variable capacitor would have its own trimmer capacitor, CT1 and CT2 respectively, for fine trimming.

Transistor TR1 is the mixer or *autodyne frequency changer,* the IF signal being selected by the IF transformer 1FT1.

The following sections, fed from 1FT1, use TR1 as an IF amplifier, and also provide the AF stage to feed the diode detector via a second IF transformer 1FT2. The whole of this circuit is shown in Fig. 10.3. An additional stage of IF amplification could be included, and also a more sophisticated output stage. Common practice is to follow a single stage of AF amplification by a push–pull output, with the driver transistor selected for high gain, and the output load formed by the primary of a phase-splitting transformer. However, keeping the number of components involved to a minimum and using only two IF transformers, considerably simplifies both construction and alignment.

Correct tracking of the aerial- and oscillator-tuned circuits to maintain the constant IF difference can be obtained by using a tuning capacitor with specially shaped vanes for the oscillator circuit; or by a conventional padded capacitor. Stray capacitance between the aerial and oscillator sections of the tuning capacitor can form a path for unwanted feedback between the two sections, so a screen is usually placed between them to prevent this. These effects can also arise between the wires connecting to the wavechange switch, so these must be kept as short as possible (or if completely incorporated on a printed circuit, the circuit elements kept short and well spaced to eliminate capacity effects).

In all cases, regardless of the type of oscillator and mixer, the first IF transformer receives a mixture of local oscillator frequency, signal frequency and the sum and difference of the two. It is therefore necessary to use a capacitor across the primary to produce an LC circuit to resonate at the IF. This capacitor is of fixed value (matched to the inductance of the coil), when any adjustment required for alignment is provided by an iron-dust core in the coil enabling the inductance to be varied over the necessary range. Once the overall LC value has been adjusted to a resonant frequency corresponding to the IF the tuning remains fixed.

Output from this stage is an AF modulated HF signal at the IF, which has also been subject to amplification.

Alignment with simple circuits should be quite straightforward and can be done without the aid of a signal generator. Particular care, however, must be taken not to overtighten the tuning slugs in miniature coils as these are easily jammed, resulting in permanent damage to the coil since it will be virtually impossible to remove the core without first removing the coil from the printed circuit; and equally almost impossible to remove the coil without damage.

To align without a signal generator, the set is tuned to the mid-way point on the long waveband and the core of L4 adjusted to receive BBC Radio 2. The tuning control should then be adjusted to the higher wavelength end of the medium waveband and the cores of 1FT1 and 1FT2 adjusted for maximum output. Further adjustment of volume can then be made by sliding the aerial coil along the ferrite slab, and once the best position is found the sleeve should be fixed with wax or cellulose tape. The receiver should then be tuned to 300 m approximately and capacitor C1 or its trimmer CT1 adjusted until an identifiable station is received and then brought up to maximum volume by adjustment of capacitor C2 or its trimmer CT2. If necessary, the alignment stages should be repeated for the medium waveband until all stations are received at good signal strength.

Using a signal generator, alignment is even simpler and more positive. The basic procedure should be:

(i) Injected signal, 600 kHz, adjust tuning to correspond to the end of the (medium) waveband.

(ii) Injected signal, 470 kHz, adjust 1FT1 and 1FT2 cores for maximum output.

(iii) Injected signal, 600 kHz, adjust coil position on ferrite rod for best results.

(iv) Injected signal, 1,450 kHz, adjust trimmers CT1 and CT2 for maximum output.

Mullard 6-transistor receiver

This design is for a simple portable receiver using alloy-junction transistors and a single 9-V battery with transformerless push–pull output. The circuit is suitable for making as a medium-size portable receiver with a Ferroxcube rod aerial, or in miniature size if preferred. The standard IF of 470 kHz is used with the local oscillator frequency above the signal frequency. One OC44 and two OC45 transistors are used in the mixer and IF stages. The detector is a germanium diode type OA70. The audio stages comprise one OC71 transistor driving a matched pair of OC72 transistors.

The OC44 operates as a self-oscillating mixer, with RF signals from the aerial coupling coil fed into the base of the OC44, leading to the

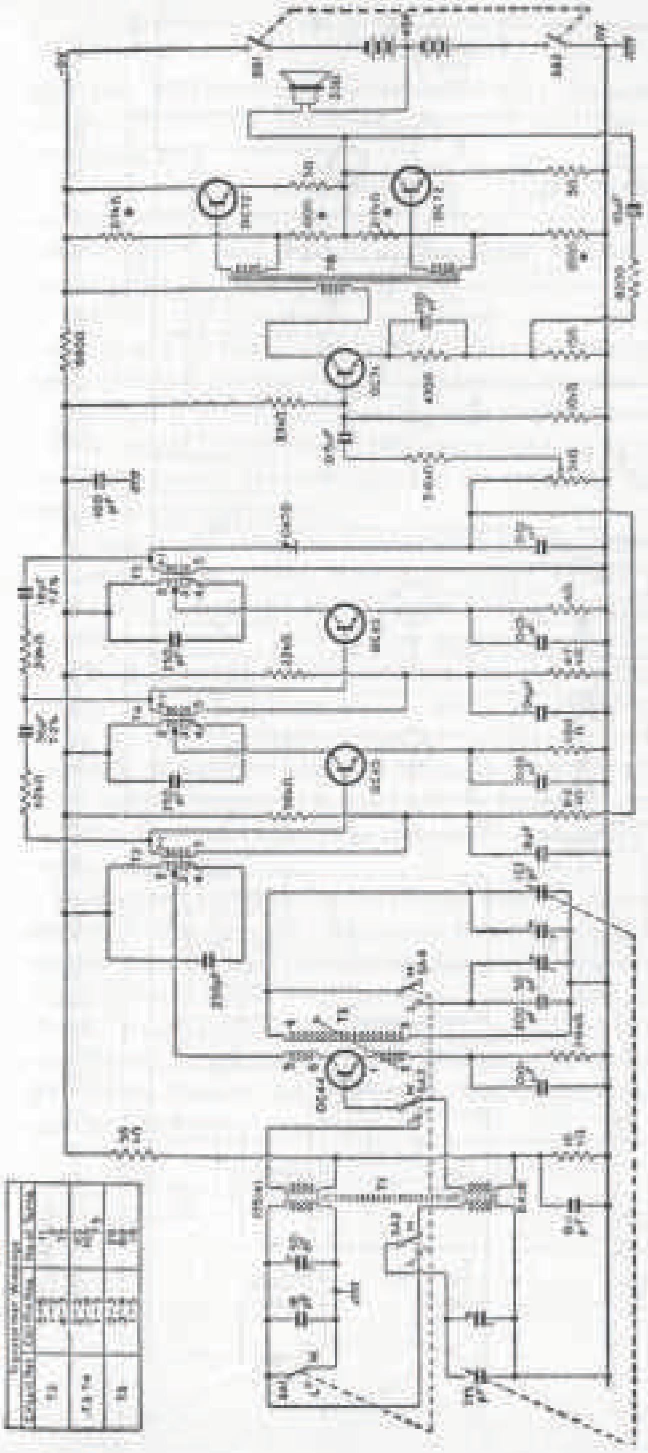

Fig. 10.4 *Circuit 24.* Mullard design for six-transistor superhet. Tolerance of resistors marked with an asterisk should be 5 per cent, others 10 per cent.

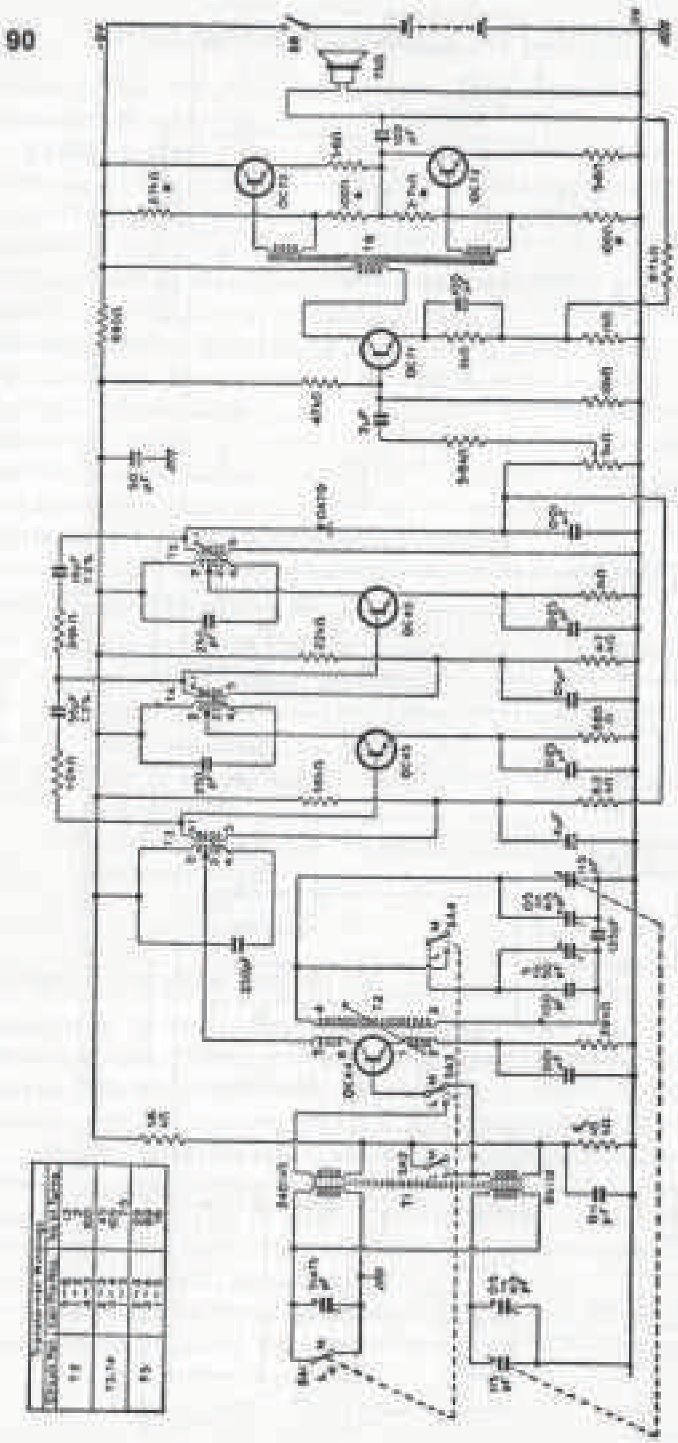

Fig. 10.5 Circuit 25. Mullard design miniature superhet. Tolerance of resistors marked with an asterisk should be 5 per cent; others 10 per cent.

generation of local oscillation feedback from the collector to the emitter. The IF is selected at the collector of the OC44 by the first IF transformer T3.

The IF amplifier comprises two OC45 common-emitter circuits operating unilateralized, with the choice of bandwidth compromising between quality and selectivity. The third IF transformer T5 is connected to the OA70 diode detector, with the d.c. output fed back to the first IF transformer to provide automatic gain control. Double-tuned IF transformers are recommended for optimum performance as regards frequency response and image rejection.

The Class B transformerless output stage requires a loudspeaker with a 35-Ω speech coil to provide the correct load for an output of 200 mW, with negative feedback applied to the emitter of the OC71 driver from the loudspeaker terminal.

All component values are shown on the circuit diagram (Fig. 10.4). The value of the tuning capacitance is not critical, but must be sufficient to provide the desired frequency coverage. The aerial section has a capacitance of 175 pF and the oscillator section a capacitance of 125 pF. A screen should be used between the oscillator and aerial sections of the tuning capacitor (i.e. the tuning capacitor so specified) to be sure of eliminating undesired feedback in the circuit. The possibility of feedback will be at maximum when the receiver is tuned to its highest frequency, and will also be increased when the tuning capacitor has a low value (e.g. as typically the case with a miniature tuning capacitor).

A miniaturized version of the original circuit is shown in Fig. 10.5, again with all component values marked. Here the output is reduced to 100 mW driving a 75-Ω miniature speaker. Current consumption of this circuit is reduced from 9 mA zero signal, 20 mA average, to 7 mA and 13 mA, respectively. This miniaturized circuit permits of further modification by substituting a Class A output with transformer drive to the speaker, reducing the number of transistors required to five, but increasing the battery consumption.

11 COMPONENTS

The following descriptions are intended to familiarize readers with the various basic components used in radio construction, as well as being a useful reference when selecting components for making a particular circuit.

Resistors

The first thing to remember about resistors is that their *size* is no indication of their actual resistance value; rather it is a rough indication of the *power rating*. Transistor circuits operate with low power ratings and so small (physical) resistors are commonly employed.

Actual *sizes* of resistors range from 4 mm long by 1.2 mm diameter (with a $\frac{1}{20}$-W power rating), up to about 50 mm long by 6 mm diameter (with a 7-W power rating); and even larger in the old-fashioned type of carbon rod resistors. A comparison of modern resistor sizes is given in Fig. 11.1; this diagram is also a useful method of identifying the various *types* of resistors by their shape.

There are five main *types* of resistors, classified by their construction.

(i) *Moulded-carbon type*, literally a rod made from a mixture of carbon and binder fired into a rigid form. This rod is usually protected with a lacquer coating, or a paper or ceramic sleeve. These are the old-fashioned type which are still available (usually as 'surplus' stock) and are suitable for any non-critical circuit. Ratings are usually $\frac{1}{4}$ W, $\frac{1}{2}$ W and 1 W.

(ii) *High-stability carbon resistors*, much smaller and compact, made from carbon film. These are miniature and sub-miniature in size and are

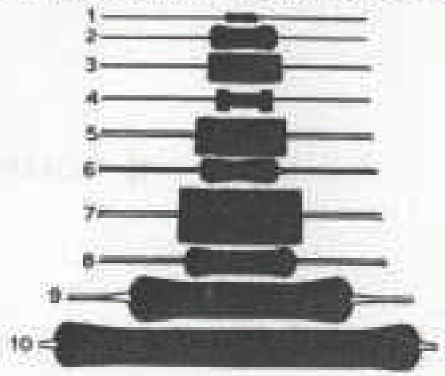

Fig. 11.1 Modern resistors.

1, $\frac{1}{20}$ W carbon-film	6, $\frac{1}{2}$ W metal-oxide
2, $\frac{1}{8}$ W carbon-film	7, 1 W carbon-film
3, $\frac{1}{4}$ W carbon-film	8, 1 W wire-wound
4, $\frac{1}{10}$ W metal-film	9, 3 W wire-wound
5, $\frac{1}{3}$ W carbon-film	10, 7 W wire-wound

the preferred type for general use because of their good stability, low noise, and quite low cost. Ratings are usually $\frac{1}{20}$ W, $\frac{1}{8}$ W, $\frac{1}{4}$ W, $\frac{1}{2}$ W, $\frac{3}{4}$ W and 1 W.

(iii) *Metal-film resistors*, which are made by depositing a film of nickel-chromium on a high-grade ceramic body and then cutting a helical track through the film to produce the required resistance values. End caps are fitted to carry the leads and the resistor body is protected by a lacquer coating. These are much more stable than carbon resistors but cost about four times as much. Ratings are from $\frac{1}{10}$ W upwards.

(iv) *Metal-oxide resistors*, made by depositing a film of tin oxide on a special glass rod, the whole being subsequently covered with a heat-resistant coating. Stability is again very high and this type is virtually proof against damage through overheating (e.g. when soldering) and is also unaffected by dampness. The usual rating is $\frac{1}{2}$ W.

(v) *Wire-wound types*, generally only required for special circuits where very low resistance values are required and/or very high currents have to be carried. Typical ratings may range from 1 to 5 W for a 0.5-Ω resistor to 25 W or more for higher resistance values.

Regardless of size, shape and type, the usual method of marking a resistor *value* is by coloured bands on the body, read in order 1, 2, 3 from the band nearest one end–Fig. 11.2. The equivalent value is determined by:

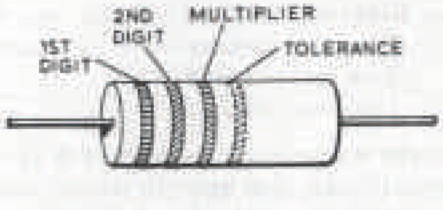

Fig. 11.2 Standard resistor colour coding.

Colour	1 gives first figure of resistance value	2 gives second figure of resistance value	3 gives number of noughts to put after first two figures
Black	0	0	None
Brown	1	1	0
Red	2	2	00
Orange	3	3	000
Yellow	4	4	0000
Green	5	5	00000
Blue	6	6	000000
Violet	7	7	0000000
Grey	8	8	00000000
White	9	9	000000000

Example: resistor colour code read as Brown, Blue, Orange.

	Brown	Blue	Orange
value read as	1	6	000

i.e. 16,000 Ω or 16 kΩ (kilohms).

On some old-type resistors the three colours are applied in a different manner–a coloured body, coloured tip and coloured spot on the body. The code is then read in the order body, tip, spot.

Many resistors have an additional (fourth) coloured band, which expresses the *tolerance* on the resistor value. The equivalent tolerances so indicated are:

Silver band	10 per cent tolerance
Gold band	5 per cent tolerance
Red band	2 per cent tolerance
Brown band	1 per cent tolerance

For most circuits resistors with a gold band (5 per cent tolerance) are the recommended choice; silver band (10 per cent tolerance) are good enough for general use. Finer tolerances (red or brown band) are not necessary, except for critical circuits. No fourth band implies a tolerance of 20 per cent.

Other variations which may be found on colour coding are:

a salmon pink band indicating a high-stability type;
a *double ring* of the first colour band, indicating a wire-wound resistor.

Some types of modern resistors are not colour coded but the values are marked directly on to them in numbers and letters. *Numbers* indicate numerical values and *letters* indicate multipliers, viz:

R = × 1
K = × 1,000
M = × 1,000,000

Tolerances are also given by a second letter, viz:

M = 20 per cent
K = 10 per cent
J = 5 per cent
H = 2.5 per cent
G = 2 per cent
F = 1 per cent

The first letter ('multiplier') comes in a position which determines the decimal point. Thus:

rating *5R* designates 5 × 1 = 5 Ω
4K7 designates 4 × 1,000 and 0.7 or 4.7 kΩ
82K designates 82 × 1,000 or 82 kΩ

The tolerance letter comes at the end, e.g.

4K7J means a 4.7-kΩ resistor with a 5 per cent tolerance

Actual resistor *values* are also normally based on *preferred numbers* and not simple arithmetical steps. The reason for this is that preferred number steps give approximately constant *percentage* change in

resistance from one value to the next. The usual resistance values obtainable are thus:

Ω	kΩ	MΩ
10*	1.0	1.0
12	1.2	1.2
15	1.5	1.5
18	1.8	1.8
22	2.2	2.2
27	2.7	2.7
33	3.3	3.3
39	3.9	3.9
47	4.7	4.7
56	5.6	5.6
68	6.8	6.8
82	8.2	8.2
100	↓	
120		
150		
180		
220		
270		
330		
390		
470		
560		
680		
820		

*Typical values for *wire-wound* resistors below 10 Ω are: 0.33, 0.5, 1, 1.5, 2, 3, 3.3, 3.9, 4, 4.7, 5, 5.6, 6, 6.8 and 8.

Variable resistors (potentiometers)

Variable resistors, or *potentiometers*, are normally constructed from a resistive element, formed into a 270° arc, with a wiper arm connected to it, and turned by a central spindle. There are three external terminal tags; the outer ones connect to the ends of the resistance element and the centre tag to the wiper—see Fig. 11.3.

The resistance element may be a carbon track or a winding of resistance wire (wire-wound potentiometers). Carbon-track potentiometers are cheaper than wire-wound types and are suitable for most general circuit applications, at low power levels, e.g. ¼ to ½ W for low

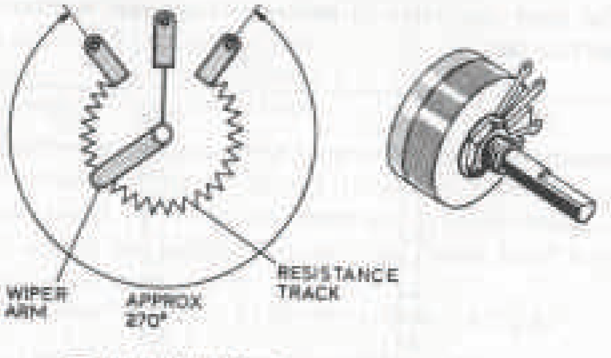

Fig. 11.3 Variable resistor or potentiometer.

resistance values, reducing with higher resistance values. Wire-wound potentiometers have a higher power rating–usually of the order of 1 to 3 W continuous for the whole track; they are also made in lower resistance values obtainable with carbon-track potentiometers.

The usual resistance values available in each type are:

Carbon-track: 100, 220, 470, 1 k, 2.2 k, 4.7 k, 10 k, 22 k, 47 k, 100 k, 220 k, 470 k, 1 M, 2.2 M and 4.7 M.

Wire-wound: 10, 22, 47, 100, 220, 470, 1 k, 2.2 k, 4.7 k, 10 k, 22 k, and 47 k.

The general appearance of typical carbon-track and wire-wound potentiometers is shown in Fig. 11.4; they are also made with a sliding

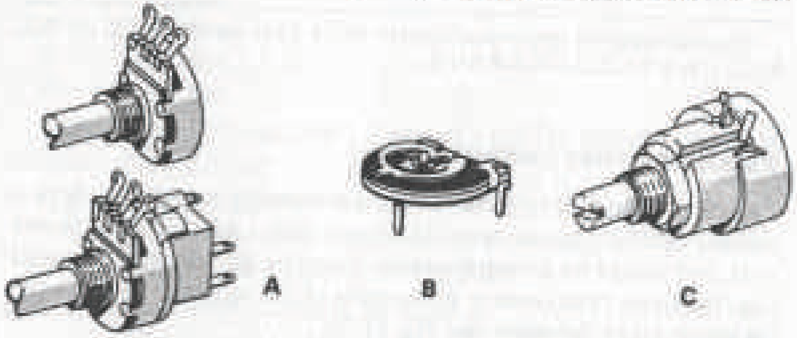

Fig. 11.4 Potentiometers
A, Typical small carbon-track, about 20 mm diameter;
B, Open-type carbon-track linear potentiometer, about 15 mm diameter;
C, Typical wire-wound potentiometer, diameter 25 to 35 mm.

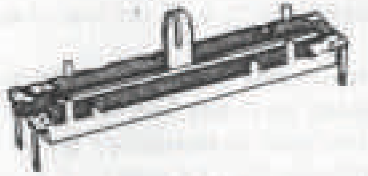

Fig. 11.5 Modern slider-type carbon-track potentiometer.

rather than a rotary movement. The old type consisted of a wire winding on a suitable cylindrical former, traversed by a sliding contact assembly. The modern miniature slider-potentiometer is much more compact and fully enclosed, except for the slot in which the slider arm travels–Fig. 11.5. The resistance track may be carbon, or wire-wound. Slider-type variable resistors have come into favour for volume controls on modern radio designs.

Potentiometers are also described as linear or non-linear, this referring to the manner in which resistance values vary with wiper movement and *not* whether the potentiometer is a slider or rotary-action type. With a *linear* potentiometer the resistance change is directly proportional to the actual movement, *e.g.* a 50 per cent

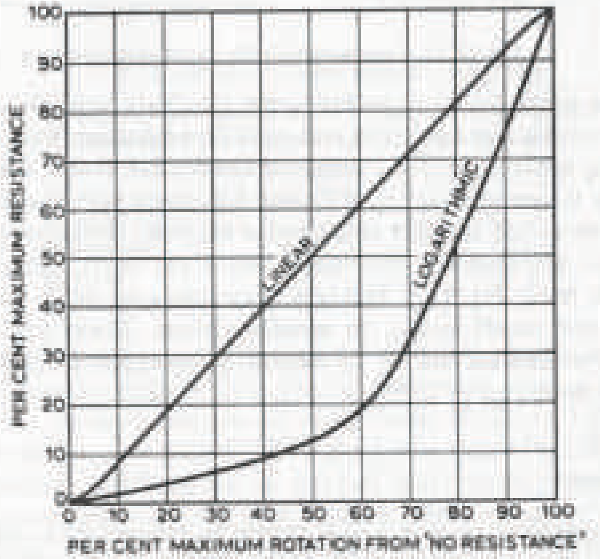

Fig. 11.6 Linear and logarithmic potentiometer characteristics.

movement will correspond to a 50 per cent change in resistance—see Fig. 11.6.

Slide-type potentiometers normally automatically provide linear characteristics. Rotary types may have linear or *logarithmic* characteristics, the latter producing an increasingly greater change in resistance with spindle rotation (see Fig. 11.6 again).

Potentiometers may also be designed with characteristics intermediate between linear and logarithmic, e.g. semi-log or linear-tapered; and also with inverse characteristics, e.g. anti-log. Either linear or logarithmic potentiometers are suitable for most volume control duties etc., although logarithmic types are generally preferred.

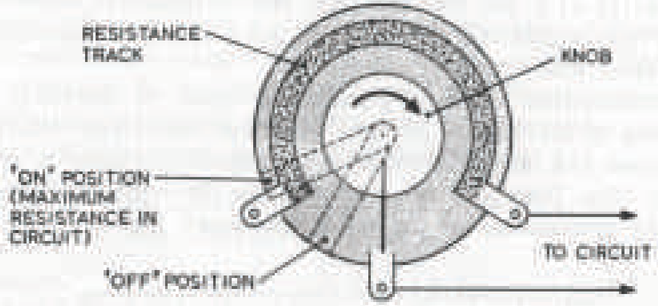

Fig. 11.7 Potentiometer with on-off switching.

Wiring connections to a potentiometer are simple, remembering that the two outside tags connect to each end of the resistance track and the centre tag to the wiper. For a simple volume control, connection is thus normally to one end tag and the centre tag. Some potentiometers are made with an 'off' location at one end of the wiper movement (usually maximum anti-clockwise movement) when the wiper runs off the resistance track—Fig. 11.7. This type can combine the duties of volume control and on-off switch, in suitable circuits. Power supplies are usually switched on and off by a switch mechanically coupled to the volume control.

Capacitors

Modern capacitors come in a wide variety of different types, sizes and constructions, many having overlapping values. The older *paper tubular* type, constructed of silver foil interleaved with mica sheets, have largely

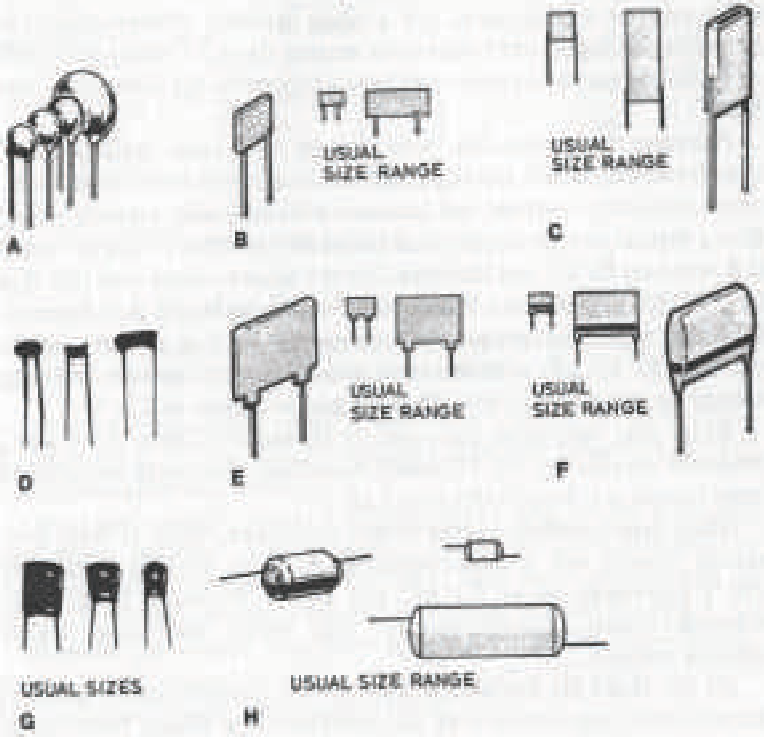

Fig. 11.8 Examples of modern miniature capacitors

A, Ceramic disc 1,000 pF to 0.1 μF (approx. actual size);
B, Ceramic plate, sizes from 4 × 2.5 mm to 12 × 5 mm;
C, Ceramic plate tubular;
D, Tubular ceramic, typical sizes;
E, Silvered mica;
F, Polyester;
G, Mylar;
H, Polystyrene.

been replaced by miniaturized ones, although they continue to be used in the capacity 0.05 to 2 μF (e.g. in preference to an electrolytic capacitor). Working voltages are of the order of 200 to 1,000 V for paper types, or up to 10,000 V with plastic-impregnated types.

Miniature capacitors are of ceramic, polystyrene, silver mica or mylar construction—see Fig. 11.8. *Ceramic capacitors* may be of 0.1 μF (but with working voltages generally substantially reduced above 5,000 pF capacity). *Tubular ceramic capacitors* have a similar value range and are usually rated for a mean working voltage of 350 V. *Silvered mica capacitors* with values ranging from 2.2 pF up to 10,000 pF (0.01 μF) are rather larger and have a higher voltage rating (typically 500 V).

Polyester capacitors are produced in two main configurations, cylindrical with offset end leads, and slab shape with radial leads for PC board mounting. Physical size increases with increasing capacity rating: thus a typical size for a cylindrical polyester capacitor of 220 pF or less is 8 mm long by 3.5 mm diameter. For the highest values with this type (e.g. 22,000 pF) size can be up to 32 mm long by 12 mm diameter. Polyester capacitors are usually constructed for high-capacity values, e.g. 0.01 to 2.2 μF, with size again increasing with capacity. Working voltage for these is normally 125 V for smaller values, or 250 V.

Mylar film capacitors are similarly constructed, with radial leads, produced specifically for PC board mounting. The range of values is more limited, e.g. from 0.001 to 0.2 μF.

Other types include *polycarbonate capacitors*, made in both rectangular ('box') and tubular configurations, with working voltages of 250 V for values up to 0.1 μF, and 100 V for values up to 1 μF, although special constructions for high values can accept higher working voltages.

All the above are *non-polarized capacitors*, meaning that it does not matter which way round they are connected in a circuit. Other types are *polarized* and must always be connected in a specific manner ('plus to plus'), otherwise they will be degraded and eventually destroyed.

The best known type of polarized capacitor is the *electrolytic capacitor*, originally based on an aluminium rod or foil plate in contact with a paste electrolyte. The capacitor is then formed by passing a direct current through it during manufacture, depositing a thin film of aluminium oxide on the aluminium surface by electrochemical action. This type of construction allows quite high values of capacitance to be produced in a relatively compact envelope, e.g. up to 1,000 μF. *Etched foil* electrolytic capacitors permit even greater capacitance values to be achieved for the same size, and so make it possible to produce miniature types with high capacity values. In the latter case the working voltage is generally reduced.

Modern electrolytic capacitors are usually of etched foil type, or the more recently developed tantalum construction, which are produced in both conventional cylindrical configuration with axial leads and *tantalum bead* form–see Fig. 11.9. Both types have low voltage ratings,

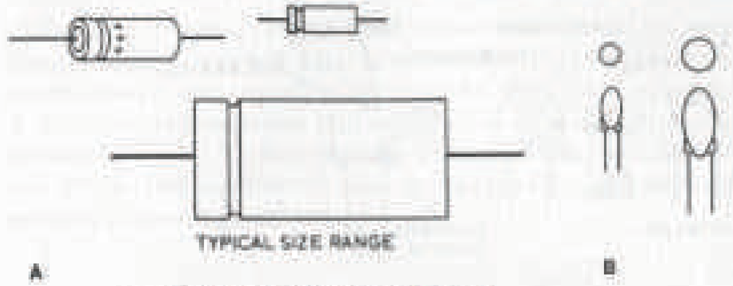

Fig. 11.9 Electrolytic capacitors

A, Metal-cased cylindrical with axial leads;
B, Tantalum bead, typical size range.

decreasing with increasing capacity value, e.g. from 35 to 40 V for 0.1 μF capacity; to 3 V at 100 μF capacity. *Tantalum* capacitors are also made in non-polarized form.

Values are normally marked directly on the body of the capacitor; some types, however, may be colour coded, the code adopted not necessarily being universal (it can vary from one manufacturer to another and from country to country in the case of older products).

Polyester slab-shaped capacitors are normally colour coded instead of marked, the colours following the same code as for resistors. Up to five bands can be used, the sequence being:

1st colour gives first significant digit in pF
2nd colour gives second significant digit in pF
3rd colour gives the multiplier
4th colour gives the *tolerance*, e.g. white 10 per cent, blue (sometimes black) 20 per cent
5th colour gives the voltage, red 250, yellow 400 V

The fourth and fifth colour bands may be missing; if only the fifth is missing, this implies a working voltage of 30 V.

Colour coding by rings may also be found on moulded-paper and some tubular ceramic capacitors. Some disc and slab-type capacitors may be colour coded by dots–see Fig. 11.10.

Variable capacitors

Variable capacitors are used for *tuning* or *trimming* to enable the capacitance in a critical circuit to be adjusted. There are physical

differences between a tuning capacitor and a trimming capacitor, both in size and construction, but both work on the same principle and could, in fact, be used for either duty.

Tuning capacitors are commonly of the air-dielectric type, consisting of two sets of intermeshing metal vanes, one set fixed and the other rotatable by about 180 degrees by means of a spindle. When fully closed (i.e. the spindle is turned so that the rotating vanes are fully in mesh with the fixed vanes) capacitance is a minimum, and when fully opened (i.e. turned to full movement the opposite way) a maximum.

The maximum capacity of air-dielectric variable capacitors of this configuration ranges from about 10 pF to 1,000 pF. Physical size may range from 'miniature', e.g. about 25 mm square and 13 mm thick, up to 50 × 60 × 80 mm, or even larger, but is no indication of the working capacity range. It is largely a matter of convenience and compactness to use miniature tuning capacitors for transistor circuits and these may be of the solid-dielectric rather than air-dielectric type. Typical forms are illustrated in Fig. 11.11, showing single and ganged condensers, the latter used where two separate circuits are required to be tuned simultaneously from a single control.

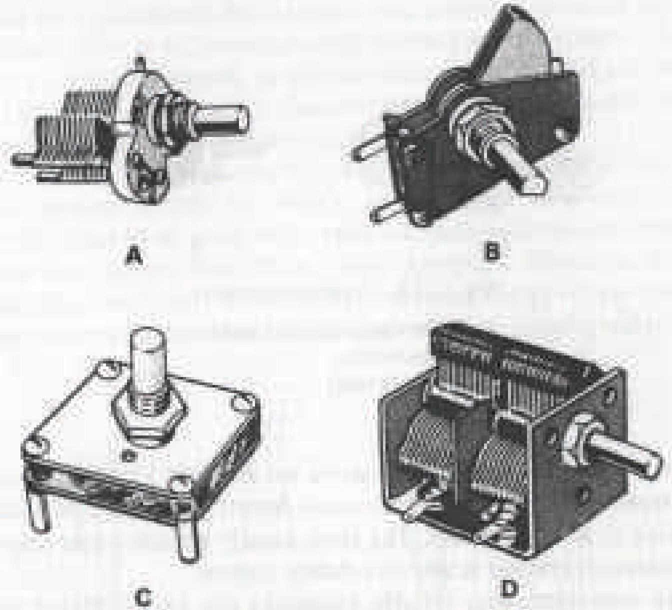

Fig. 11.11 Tuning capacitors

A, Air-dielectric;
B, Solid-dielectric;
C, Solid-dielectric, miniature;
D, Two-gang air-dielectric.

Trimming capacitors are usually based on a mica-dielectric and consist of two or more plates separated by very thin sheets of mica. Capacity is reduced by turning a central screw to adjust the pressure between plates and mica. They are designed primarily to be adjusted to a required capacity value and then left set in this position but can, however, be used as a tuning capacitor where their small physical size is an advantage (e.g. in a sub-miniature receiver); they are also cheaper than tuning capacitors.

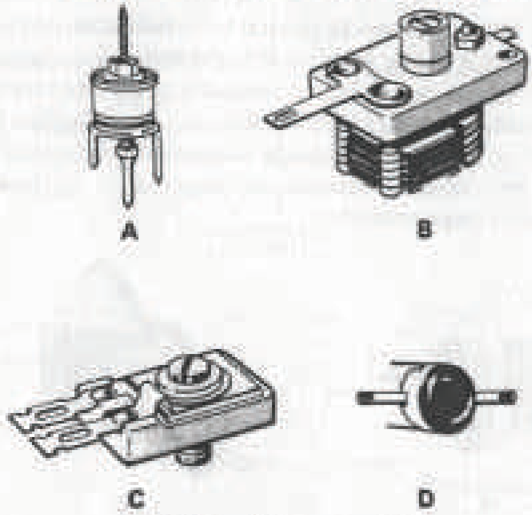

Fig. 11.12 Trimmer capacitors

A, Beehive type (air-dielectric);
B, Air-dielectric;
C, Mica-dielectric;
D, Ceramic.

Some forms of trimming capacitors are shown in Fig. 11.12. Not all such types have a mica-dielectric, some designs being based on a plastic dielectric or even air-spaced. The latter usually provide better response if a trimming capacitor is used as a *tuning* control.

Like potentiometers, variable capacitors can have different working characteristics, i.e. linear, logarithmic etc., depending primarily on the shape of the plates. These characteristics are usually:

(i) *Linear capacitance*, where each degree of spindle rotation produces an equal change in capacitance.
(ii) *Even frequency*, where each degree of spindle rotation produces an equal change in *frequency* in a tuned circuit.
(iii) *Square law*, where the change in capacitance is proportional to the *square* of the angle of movement.
(iv) *Logarithmic*, where each degree of spindle movement produces a constant *percentage* change in frequency.

Linear-frequency characteristics are usually preferred for a radio receiver tuning capacitor.

Transistors

Transistors are classified generally under two main types depending on the material used in their construction, germanium or silicon. Germanium transistors are the earlier type, but performance has been considerably improved by adoption of alloy-junction or alloy-diffusion methods of manufacture; silicon-junction transistors are normally made by the planar process. Where special characteristics are required (e.g. RF and IF applications), the manufacturing process is modified slightly to produce what is called an epitaxial (silicon-planar) transistor. There is also a third type known as a field-effect transistor (FET) in which both the construction and characteristics differ appreciably from germanium and silicon-junction types.

In general, germanium transistors are well suited to low-voltage AF circuits because of their low voltage losses and also because they can easily be matched in p-n-p/n-p-n pairs for push–pull output circuits; they are also cheaper than silicon-planar transistors. Silicon transistors, on the other hand, have lower leakage losses and higher voltage ratings, making them more suitable for higher output audio circuits, and for use

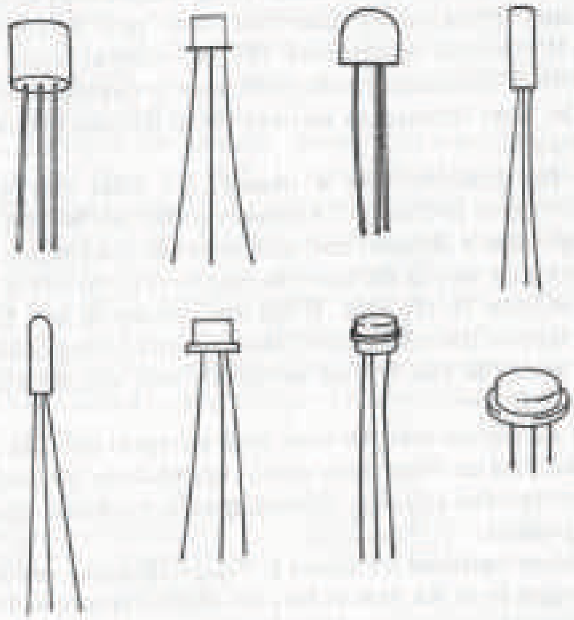

Fig. 11.13 Some transistor outline shapes.

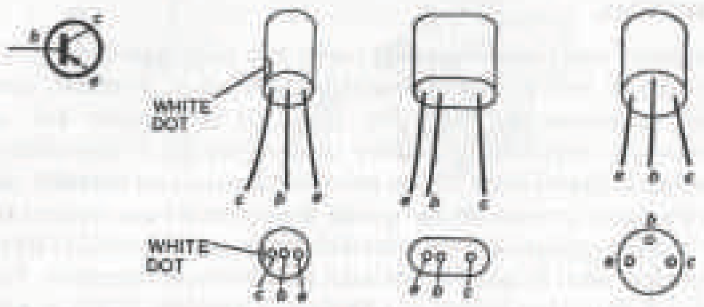

Fig. 11.14 Common transistor lead configurations.

at higher frequencies. They have the further advantage that they can operate successfully at temperatures up to 150°C or more, whereas the maximum working temperature for germanium transistors is normally below 100°C.

Transistors are basically three-element devices, the connections to the elements being in the form of three wires emerging from the bottom of the transistor, the whole being encapsulated in a metal or plastic case. Transistor outlines and sizes vary enormously (see Fig. 11.13), but the arrangement of the emergent wires normally follows one of the standard patterns to assist in identification—see Fig. 11.14. The three connections involved are to the *base* (*b*), *emitter* (*e*) and *collector* (*c*).

When the transistor base is circular, the wires may emerge in triangular form or in line. In the former case the two bottom points of the triangle lie in a diameter line, and viewed in this position from the bottom the apex wire is the base, the emitter is to the left of the base, and the collector to the right. If the wires emerge in line, a white or coloured spot on the can or body marks the end corresponding to the collector lead. The base is then the middle one, and the emitter the other end lead.

With a rectangular base the wires again emerge in line. The collector lead is identified as being more widely spaced from the middle wire (base) than the other end wire, although specific types may depart from this configuration.

Some other variations are shown in Fig. 11.15. Some may have *four* wires emerging from the base in line; the additional wire is the middle one connected to an internal shield (*s*). This does not form part of any connection to a circuit and is either ignored or connected externally to

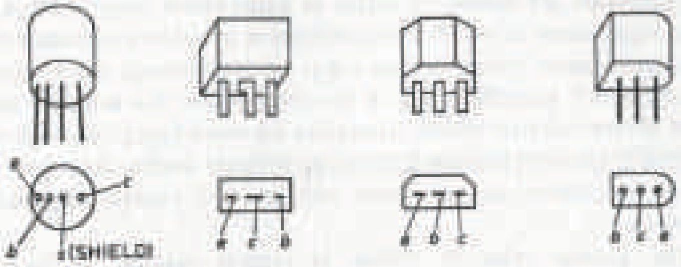

Fig. 11.15 Some other types of transistor shapes and lead configurations.

the case. Other types are designed specifically to plug into PC boards and have rigid terminal *strips* rather than wires—again connections can vary, so it is important to verify them for a particular type.

Power transistors are of more rugged construction and generally have different connections again. Some may have three wire connections, others just two terminal strips—see Fig. 11.16. In the latter case the collector connection is absent, the collector being connected internally to the case. Emitter and base leads are normally marked 'E' and 'B' respectively. The *collector* connection is then normally made to one of the screws mounting the transistor (or to an external terminal tag suitably connected to the case).

Power transistors are normally mounted on a *heat sink* to assist in dissipating heat from the case. It is usually necessary (except in a grounded collector circuit) to electrically insulate the transistor from this heat sink; at the same time this insulator must be a good conductor of heat. Suitable insulators are readily available to make heat sinks, consisting of a simple gasket or washer of mica, anodised aluminium or fabric. Fabric washers require greasing with silicon grease to make them heat-conducting. Some types of power transistors have tubular bodies when a finned cooling clip may be used to dissipate heat, instead of a heat sink.

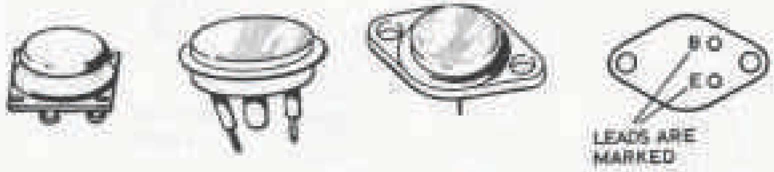

Fig. 11.16 Power transistors.

Transistors are further classified as being either p-n-p or n-p-n, the main significance of which is the difference in polarity of connections. Most germanium transistors are p-n-p types (although n-p-n ones are made for AF amplifiers and as the complement for matched pairs); most general-purpose silicon transistors are n-p-n types, although again p-n-p ones are also produced. If in the slightest doubt, the actual type should be checked as connection with reversed polarity can ruin the transistor.

The general rules to follow as regards polarity of transistor connections are:

with a p-N-p transistor the *collector* must be *Negative*;
with a n-P-n transistor the *collector* must be *Positive*.

12 CIRCUIT CONSTRUCTION

The general rule for designing a circuit layout is to follow, as far as possible, the same disposition and relative positioning of the individual components as on the circuit diagram. This should eliminate over-long wires and avoid unnecessary crossing over of leads.

Tag strips form a convenient method of assembling simple circuits involving a relatively small number of components. Two tag strips, mounted an inch or so apart on a Paxolin panel, enable individual components to be soldered between pairs of tags with common connecting leads where necessary—Fig. 12.1. Alternatively, ready-mounted tag strips can be purchased as *tag boards*. A component continuing a circuit from a 'common' point has its second lead soldered to a spare tag, which can become a 'common' connecting point for another component, and so on.

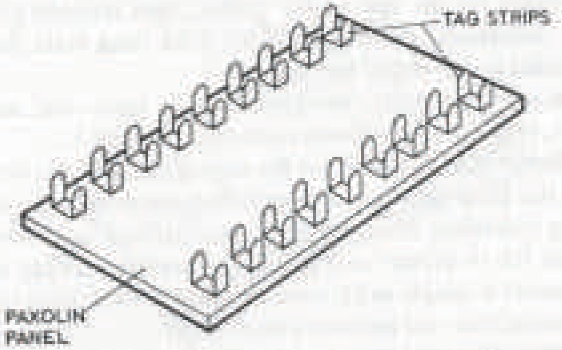

Fig. 12.1 Tag boards can be made by mounting tag strips on a Paxolin panel, or bought ready-made.

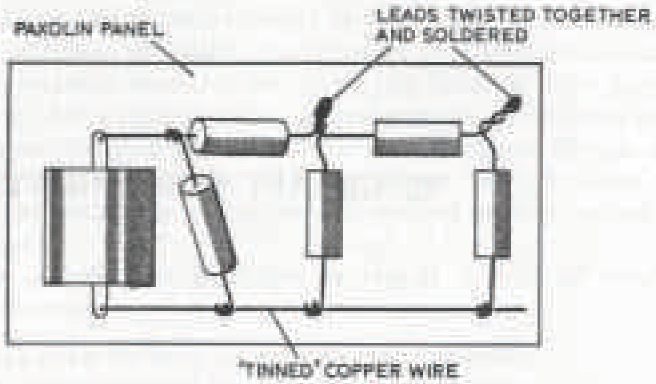

Fig. 12.2 Suitable method of circuit construction involving small number of components.

This technique was illustrated in the construction of simple crystal sets in Chapter 3. It is adaptable to more complex circuits, particularly for experimental work, but is generally untidy and unnecessarily bulky for general use. The greater the number of components, the more the circuit assembly tends to expand lengthwise, with lots of wasted space.

Direct assembly can be an attractive alternative where the components are laid out in order on a Paxolin panel. Connections are made by twisting appropriate leads together, then soldering (cutting off surplus length of leads where necessary). Larger common connections can be made to a length of 'tinned' copper wire of about 16 s.w.g. laid flat on the panel. One or two major components, such as aerial coils and the tuning capacitor, can be secured to the panel, forming an anchor point for the rest of the circuit. Main terminal point, e.g. for battery connectors, can be formed by 6-BA brass bolts fitted through holes drilled at one end of the panel.

Constructed correctly, the result can be quite neat and relatively compact, with the whole circuit quite rigid–Fig. 12.2.

'Christmas tree' layout is for the experimental or test circuit only; it follows the same principle of connecting components by twisting and soldering individual leads together, but without any attempt to lay them out flat or mount on a panel. The result invariably looks pretty messy, but it is simple and it works–provided leads do not accidentally touch one another and produce a short-circuit.

Breadboard construction is probably the best for the more serious experimenter, and can also be used for permanent circuits where overall

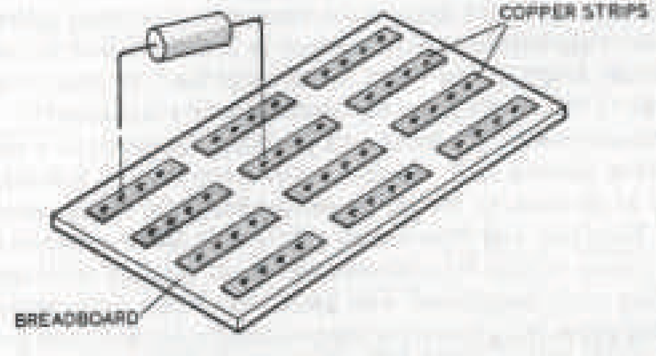

Fig. 12.3 'Breadboard' panel with pre-drilled contact strips. In some cases the copper is in long strips, sections being isolated by cutting through, as required.

size is not important. It is similar to tag-strip assembly except that the terminal points are laid out in the form of strips on a flat panel. Each strip has a number of holes into which individual component leads can be inserted for common connection, the other lead(s) connecting across to further separate strips as required to continue the circuit–Fig. 12.3. Some proprietary breadboards have small spring clips fitted under individual holes both to provide positive contact and hold the component in position without soldering–Fig. 12.4. In others the strips

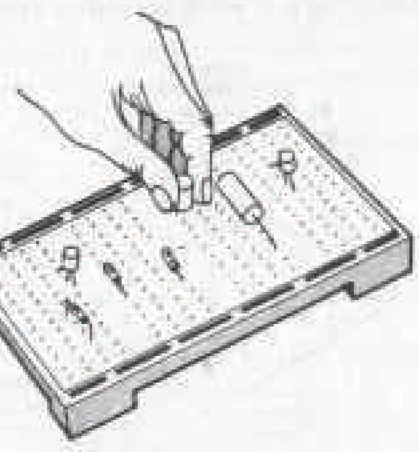

Fig. 12.4 Modern breadboard unit with spring location for components pushed in position.

are simply copper with drilled holes, component leads being soldered in position; strip lengths in this case may be in separate sections, or run the whole length of the panel, in the latter case the strip being cut through to isolate each group of connection points as required.

Pegboard assembly is based on a perforated baseboard of a suitable insulating material with terminal pillars which can be inserted into holes, as required, to provide connecting points for components—Fig. 12.5. The pillars may have a screw top for solderless assembly, or be of plain copper or brass for soldered connections. A similar technique can be allied to a 'breadboard' with prefabricated connecting strips, the terminal pillars being inserted in the pre-drilled holes, and strips isolated as necessary.

Proprietary constructional panels of these two types are designed for both amateur and general use and are widely favoured by many constructors who find designing their own component layout a tricky problem. A feature of many of these is that they can be used over and over again. The best advice regarding their suitability is to experiment and find by experience which appeals most to the individual builder, or is found easiest to use.

An alternative 'home-made' system, which would be regarded as crude by most professionals, is to cut a panel of ply or even hard balsa for the base, draw on the position of the components (as near to scale as possible) and clearly mark the common connection points required. A copper nail is then driven into the base at each end of these points, forming terminal posts to which component leads can be soldered—Fig. 12.6. Longer common leads can again be a length of tinned copper wire soldered between two end nails.

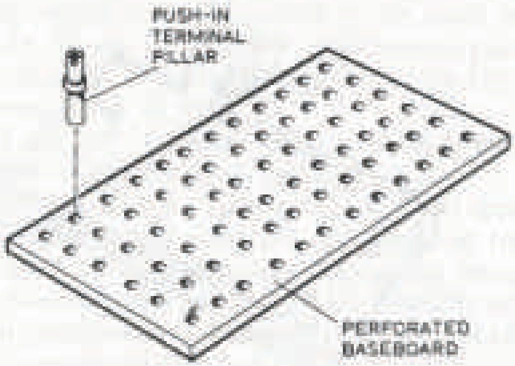

Fig. 12.5 'Pegboard' construction using a perforated baseboard and push-in terminal pillars.

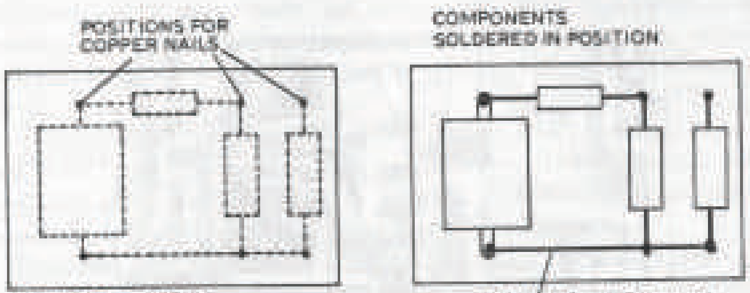

Fig. 12.6 'Copper nail' technique—again suitable for small circuits.

A refinement of this is to use a Paxolin panel, and screw or bolt small individual tags to main and common connecting points; the longer common connections are formed from tinned copper wire soldered between two tags; individual common connecting points are formed by separate tags—Fig. 12.7.

The best technique, particularly where miniaturization of the circuit is required, is printed-circuit assembly—Fig. 12.8. Printed-circuit stock is invariably purchased in panels which can be cut to the overall size required, one face of which is coated with copper foil and the actual circuit pattern produced by etching. This involves transferring a drawing of the circuit on to the copper, coating all copper areas which are to remain with a suitable resist, and then immersing the panel in an acid bath to etch or dissolve away the remaining unwanted copper. The

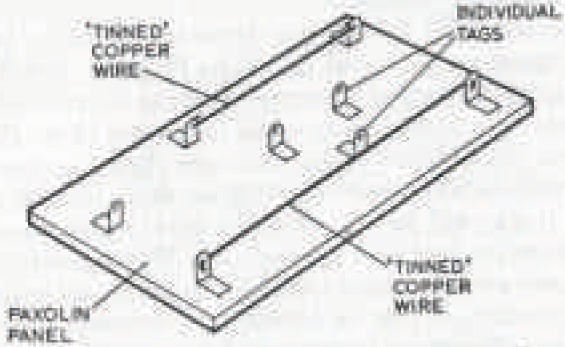

Fig. 12.7 Home-fabricated tag- and bus-bar panel.

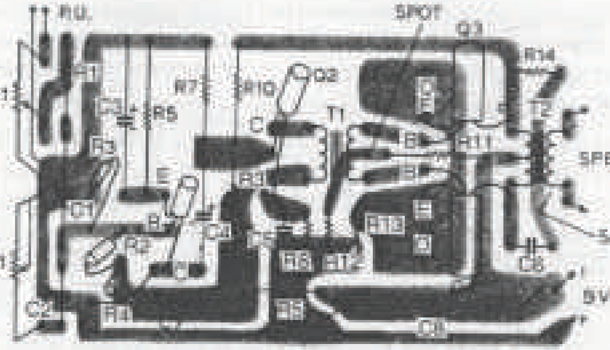

Fig. 12.8 Printed-circuit drawing layout for a push–pull amplifier.

resist is then removed with a solvent, when the PC panel can be prepared for component assembly by drilling, etc.

All this work is well within the scope of the amateur enthusiast, either working from a PC plan or designing a suitable printed pattern equivalent to a theoretical circuit design, although the latter can become quite an involved business. Alternatively, many standard radio designs etc., are available as kits or in component form for home assembly, including a complete PC, ready drilled as necessary; this latter feature saves a lot of time and effort, being a point of design on which the less experienced constructor is likely to go wrong. One of the basic essentials of PC design, in fact, is complete familiarity with component sizes so that mounting holes or holes for leads properly match the components to be accommodated, all arranged in logical order, both physically and electrically. Unlike ordinary wiring-up, PC conductors cannot be crossed over each other.

The important thing to remember is that the PC pattern has to be etched 'in reverse' on the copper side of the PC board. Simply make a tracing of the original drawing of the component layout and connections and turn this over to transfer on to the copper side of the PC board.

The layout should follow basically the same physical arrangement as the theoretical circuit. Where this diagram itself includes crossing conductors it may well be of considerable advantage to discover if it can be replanned so that these are eliminated. If this proves physically impossible, and a solution cannot be found by altering the arrangement of the components, it may be necessary to terminate certain connections on the PC lands and interconnect to cross other lands with an

insulated jumper wire. Whilst this may be considered bad design, it is perfectly suitable for one-off or amateur construction. Bear in mind, too, that components themselves can be used for bridging over adjacent conductors.

The current-carrying capacity of conductors varies with foil thickness but, since the current values in transistor receiver circuits are invariably low, conductor size is unlikely to be critical, although recommended minimum figures should be adhered to.

Minimum recommended conductor width is $\frac{1}{16}$ in., with at least $\frac{1}{32}$ in. clear spacing between adjacent conductors to reduce the possibility of accidental shorts or 'bridging' between them when soldering. The drawing should also allow for a minimum spacing of at least $\frac{1}{32}$ in. between the outside conductor and the edge of the PC board.

Where holes have to be drilled to take component leads, the diameter should closely match the lead size, e.g. with a typical resistor lead of 0.028 in. (22 s.w.g.) the corresponding hole diameter should be at least $\frac{1}{32}$ in. or No. 67 drill. Sufficient area of copper 'land' should be provided around each hole for a minimum width of $\frac{1}{16}$ in. (Fig. 12.9). The holes should be correctly spaced to match component leads, allowing for a 'finger bend' at each end or down the side of the component, according to whether horizontal or vertical assembly is to be used (Fig. 12.10). The former is to be preferred except where a minimum size panel is aimed at, when vertical mounting of resistors etc., will occupy minimum base area. At no point, however, should spacing between adjacent holes be less than twice the laminate thickness (*i.e.* normally not less than $\frac{1}{8}$ in. on standard laminate).

Other points to watch are that where conductors join at an acute angle they should be faired in with a generous fillet, increasing the area

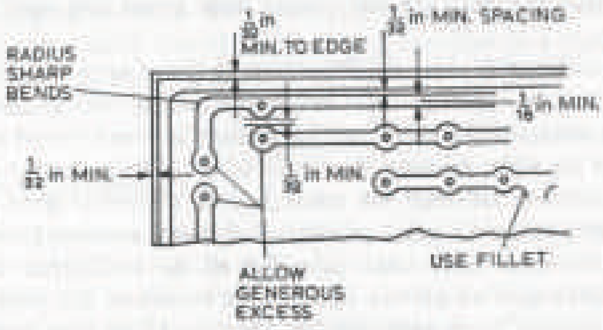

Fig. 12.9 Recommended proportions for conductors, spacing etc.

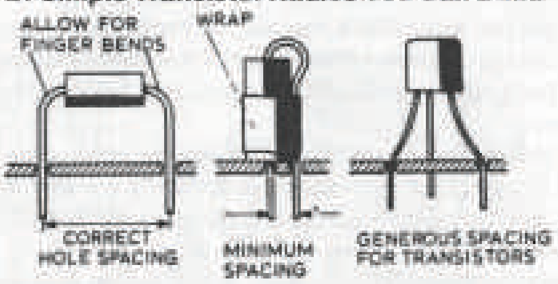

Fig. 12.10 Mounting of components on a printed-circuit board. Vertical mounting saves space.

bonded at the joint and making the copper far less liable to be lifted. Also, do not leave unnecessarily wide or large areas of copper as conductors as these may be subject to excessive heating and expansion, with the result that the copper tends to lift from the base. Either reduce the outline of such areas or relieve the surface area with slots to be etched away. This is not so important on low-voltage circuits, but on mains-operated ones no copper area of more than about one square inch should be left 'solid'.

The first step, having prepared a PC drawing, is to cut the laminate to the required overall size using a fine-tooth saw. The copper surface has probably become greasy and dirty through handling, and so should now be thoroughly cleaned by washing with a detergent and rubbing dry with a clean cloth. If the copper is discoloured through corrosion, use a domestic abrasive cleaner to bring it up bright clean.

A test of cleanliness is to hold the panel under a tap, copper side up, and allow water to run on to it. If the water flows smoothly over the whole area, the surface is clean and grease-free; if isolated patches of copper stay dry they are still coated with grease and need further cleaning.

Once completely clean the PC pattern is drawn or traced on to the copper. Cellulose paint or resist ink should then be used to paint in all the land areas, using a ruling pen for straight lines and a small brush to complete the wider sections; the whole of the pattern may be painted on, if preferred, although the result may be somewhat more ragged. Avoid using too much paint or resist, as this may overrun the outlines but, at the same time, make sure that all the land areas are fully covered. The painted pattern should then be left to dry, which may take an hour or more with cellulose paint or 10 to 15 minutes with resist inks.

The solution normally used for etching is ferric chloride mixed with a little hydrochloric acid, or straight dilute nitric acid. The former is generally preferred since it does not 'gas' as much as the acid alone, but either will be equally effective. This solution is poured into a suitable shallow container, and the laminate immersed in it. Rate of etching will depend on the temperature of the solution and also the degree of agitation. Thus, at a temperature of 10°C a ferric-chloride bath will etch the copper at a rate of about 1 thou. in 20 minutes—or nearly an hour to etch 3 thou. foil; at 20°C the rate of etching is increased to about 10 minutes per thou.; and at 35°C is almost twice as fast again. The rate can also be increased by gentle agitation, moving the board gently backwards and forwards in the bath, or gently rocking the container to swill the etching solution from end to end.

Etching should be allowed to proceed until all traces of copper have disappeared from the surface. The board can then be removed and rinsed under running water to remove any traces of etchant. The paint or resist ink covering the lands is then removed either with a solvent (e.g. cellulose thinners, for cellulose paint) or a cleaner (resist inks). After this, again wash and dry the board; then it is ready for drilling.

Three basic rules must be observed when drilling the PC panels:

(i) Always use a sharp drill (preferably a new one, or one which has been re-sharpened prior to use).
(ii) Always drill from the copper side (i.e. copper face up).
(iii) Always use a backing of hard material underneath so that the drill point will not tear out a section of the laminate when it breaks through.

Drilling may be done with a hand or electric drill, the latter being far less tiring to use when there are a large number of holes to be made, although the small size of drill required may lead to a high breakage rate unless special care is taken.

Notes on soldering

Electric irons are invariably used for electronic assemblies together with resin-cored solder (i.e. the solder is in the form of a hollow wire with the core filled with resin flux). Flame-heated irons are not satisfactory for they are usually too large and cumbersome, and also do not permit good temperature control. Equally, one should always use an electrical (cored) solder when no separate flux is required; an acid-type flux should *never* be used on electrical work as this will inevitably produce corrosion.

The basic rules for good soldering are extremely simple, although they are frequently ignored. They may be summarized as:

(i) The iron should be of the right size and type.
(ii) The iron should be hot enough to melt the solder freely.
(iii) The tip of the iron must be kept 'tinned' and clean.
(iv) The work surfaces to be soldered must be clean and grease-free.

The correct size of iron is important for if too small it will rapidly lose heat when applied to the work, and if too large may overheat adjacent components or be awkward to apply. For PC assemblies a $\frac{1}{8}$-in. bit diameter is about right for general work–not too large, but large enough to retain enough heat for more or less continuous work. It may be awkward to use when soldering up a miniature panel where the lands are close together, when a $\frac{3}{32}$-in. or even a $\frac{1}{16}$-in. bit may be preferred. This smaller size will, however, usually lose so much heat in completing a single joint that it has to be left to heat up again before it can be applied to the second joint.

Iron size is also specified by wattage, but this is more of a nominal rating than anything else, for irons by different manufacturers but of the same stated wattage can have a considerable difference in performance, e.g. differences in heating-up times and in bit temperature achieved (and variations in the latter can be as high as 100°C). To avoid the possibility of over-heating, an iron with a rating of more than 50 W should never be used for PC assemblies.

Iron voltage must be matched to the mains voltage available and it is usual to operate an electric iron on the middle voltage of the range, e.g. for a 240-V mains a 230/250-V iron would be correct. An iron should never be operated on a mains voltage below the lowest figure of its rating as in such a case it will not develop its correct bit temperature.

Typically, a good electric iron will achieve a saturation temperature of approximately 375°C. The time taken to reach this temperature will vary with the size and design, but very roughly should be of the order of wattage divided by four (in seconds), e.g. in the case of a 30-W iron the bit should reach its maximum or saturation temperature in about $30 \div 4 = 7\frac{1}{2}$ seconds. It should also take about one-third of this time (e.g. watts divided by 12) to reach a satisfactory bit temperature for

soldering (250°C), although this can readily be judged by trying the solder on the bit to see if it runs freely.

The *minimum* bit temperature required for satisfactory soldering is 40°C above the melting point of the solder used, which will vary with the composition of the solder.

Whether the temperature of the bit is satisfactory or not can readily be judged by the time it takes to complete a joint. This should be not more than three to four seconds, and the resulting joint should be bright clean, with the solder completely 'wetting' both surfaces. If the joint takes longer to make and/or the solder has a pasty or dull appearance, the iron is not hot enough. If the solder is reluctant to take or flow over the joint, or collects in blobs rather than spreading out, then the surfaces are dirty.

Before attempting assembly on a PC board the panel should always be cleaned so that the lands are bright all over with no dull spots, and subsequently should not be finger-marked by handling. An ordinary domestic powder cleaner is as good as anything for cleaning the PC lands, used wet or dry, the panel then being rinsed under running water to remove any traces of abrasive, and dried on a clean rag.

Component leads are normally 'tinned' and therefore in a suitable state for soldering. Almost certainly, however, the 'tinned' surface will have become dirty or partly corroded during handling and storage and it is generally recommended to clean leads immediately prior to assembly and soldering in position. A scrap of fine emery paper is excellent for this, simply wrapped around and pulled along the length of the lead, taking care not to impose excess mechanical strain; similarly with tags etc. Time taken in cleaning leads etc., is usually time saved, for one can then be sure of a satisfactory soldered joint at the first attempt.

Then there is the question of heat damage to consider. Provided the joint is completed quickly–i.e. within three or four seconds of application of the iron–no component is likely to suffer heat damage. This even applies to transistors which are normally rated to withstand continuous application of a soldering bit no closer than $\frac{1}{4}$ in. from the base for a period of up to ten seconds without damage. Thus if all goes well and soldered joints are completed quickly and neatly, it is seldom necessary to worry about heat damage.

It is still, however, commonly recommended that a 'heat sink' should always be used on each lead of a transistor when soldering in position. A heat sink, basically, is a mass of conducting material which will absorb heat from the iron rather than let the full heat flow up the lead. The jaws of a pair of pliers gripping the transistor lead form a suitable heat sink; or, if these are not convenient to use, a crocodile clip can serve the same purpose (especially if the jaws are filed flat to provide maximum surface contact with the lead).

The most likely cause of heat damage is re-working a joint which has not been made properly, or trying to unsolder a lead which has been wrongly positioned. This may entail leaving the iron in contact with the joint far longer than the 'safe' three or four seconds, when damage can result to the component. Excessive heat applied locally in this manner will also tend to 'lift' the copper land away from the base material on a PC panel.

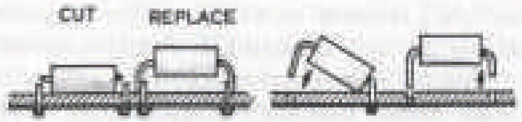

Fig. 12.11 The safest way to remove a faulty component is usually to cut it off.

Removing a component which has been mounted on a PC can, in fact, be a tricky process. If it is a faulty component which is to be replaced the *safest* way to go about such a job is to cut it off, as shown in Fig. 12.11, leaving stub lengths of the original lead protruding from the plain side of the PC panel. The new component can then be soldered in place *to* these stub leads. Alternatively, having cut off the component, each lead can be removed in turn by laying the tip of the iron on the solder joint (PC side) and withdrawing the lead with pliers as soon as the solder has melted. Then, before it has had time to set again, blow surplus solder out of the hole (Fig. 12.12).

To remove a component intact usually means working on one lead at a time, lifting first one end of the component and then the other. This is not always possible when the component is mounted on rigid leads or tags, generally demanding working on pairs of tags at a time and gradually levering the component upwards. This usually entails considerable risk of overheating the component and of 'lifting' the PC lands if too much heat is applied to the tag side.

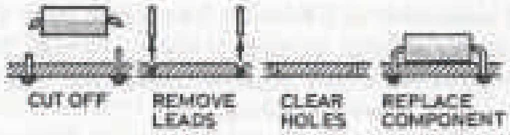

Fig. 12.12 Remaining leads can then be removed, ready to fit new component.

A trick which often helps in removing a rigidly mounted component, such as an IF transformer, is to heat the tags and remove the solder with a suitable stiff-bristled brush. This is repeated on each tag until the component is sufficiently loosened to be prised free. It is important, however, to avoid splashing excess solder on to other parts of the PC board.

Unless obviously faulty, transistors or diodes should not be removed from a PC board once assembled, as the possibility of permanent damage resulting is high. If imperative that they should be removed (e.g. if they have been connected up wrongly), a heat shunt should always be used (e.g. a pair of thin-nosed pliers gripping the lead between the transistor body and the PC board).

Where the board itself is damaged—e.g. foil has come unstuck through excessive local heating—loosened lands can usually be stuck back again by carefully heating the foil with the soldering iron and then pressing in place on the board until the adhesive has reset. If not, the loose land may have to be stuck down with an application of a general-purpose domestic or epoxy adhesive.

Mechanical damage to PC boards can be repaired by bridging breaks or cracks in the copper lands with 'jumper' wires soldered in place. These can be plain 'tinned' copper wire, but if a longer jumper is required which passes over adjacent lands, either insulated wire should be used or the wire length fitted with insulating sleeving. All repaired areas should then be coated with clear lacquer for protection.

Where a PC board is quite extensively damaged, or needs to have a number of components changed, it is usually more satisfactory in the long run to scrap the original board and start again with a new one; and preferably new components, rather than to try to salvage all the original ones, as these may be damaged in the process of removal from the old board.

13 FETs AND ICs

Field-effect transistors (FETs) have a construction, and characteristics, that differ from conventional junction transistors. Their behaviour, in fact, is more like that of a triode valve, although retaining the characteristic low-power requirements of a transistor.

The electrodes of an FET are designated gate, source and drain with the following approximate equivalents:

FET	Transistor	Triode valve
Gate	Base	Grid
Source	Emitter	Cathode
Drain	Collector	Anode

The standard symbol for an FET differs from that of a conventional transistor, with the gate carrying an arrow, which points outwards for a *P*-channel FET and inwards for an *N*-channel FET–Fig. 13.1. The general rule is that the polarity of the *drain* supply is negative for a *P*-channel FET and positive for an *N*-channel FET.

A simple regenerative receiver based on two *P*-channel FETs is shown in Fig. 13.2. This is adjusted for optimum working by the

Fig. 13.3 shows a typical arrangement for an FET amplifier stage. This could be added on to the receiver circuit to provide amplification which should be sufficient to power a small loudspeaker.

Integrated circuits

Integrated circuits (ICs) are one of the latest products of modern electronic technology–small integrated circuit modules in which a complete circuit duplicates the performance of perhaps a dozen or more active devices (e.g. transistors and diodes) and a similar number of passive components (e.g. resistors and capacitors) in a silica 'chip' only a few millimetres square.

Depending on their design function, ICs may be used as a complete stage or logic element in a circuit; or, more usually, associated with a number of conventional external components to complete the circuit. Fig. 13.4, for example, shows the equivalent circuit diagram of one IC (Siemens TAA 861), and Fig. 13.5 the incorporation of that particular IC in a 4-W amplifier.

DIMENSIONS IN MILLIMETRES

Fig. 13.6 Example of outlines of typical ICs.

Examples of outline appearance of some typical ICs are given in Fig. 13.6. They are best mounted by plugging into IC holders, which are normally designed for mounting on PC boards.

Integrated circuits are not necessarily expensive, e.g. from a little over 50p upwards, depending on type and complexity, and they offer an interesting new field of experiment for the amateur constructor. Manufacturers of ICs normally provide suggested applications for their various types.

Low Frequency TRF Receiver

Because the LM172 is a broadband functional module, it may be used to amplify and detect signals below 2 MHz directly, without the more complex frequency conversion of superheterodyne receivers. In the AM Broadcast Band (550-1650 kHz), the strip has sufficient sensitivity to operate alone in urban reception areas, since AGC action is useful down to about 50 microvolts at Pin 2. With additional gain either preceding the module, or inserted between Pins 1 and 3, it may also be useful in monitoring Loran (1.8-2.0 MHz), or the numerous directional and informational channels below 550 kHz.

While the complete TRF (Tuned Radio Frequency) broadcast receiver of Fig. 13.7 has relatively poor selectivity, because only a single, low "Q" tuned circuit is used in the entire receiver, it serves to illustrate the straightforward design possible in TRF construction. More sophisticated designs might use multisection tuning, ahead of the strip. The prototype was constructed using very inexpensive imported "transistor-radio" components.

A ferrite loopstick antenna, L1, resonates with a small, polyethylene dielectric tuning capacitor within the broadcast band. The LM172 performs its gain function just as it would in an IF application, but in this case, directly drives a class A power amplifier. Since the DC output voltage at Pin 6 is relatively constant (from 2.1 to about

2.4 volts as a function of AGC). It is used to bias the class A stage directly, eliminating a number of components. C7 and C8 are needed to prevent regenerative audio oscillations with weak batteries. Total receiver drain from the 9-volt supply is 10 mA, of which only 1.9 mA is used in the LM172; the rest is needed for the audio amplifier.

A volume control was not provided in the prototype, as volume was excellent with the small (2" diameter) speaker used, and AGC was so effective that no perceptible difference in stations was heard. Volume control is possible by inserting a potentiometer between the emitter of the audio output transistor and R1.

Wireless Microphone

This wireless microphone (Fig. 13.8) transmits on any desired FM broadcast-band frequency from 88 to 108 MHZ (tuning controlled by C7). The range of the wireless microphone is 50 to 150 feet depending on the location of the receiver and its antenna. Circuit features include small size, high quality, and low current drain; the antenna length has been limited to keep radiation within FCC wireless-microphone regulations. The low-impedance microphone to be used with this circuit is the RCA HK-99.

Marine-Band Converter

This marine-band converter (Fig. 13.9) converts any standard AM broadcast receiver to one capable of receiving transmission in the 2 to 3-MHz marine band. The output is connected to the AM receiver antenna terminals. If the receiver does not have antenna terminals the output is connected to 10 turns of No. 32 wire wound over the loopstick antenna in the receiver.

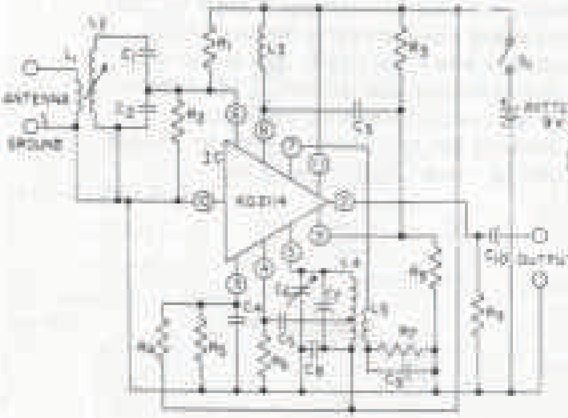

Fig. 13.9 Marine-band converter.

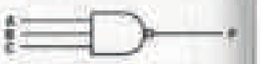
condition indicators

state (logic negation)

a Logic Negation output becomes 1-state if and only if the input is not 1-state

an AND func. where outp
is low if and only if a
inputs are high



electric inverter

(elec. invtr. output becomes 1-state if and on
if the input is 1-state
(elec. invtr. output is more pos. if and only i
input is less pos.)

level (relative)

1-state is less + 1-state is more +

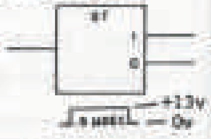
(symbol is a rt. triang
pointing in direction o
flow)

an AND func. with inpu
1-states at more pos. level and output 1-stat
at less pos. level

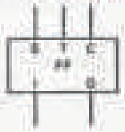
single shot (one output)

(waveform data replaces inside/outside (*))

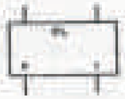
schmitt trigger, wavefor
and two outputs



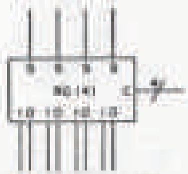
flip-flop, complementar



flip-flop, latch



register



(binary register denoting four flip-flops and bits)

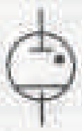
amplifier (see AMPLIFIER)

stereo

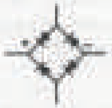
RECTIFIER (65)

semiconductor diode; metallic rectifier; electrolytic rectifier; asymmetrical varistor

mercury-pool tube power rectifier



fullwave bridge-type



RESISTOR (68)

general

tapped

heating

symmetrical varistor resistor, voltage sensitive (silicon carbide, etc.)

(identification marks replace (*) asterisk)
with adjustable contact

adjustable or continuously adjustable (variable)

(identification replaces (*) asterisk)

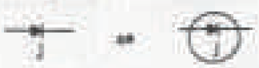
SEMICONDUCTOR DEVICE (73)

(Two Terminal, diode)

semiconductor diode; rectifier

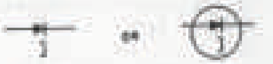
capacitive diode (also Varicap, Varactor, reactance diode, parametric diode)

breakdown diode, unidirectional (also backward diode, avalanche diode, voltage regulator diode, Zener diode, voltage reference diode)

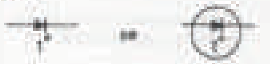


breakdown diode, bidirectional and backward diode (also bipolar voltage limiter)

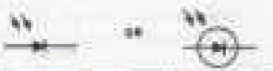
tunnel diode (also Esaki diode)



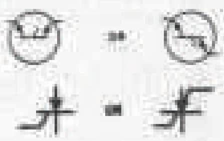
temperature-dependent diode



photodiode (also solar cell)

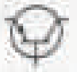


semiconductor diode, PNPN switch (also Shockley diode, four-layer diode and SCR)

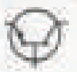


(Multi-Terminal, transistor, etc.)

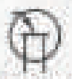
PNP transistor



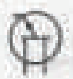
NPN transistor



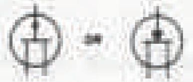
unijunction transistor, N-type base



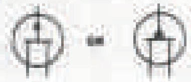
unijunction transistor, P-type base



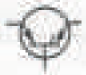
field-effect transistor, N-type base



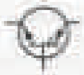
field-effect transistor, P-type base



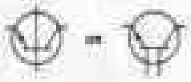
semiconductor triode, PNPN-type switch



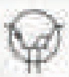
semiconductor triode, NPNP-type switch



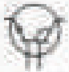
NPN transistor, transverse-biased base



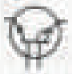
PNIP transistor, ohmic connection to the intrinsic region



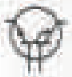
NPIN transistor, ohmic connection to the intrinsic region



PNIN transistor, ohmic connection to the intrinsic region



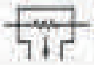
NPIP transistor, ohmic connection to the intrinsic region



SQUIB (75)

explosive

igniter



sensing link; fusible link operated

SWITCH (76)

push button, circuit closing (make)

push button, circuit opening (break)

nonlocking; momentary circuit closing (make)

nonlocking; momentary circuit opening (break)

transfer

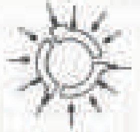
locking, circuit closing (make)

locking, circuit opening (break)

transfer, 3-position

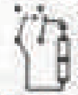
wafer

(example shown: 3-pole 3-circuit with 2 non-shorting and 1 shorting moving contacts)



safety interlock, circuit opening and closing

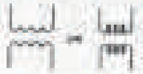
2-pole field-discharge knife, with terminals and discharge resistor



(identification replaces (*) asterisk)

TRANSFORMER (86)

general



magnetic-core

one winding with adjustable inductance

separately adjustable inductance

adjustable mutual inductor, constant-current

About the Author

Thomas Petruzzellis is an electronics engineer currently working at the geophysical laboratory at the State University of New York, Binghamton. Also an instructor at Binghamton, with 30 years' experience in electronics, he is a veteran author who has written extensively for industry publications, including *Electronics Now*, *Modern Electronics*, *QST, Microcomputer Journal*, and *Nuts & Volts*. Tom wrote five previous books, including an earlier volume in this series, *Electronic Sensors for the Evil Genius*. He is also the author of *Create Your Own Electronics Workshop*; *STAMP 2 Communications and Control Projects*; *Optoelectronics, Fiber Optics, and Laser Cookbook*; *Alarm, Sensor, and Security Circuit Cookbook*, all from McGraw-Hill. He lives in Vestal, New York.

Introduction

22 Radio Receiver Projects for the Evil Genius was created to inspire readers both young and old to build and enjoy radio and receiver projects, and perhaps propel interested experimenters into a career in radio, electronics or research. This book is for people who are interested in radio and electronics and those who enjoy building and experimenting as well as those who enjoy research.

Radio encompasses many different avenues for enthusiasts to explore, from simple crystal radios to sophisticated radio telescopes. This book is an attempt to show electronics and radio enthusiasts that there is a whole new world "out there" to explore.

Chapter 1 will present the history and background and elements of radio, such as modulation techniques, etc. Chapter 2 will help the newcomers to electronics, identifying components and how to look and understand schematics vs. pictorial diagrams. Next, Chapter 3 will show the readers how to install electronic components onto circuit boards and how to correctly solder before embarking on their new radio building adventure.

We will start our adventure with the simple "lowly" crystal radio in Chapter 4. Generally crystal radios are only thought of as simple AM radios which can only pickup local broadcast stations. But did you know that you can build crystal radios which can pickup long-distance stations as well as FM and shortwave broadcasts from around the world? You will learn how to build an AM, FM and shortwave crystal radio, in this chapter.

In Chapter 5, you will learn how AM radio is broadcast, from a radio station to a receiver in your home, and how to build your own TRF or Tuned Radio Frequency AM radio receiver. In Chapter 6, we will discover how FM radio works and how to build an FM radio with an SCA output for commercial free radio broadcasts.

Chapter 7 will present the exciting world of shortwave radio. Shortwave radio listening has a large following and encompasses an entire hobby in itself. You will be able to hear shortwave stations from around the world, including China, Russia, Italy, on your new shortwave broadcast receiver. Old time radio buffs will be interested in the single tube Doerle super-regenerative shortwave radio.

If you are interested in a portable shortwave receiver that you could take on a camping trip, then you may want to construct the multi-band integrated circuit shortwave radio receiver described in Chapter 8.

If you are interested in Amateur Radio or are thinking of learning Morse code or want to increase your code speed, you may want to consider building this 80 and 40-meter code receiver. This small lightweight portable receiver can be built in a small enclosure and taken on camping trips, etc.

In Chapter 10, you will learn how to build and use a WWW time code receiver, which can be used to pick up time signal broadcast from the National Institute of Standards and Technology (NIST) or

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

National Atomic Time Clock in Boulder CO. Time signal broadcasts present geophysical and propagation forecasts as well as marine and sea conditions. They will also help you set the time on your best chronometer.

With the VHF Public service receiver featured in Chapter 11, you will discover the high frequency "action bands" which cover the police, fire, taxis, highway departments and marine frequencies. You will be able to listen-in to all the exciting communications in your hometown.

The 6-meter and 2-meter dual VHF Amateur Radio receiver in Chapter 12 will permit to discover the interesting hobby of Amateur Radio. The 6-meter and 2-meter ham radio bands are two of the most popular VHF bands for technician class licensees. You may discover that you might just want to get you own ham radio license and talk to ham radio operators through local VHF repeaters or to the rest of the world.

Why not build an aircraft radio and listen-in to airline pilots talking from 747s to the control tower many miles away. You could also build the passive Air-band radio which you use to listen-in to your pilot during your own flight. Passive aircraft radios will not interfere with airborne radio so they are permitted on airplanes, without restriction. Check out these two receivers in Chapter 13.

Chapter 14 will also show you how to build an induction communication system, which will allow you to broadcast a signal around home or office using a loop of wire, to a special induction receiver. The induction loop broadcast system is a great aid to the hearing impaired, since it can broadcast to hearing aids as well.

The VLF, or "whistler" radio in Chapter 15, will pickup very very low frequency radio waves from around the world. You will be able to listen to low frequency beacon stations, submarine transmissions and "whistlers" or the radio waves created from electrical storms on the other side of the globe. This project is great for research projects where you can record and later analyze your results by feeding your recorded signal into a sound card running an FFT program. Use your computer to record and analyze these interesting signals. There are many free programs available over the Internet. An FFT audio analyzer program can display the audio spectrum and show you where the signals plot out in respect to frequency.

If you are interested in weather, then you will appreciate the Lightening to Storm Receiver in Chapter 16, which will permit you to "see" the approaching storm berfore it actually arrives. This receiver will permit you to have advanced warning up to 50 miles or more away; it will warn you well in advance of an electrical storm, so you can disconnect any outdoor antennas.

The Ambient Power Module receiver project illustrated in Chapter 17, will allow to you pickup a broad spectrum of radio waves which get converted to DC power, and which can be used to power low current circuits around your home or office. This is a great project for experimentation and research. You can use it to charge cell phones, emergency lights, etc.

Our magnetometer project shown in Chapter 18 can be used to see the diurnal or daily changes in the Earth's magnetic field, and you can record the result to a data-logger or recording multi-meter.

If you are an avid amateur radio operator or shortwave listener, you many want to build a SIDs receiver shown in Chapter 19. A SIDs receiver can be used to determine when radio signals and/or propagation is disturbed by solar storms. This receiver will quickly alert you to unfavorable radio conditions. You can collect the receiver to your personal computer's sound card and use the data recorded to correlate radio propagation against storm conditions.

The Aurora receiver project in Chapter 20 will alert you, with both sound and meter display, when the Earth's magnetic increases just before an Aurora display is about to take place. UFO and Alien contact buffs can use this receiver to know when UFOs are close by.

For those interested in more earthly research projects, why not build your own ULF or ultra low frequently receiver, shown in Chapter 21, which can be utilized for detecting low frequency wave generated by earthquakes and fault lines. With this receiver you will be able to conduct your own research projects on monitoring the pulse of the Earth. You can connect your ELF receiver to a data-logger and record the signals over time to correlate your research with that of others.

You can explore the heavens by constructing your own radio telescope to monitor the radio signals generated from the planet Jupiter. This radio receiver, illustrated in Chapter 22, will pick up radio signals which indicate electrical and or magnetic storms on the Jovian planet. The Radio Jupiter receiver can be coupled to your personal computer, and can be used for a research project to record and analyze these radio storm signals.

Why not construct your own weather satellite receiving station, shown in Chapter 23. This receiver will allow you to receive APT polar satellites broadcasting while passing overhead. You can display the satellite weather maps on the computer's screen or save them later to show friends and relatives.

Chapter 24 discusses different analog to digital converters which you can use to collect and record data from the different receiver projects.

We hope you will find the *22 Radio Projects for the Evil Genius* a fun and thought-provoking book, that will find a permanent place on your electronics or radio bookshelf. Enjoy!

Chapter 1

Radio Background and History

Electromagnetic energy encompasses an extremely wide frequency range. Radio frequency energy, both natural radio energy created by lightning and planetary storms as well as radio frequencies generated by man for communications, entertainment, radar, and television are the topic of this chapter. Radio frequency energy, or RF energy, covers the frequency range from the low end of the radio spectrum, around l0 to 25 kHz, which is used by high-power Navy stations that communicate with submerged nuclear submarines, through the familiar AM broadcast band from 550 to 1600 kHz. Next on the radio frequency spectrum are the shortwave bands from 2000 kHz to 30,000 kHz. The next band of frequencies are the very high frequency television channels covering 54 to 2l6 MHz, through the very popular frequency modulation FM band from 88 to l08 MHz. Following the FM broadcast band are aircraft frequencies on up through UHF television channels and then up through the radar frequency band of 1000 to 1500 MHz, and extending through approximately 300 gHz. See frequency spectrum chart in Figure 1-1. The radio frequency spectrum actually extends almost up to the lower limit of visible light frequencies.

Radio history

One of the more fascinating applications of electricity is in the generation of invisible ripples of energy called radio waves. Following Hans Oersted's accidental discovery of electromagnetism, it was realized that electricity and magnetism were related to each other. When an electric current was passed through a conductor, a magnetic field was generated perpendicular to the axis of flow. Likewise, if a conductor was exposed to a change in magnetic flux perpendicular to the conductor, a voltage was produced along the length of that conductor.

Joseph Henry, a Princeton University professor, and Michael Faraday, a British physicist, experimented separately with electromagnets in the early 1800s. They each arrived at the same observation: the theory that a current in one wire can produce a current in another wire, even at a distance. This phenomenon is called electromagnetic induction, or just induction. That is, one wire carrying a current induces a current in a second wire. So far, scientists knew that electricity and magnetism always seemed to affect each other at right angles. However, a major discovery lay hidden just beneath this seemingly simple concept of related perpendicularity, and its unveiling was one of the pivotal moments in modern science.

The man responsible for the next conceptual revolution was the Scottish physicist James Clerk Maxwell (1831–1879), who "unified" the study of electricity and magnetism in four relatively tidy equations. In essence, what he discovered was that electric and magnetic fields were intrinsically related to one another, with or without the presence of a conductive path for electrons to flow. Stated more formally, Maxwell's discovery was this: a changing electric field produces a perpendicular magnetic field, and a changing magnetic field produces a perpendicular electric field. All of this can take place in open space, the alternating electric and magnetic fields supporting each other as they travel through space at the speed of light. This dynamic structure of electric and magnetic fields propagating through space is better known as an electromagnetic wave.

Later, Heinrich Hertz, a German physicist, who is honored by our replacing the expression "cycles per second" with hertz (Hz), proved Maxwell's theory between the years 1886 and l888. Shortly after that, in 1892, Eouard Branly, a French physicist, invented a device that could receive radio waves (as we know them today) and could cause them to ring an electric bell.

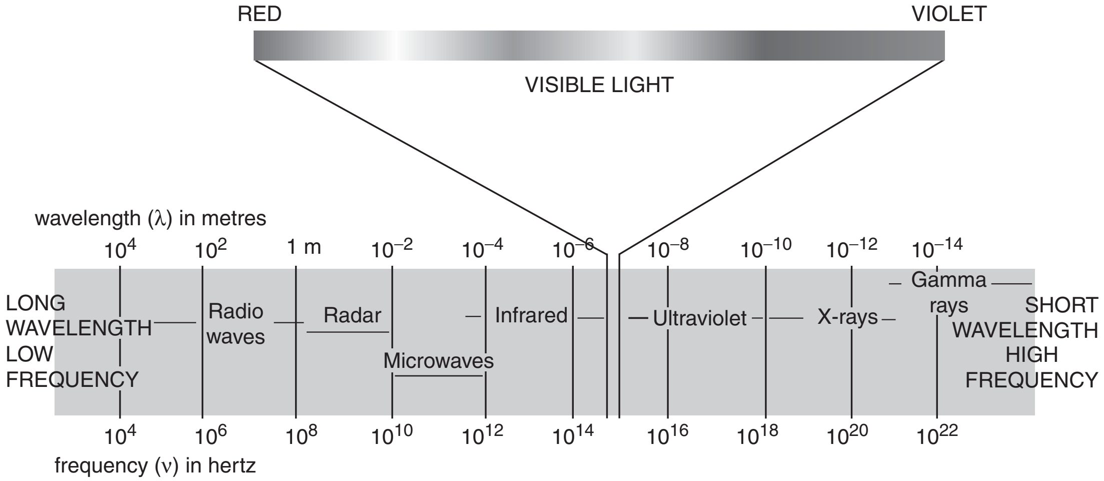

Figure 1-1 *Electromagnetic spectrum*

Note that at the time all the research being conducted in what was to become radio and later radio-electronics, was done by physicists.

In 1895, the father of modem radio, Guglielmo Marconi, of Italy, put all this together and developed the first wireless telegraph and was the first to commercially put radio into ships. The wire telegraph had already been in commercial use for a number of years in Europe. The potential of radio was finally realized through one of the most memorable events in history. With the sinking of the Titanic in 1912, communications between operators on the sinking ship and nearby vessels, and communications to shore stations listing the survivors brought radio to the public in a big way.

AM radio broadcasting began on November 2, 1920. Four pioneers: announcer Leo Rosenberg, engineer William Thomas, telephone line operator John Frazier and standby R.S. McClelland, made their way to a makeshift studio—actually a shack atop the Westinghouse "K" Building in East Pittsburgh—flipped a switch and began reporting election returns in the Harding vs. Cox Presidential race. At that moment, KDKA became the pioneer broadcasting station of the world.

Radio spread like wildfire to the homes of everyone in America in the 1920s. In a few short years, over 75 manufacturers began selling radio sets. Fledgling manufacturers literally came out of garages over-night. Many young radio enthusiasts rushed out to buy parts and radio kits which soon became available.

Radio experimenters discovered that an amplitude-modulated wave consists of a carrier and two identical sidebands which are both above and below the carrier wave. The Navy conducted experiments in which they attempted to pass one sideband and attenuate the other. These experiments indicated that one sideband contained all the necessary information for voice transmission, and these discoveries paved the way for development of the concept of single-sideband or SSB transmission and reception.

In 1923, a patent was granted to John R. Carson on his idea to suppress the carrier and one sideband. In that year the first trans-Atlantic radio telephone demonstration used SSB with pilot carrier on a frequency of 52 kc. Single sideband was used because of limited power capacity of the equipment and the narrow bandwidths of efficient antennas for those frequencies. By 1927, trans-Atlantic SSB radiotelephony was open for public service. In the following years, the use of SSB was limited to low-frequency and wire applications. Early developments in FM transmission suggested that this new mode might prove to be the ultimate in voice communication. The resulting slow development of SSB technology precluded practical SSB transmission and reception at high frequencies. Amateur radio SSB activity followed very much the same pattern. It wasn't until 1948 that amateurs began seriously experimenting with SSB, likely delayed by the wartime blackouts.

The breakthroughs in the war years, and those following the war, were important to the development of HF-SSB communication. Continued advances in technology made SSB the dominant mode of HF radio communication.

The radio-frequency spectrum, once thought to be adequate for all needs, has become very crowded. As the world's technical sophistication progresses, the requirements for rapid and dependable radio communications increase. The competition for available radio spectrum space has increased dramatically. Research and development in modern radio systems has moved to digital compression and narrow bandwidth with highly developed modulation schemes and satellite transmission.

The inventor most responsible for the modern day advances in radio systems was Edwin H. Armstrong. He was responsible for the Regenerative circuit in 1912, the Superheterodyne radio circuit in 1918, the Superregenerative radio circuit design in 1922 and the complete FM radio system in 1933. His inventions and developments form the backbone of radio communications as we know it today. The majority of all radio sets sold are FM radios, all microwave relay links are FM, and FM is the accepted system in all space communications. Unfortunately, Armstrong committed suicide while still embittered in patent lawsuits: later vindicated, his widow received a windfall.

Sony introduced their first transistorized radio in 1960, small enough to fit in a vest pocket, and able to be powered by a small battery. It was durable, because there were no tubes to burn out. Over the next 20 years, transistors displaced tubes almost completely except for very high power, or very high frequency, uses. In the 1970s; LORAN became the standard for radio navigation system, and soon, the US Navy experimented with satellite navigation. Then in 1987, the GPS constellation of satellites was launched and navigation by radio in the sky had a new dimension. Amateur radio operators began experimenting with digital techniques and started to send pictures, faxes and teletype via the personal computer through radio. By the late 1990s, digital transmissions began to be applied to radio broadcasting.

Types of radio waves

There are many kinds of natural radiative energy composed of electromagnetic waves. Even light is electromagnetic in nature. So are shortwaves, X-rays and "gamma" ray radiation. The only difference between these kinds of electromagnetic radiation is the frequency of their oscillation (alternation of the electric and magnetic fields back and forth in polarity). By using a source of AC voltage and a device called an antenna, we can create electromagnetic waves.

It was discovered that high frequency electromagnetic currents in an antenna wire, which in turn result in a high frequency electromagnetic field around the antenna, will result in electromagnetic radiation which will move away from the antenna into free space at the velocity of light, which is approximately 300,000,000 meters per second.

In radio transmission, a radiating antenna is used to convert a time-varying electric current into an electromagnetic wave, which freely propagates through a nonconducting medium such as air or space. An antenna is nothing more than a device built to produce a dispersing electric or magnetic field. An electromagnetic wave, with its electric and magnetic components, is shown in Figure 1-2.

When attached to a source of radio frequency signal generator, or transmitter, an antenna acts as a transmitting device, converting AC voltage and current into electromagnetic wave energy. Antennas also have the ability to intercept electromagnetic waves and convert their energy into AC voltage and current. In this mode, an antenna acts as a receiving device.

Radio frequencies spectrum

Radio frequency energy is generated by man for communications, entertainment, radar, television,

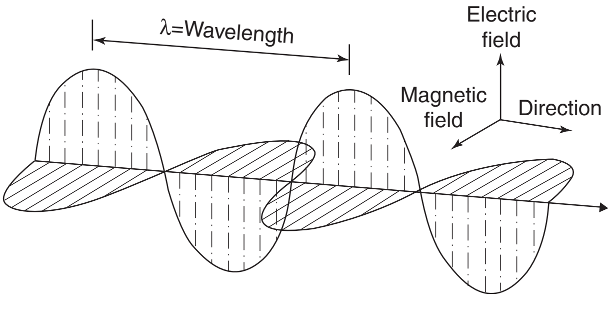

Figure 1-2 *Magnetic vs. electric wave*

navigation, etc. This radio frequency or (RF) energy covers quite a large range of radio frequencies from the low end of the radio spectrum from l0 to 25 kHz, which is the domain occupied by the high-power Navy stations that communicate with submerged nuclear submarines: these frequencies are called Very Low Frequency waves or VLF. Above the VLF frequencies are the medium wave frequencies or (MW), i.e. the AM radio broadcast band from 550 to 1600 kHz. The shortwave bands or High Frequency or (HF) bands cover from 2000 kHz to 30,000 kHz and make use of multiple reflections from the ionosphere which surrounds the Earth, in order to propagate the signals to all parts of the Earth. The Very High Frequencies or VHF bands begin around 30 MHz; these lower VHF frequencies are called low-band VHF. Mid-band VHF frequencies begin around 50 MHz which cover the lowest TV channel 2. Low-band television channels 2 through 13 cover the 54 to 2l6 MHz range. The popular frequency modulation or (FM) broadcast band covers the range from 88 to l08 MHz, which is followed by low-band Air-band frequencies from 118 to 136 MHz. High-band VHF frequencies around 144 are reserved for amateur radio, public service around 150 MHz, with marine frequencies around 156 MHz. UHF frequencies begin around 300 MHz and go up through the radar frequency band of 1000 to 1500 MHz, and extending through approximately 300 gHz. Television channels 14 through 70 are placed between 470 and 800 MHz. American cell phone carriers have cell phone communications around 850 MHz. Geosynchronous weather satellites signals are placed around 1.6 GHz, and PCS phone devices are centered around 1.8 GHz. The Super-high frequency (SHF) bands range from 3 to 30 GHz, with C-band microwave frequencies around 3.8 GHz, then X-band, from 7.25 to 8.4 GHz, followed by the KA and KU-band microwave bands.

Table 1-1 illustrates the division of radio frequencies. The radio frequency spectrum extends almost up to the lower limit of visible light frequencies, with just the infrared frequencies lying in between it and visible light. The radio frequency spectrum is a finite resource which must be used and shared with many people and agencies around the world, so cooperation is very important.

So how does a radio work? As previously mentioned, radio waves are part of a general class of waves known as electromagnetic waves. In essence, they are electrical and magnetic energy which travels through space in the form of a wave. They are different from sound waves (which are pressure waves that travel through air or water, as an example) or ocean waves (similar to sound waves in water, but much lower in frequency and are much larger). The wave part is similar, but the energy involved is electrical and magnetic, not mechanical.

Electromagnetic waves show up as many things. At certain frequencies, they show up as radio waves. At much higher frequencies, we call them infrared light. Still higher frequencies make up the spectrum known as visible light. This goes on up into ultraviolet light, and X-rays, things that radio engineers rarely have to worry about. For our discussions, we'll leave light to the physicists, and concentrate on radio waves.

Radio waves have two important characteristics that change. One is the amplitude, or strength of the wave. This is similar to how high the waves are coming into shore from the ocean. The bigger wave has a higher amplitude. The other thing is frequency. Frequency is how often the wave occurs at any point. The faster the wave repeats itself, the higher the frequency. Frequency is measured by the number of times in a second that the wave repeats itself. Old timers remember when frequency was described in units of cycles per second. In more recent times we have taken to using the simplified term of hertz (named after the guy who discovered radio waves). Metric prefixes are often used, so that 1000 hertz is a kilohertz, one million hertz is a megahertz, and so on.

A typical radio transmitter, for example, takes an audio input signal, such as voice or music and amplifies it. The amplified audio is in turn sent to a modulator and an RF exciter which comprises the radio frequency transmitter. The exciter in the transmitter generates a main carrier wave. The RF signal from the exciter is further amplified by a power amplifier and then the RF signal is sent out to an antenna which radiates the signal into the sky and out into the ionosphere. Depending upon the type of transmitter used the modulation technique can be either AM, FM, SSB signal sideband, CW, or digital modulation, etc.

AM modulation

Amplitude modulation (AM) is a technique used in electronic communication, most commonly for transmitting information via a carrier wave wirelessly.

Table 1-1

Radio frequency spectrum chart

Frequency range			
Extremely Low Frequency (ELF)	0	to	3 kHz
Very Low Frequency (VLF)	3 kHz	to	30 kHz
Radio Navigation & maritime/aeronautical mobile	9 kHz	to	540 kHz
Low Frequency (LF)	30 kHz	to	300 kHz
Medium Frequency (MF)	300 kHz	to	3000 kHz
AM Radio Broadcast	540 kHz	to	1630 kHz
Travellers Information Service	1610 kHz		
High Frequency (HF)	3 MHz	to	30 MHz
Shortwave Broadcast Radio	5.95 MHz	to	26.1 MHz
Very High Frequency (VHF)	30 MHz	to	300 MHz
Low Band: TV Band 1 - Channels 2-6	54 MHz	to	88 MHz
Mid Band: FM Radio Broadcast	88 MHz	to	174 MHz
High Band: TV Band 2 - Channels 7-13	174 MHz	to	216 MHz
Super Band (mobile/fixed radio & TV)	216 MHz	to	600 MHz
Ultra-High Frequency (UHF)	300 MHz	to	3000 MHz
Channels 14-70	470 MHz	to	806 MHz
L-band:	500 MHz	to	1500 MHz
Personal Communications Services (PCS)	1850 MHz	to	1990 MHz
Unlicensed PCS Devices	1910 MHz	to	1930 MHz
Superhigh Frequencies (SHF)			
(Microwave)	3 GHz	to	30.0 GHz
C-band	3600 MHz	to	7025 MHz
X-band	7.25 GHz	to	8.4 GHz
Ku-band	10.7 GHz	to	14.5 GHz
Ka-band	17.3 GHz	to	31.0 GHz
Extremely High Frequencies (EHF)			
(Millimeter Wave Signals)	30.0 GHz	to	300 GHz
Additional Fixed Satellite	38.6 GHz	to	275 GHz
Infrared Radiation	300 GHz	to	430 THz
Visible Light	430 THz	to	750 THz
Ultraviolet Radiation	1.62 PHz	to	30 PHz
X-Rays	0.30 PHz	to	30 EHz
Gamma Rays	0.30 EHz	to	3000 EHz

It works by varying the strength of the transmitted signal in relation to the information being sent.

In the mid-1870s, a form of amplitude modulation was the first method to successfully produce quality audio over telephone lines. Beginning in the early 1900s, it was also the original method used for audio radio transmissions, and remains in use by some forms of radio communication—“AM” is often used to refer to the medium-wave broadcast band (see AM Radio–Chapter 5).

Amplitude modulation (AM) is a type of modulation technique used in communication. It works by varying

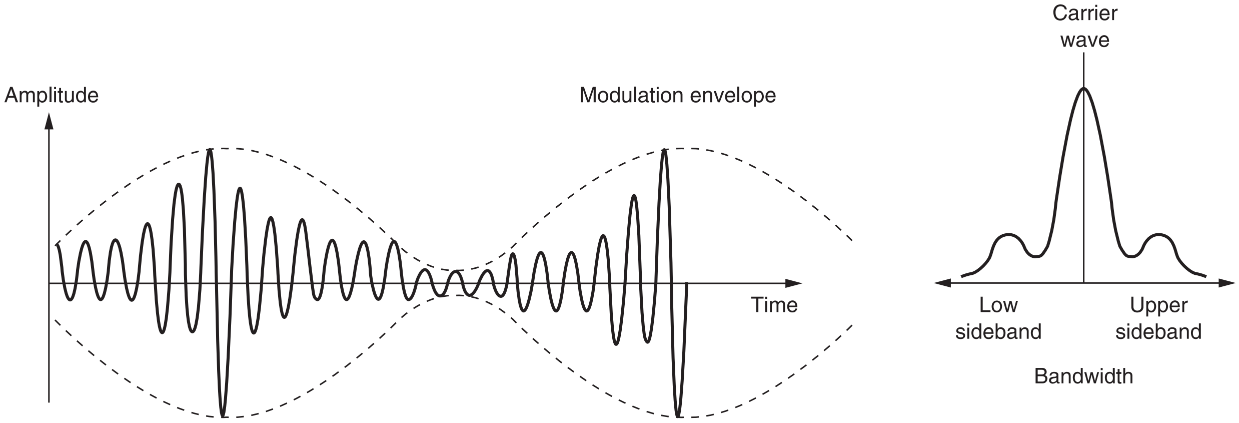

Figure 1-3 *Amplitude modulation waveform*

the strength of the transmitted signal in relation to the information being sent, for example, changes in the signal strength can be used to reflect sounds being reproduced in the speaker. This type of modulation technique creates two sidebands with the carrier wave signal placed in the center between the two sidebands. The transmission bandwidth of AM is twice the signal's original (baseband) bandwidth—since both the positive and negative sidebands are 'copied' up to the carrier frequency, but only the positive sideband is present originally. See Figure 1-3. Thus, double-sideband AM (DSB-AM) is spectrally inefficient. The power consumption of AM reveals that DSB-AM with its carrier has an efficiency of about 33% which is too efficient. The benefit of this system is that receivers are cheaper to produce. The forms of AM with suppressed carriers are found to be 100% power efficient, since no power is wasted on the carrier signal which conveys no information. Amplitude modulation is used primarily in the medium wave band or AM radio band which covers 520 to 1710 kHz. AM modulation is also used by shortwave broadcasters in the SW bands from between 5 MHz and 24 MHz, and in the aircraft band which covers 188 to 136 MHz.

FM modulation

Frequency modulation (FM) is a form of modulation which represents information as variations in the instantaneous frequency of a carrier wave. Contrast this with amplitude modulation, in which the amplitude of the carrier is varied while its frequency remains constant. In analog applications, the carrier frequency is varied in direct proportion to changes in the amplitude of an input signal. Digital data can be represented by shifting the carrier frequency among a set of discrete values, a technique known as frequency-shift keying. The diagram in Figure 1-4, illustrates the FM modulation scheme, the RF frequency is varied with the sound input rather than the amplitude.

FM is commonly used at VHF radio frequencies for high-fidelity broadcasts of music and speech, as in FM broadcasting. Normal (analog) TV sound is also broadcast using FM. A narrowband form is used for voice communications in commercial and amateur radio settings. The type of FM used in broadcast is generally called wide-FM, or W-FM. In two-way radio, narrowband narrow-FM (N-FM) is used to conserve bandwidth. In addition, it is used to send signals into space.

Wideband FM (W-FM) requires a wider bandwidth than amplitude modulation by an equivalent modulating signal, but this also makes the signal more robust against noise and interference. Frequency modulation is also more robust against simple signal amplitude fading phenomena. As a result, FM was chosen as the modulation standard for high frequency, high fidelity radio transmission: hence the term "FM radio." FM broadcasting uses a well-known part of the VHF band between 88 and 108 MHz in the USA.

FM receivers inherently exhibit a phenomenon called capture, where the tuner is able to clearly receive the stronger of two stations being broadcast on

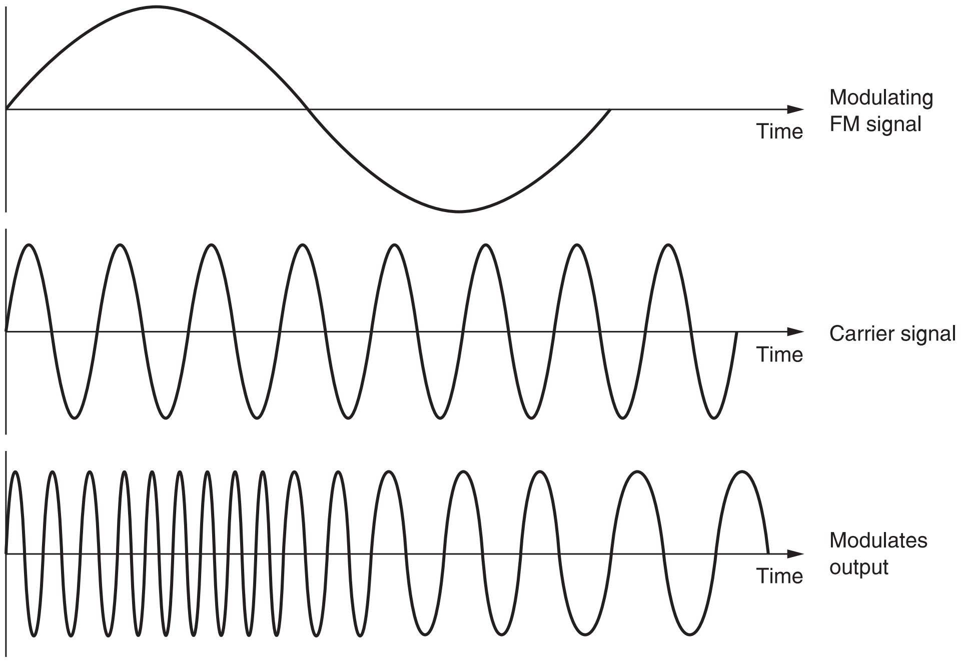

Figure 1-4 *FM modulation waveform*

the same frequency. Problematically, however, frequency drift or lack of selectivity may cause one station or signal to be suddenly overtaken by another on an adjacent channel. Frequency drift typically constituted a problem on very old or inexpensive receivers, while inadequate selectivity may plague any tuner. Frequency modulation is used on the FM broadcast band between 88 and 108 MHz as well as in the VHF and UHF bands for both public service and amateur radio operators.

Single sideband (SSB) modulation

Single sideband modulation (SSB) is a refinement upon amplitude modulation, which was designed to be more efficient in its use of electrical power and spectrum bandwidth. Single sideband modulation avoids this bandwidth doubling, and the power wasted on a carrier, but the cost of some added complexity.

The balanced modulator is the most popular method of producing a single sideband modulated signal. The balanced modulator provides the “sidebands” of energy that exist on either side of the carrier frequency but eliminates the RF carrier, see Figure 1-5. The carrier is removed because it is the sidebands that provide the actual meaningful content of material, within the modulation envelope. In order to make SSB even more efficient, one of these two sidebands is removed by a bandpass. So the intelligence is preserved with SSB and it becomes a more efficient use of radio spectrum energy. It provides almost 9 Decibels (dBs) of signal gain over an amplitude modulated signal that includes an RF “carrier” of the same power level! As the final RF amplification is now concentrated in a single sideband, the effective power output is greater than in normal AM (the carrier and redundant sideband account for well over half of the power output of an AM transmitter). Though SSB uses substantially less bandwidth and power, it cannot be demodulated by a simple envelope detector like standard AM.

SSB was pioneered by telephone companies in the 1930s for use over long-distance lines, as part of a technique known as frequency-division multiplexing (FDM). This enabled many voice channels to be sent down a single physical circuit. The use of SSB meant that the channels could be spaced (usually) just 4000 Hz apart, while offering a speech bandwidth of nominally 300–3400 Hz. Amateur radio operators began to experiment with the method seriously after World War II. It has become a *de facto* standard for long-distance voice radio transmissions since then.

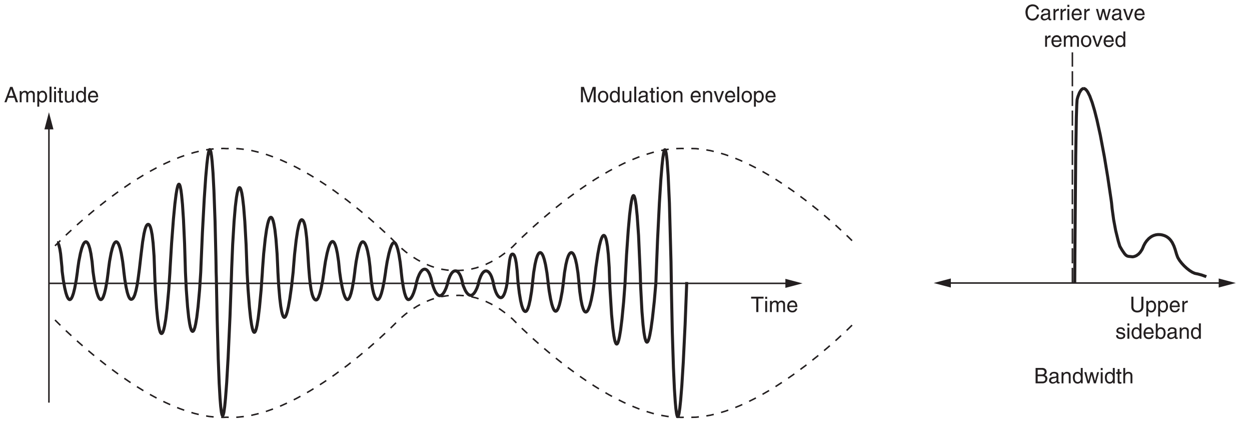

Figure 1-5 *Single sideband modulation waveform*

Single Sideband Suppressed Carrier (SSB-SC) modulation was the basis for all long-distance telephone communications up until the last decade. It was called "L carrier." It consisted of groups of telephone conversations modulated on upper and/or lower sidebands of contiguous suppressed carriers. The groupings and sideband orientations (USB, LSB) supported hundreds and thousands of individual telephone conversations. Single sideband communications are used by amateur radio operators and government, and utility stations primarily in the shortwave bands for long-distance communications.

Shortwave radio

Shortwave radio operates between the frequencies of 1.80 MHz and 30 MHz and came to be referred to as such in the early days of radio because the wavelengths associated with this frequency range were shorter than those commonly in use at that time. An alternate name is HF or high frequency radio. Short wavelengths are associated with high frequencies because there is an inverse relationship between frequency and wavelength. Shortwave frequencies are capable of reaching the other side of the Earth, because these waves can be refracted by the ionosphere, by a phenomenon known as Skywave propagation. High-frequency propagation is dependent upon a number of different factors, such as season of the year, solar conditions, including the number of sunspots, solar flares, and overall solar activity. Solar flares can prevent the ionosphere from reflecting or refracting radio waves.

Another factor which determines radio propagation is the time of the day; this is due to a particular transient atmosphere ionized layer forming only during day when atoms are broken up into ions by sun photons. This layer is responsible for partial or total absorption of particular frequencies. During the day, higher shortwave frequencies (i.e., above 10 MHz) can travel longer distances than lower ones; at night, this property is reversed.

Different types of modulation techniques are used on the shortwave frequencies in addition to AM and FM. AM, amplitude modulation, is generally used for shortwave broadcasting, and some aeronautical communications, while Narrow-band frequency modulation (NFM) is used at the higher HF frequencies. Single sideband or (SSB), is used for long-range communications by ships and aircraft, for voice transmissions by amateur radio operators. CW, Continuous Carrier Wave or (CW), is used for Morse code communications. Various other types of digital communications such as radioteletype, fax, digital, SSTV and other systems require special hardware and software to decode. A new broadcasting technique called Digital Radio Mondiale or (DRM) is a digital modulation scheme used on bands below 30 MHz.

Shortwave listening

Many hobbyists listen to shortwave broadcasters and for some listeners the goal is to hear as many stations from as many countries as possible (DXing); others listen to specialized shortwave utility, or "UTE," transmissions such as maritime, naval, aviation, or military signals. Others focus on intelligence signals. Many, though, tune the shortwave bands for the program content of shortwave broadcast stations, aimed to a general audience (such as the Voice of America, BBC World Service, Radio Australia, etc.). Some even listen to two-way communications by amateur radio operators. Nowadays, as the Internet evolves, the hobbyist can listen to shortwave signals via remotely controlled shortwave receivers around the world, even without owning a shortwave radio (see for example http://www.dxtuners.com). Alternatively, many international broadcasters (such as the BBC) offer live streaming audio on their web-sites. Table 1-2, lists some of the popular shortwave broadcast bands.

Shortwave listeners, or SWLs, can obtain QSL cards from broadcasters, utility stations or amateur radio operators as trophies of the hobby. Some stations even give out special certificates, pennants, stickers and other tokens and promotional materials to shortwave listeners.

Major users of the shortwave radio bands include domestic broadcasting in countries with a widely dispersed population with few long-wave, medium-wave, or FM stations serving them. International broadcasting stations beamed radio broadcasts to foreign audiences.

Table 1-2
Shortwave broadcast chart

Band	*Megahertz Band (MHz)*	*Kilohertz (KHz)*
120 Meter	2.3–2.5 MHz	2300–2500 KHz
90 Meter	3.2–3.40 MHZ	3200–3400 KHz
75 Meter	3.90–4.00 MHZ	3900–4000 KHz
60 Meter	4.750–5.060 MHz	4750–5060 KHz
49 Meter	5.950–6.20 MHz	5950–6200 KHz
41 Meter	7.10–7.60 MHz	7100–7600 KHz
31 Meter	9.20–9.90 MHz	9500–9900 KHz
25 Meter	11.60–12.200 MHz	11600–12200 KHz
22 Meter	13.570–13.870 MHZ	13570–13870 KHz
19 Meter	15.10–15.800 MHz	15100–15800 KHz
16 Meter	17.480–17.900 MHz	17480–17900 KHz
13 Meter	21.450–21.850 MHz	21450–21850 KHz
11 Meter	25.60–26.100 MHz	25600–26100 KHz

Speciality political, religious, and conspiracy theory radio networks, individual commercial and non-commercial paid broadcasts for the north American and other markets. Utility stations transmitting messages not intended for a general public, such as aircraft flying between continents, encoded or ciphered diplomatic messages, weather reporting, or ships at sea. Amateur radio operators have rights to use many frequencies in the shortwave bands; you can hear their communications using different modulation techniques and even obtain a license to communicate in these bands yourself. Contact the Amateur Radio Relay League for more information. Table 1-3 illustrates the amateur radio frequencies and how they are divided between the different license classes. On the shortwave band you will also encounter time signal stations and number stations, thought to be spy stations operating on the shortwave bands.

Types of receivers

A radio signal is transmitted through the ionosphere and is picked up by the antenna in your radio receiver. The antenna is fed to an RF amplifier and usually an intermediate amplifier or IF amplifier and then on to a detector of some sort depending upon the type of receiver you are using. From the detector, the resultant audio signal is amplified and sent to a loudspeaker for listening. Figure 1-6 illustrates a block diagram of a typical AM radio receiver. The antenna is sent to the RF amplifier. The mixer is fed by both the local oscillator and the RF amplifier. The signal from the mixer is sent to a bandpass filter and then on to the first IF amplifier. The first IF amplifier is next sent to the detector and then on to the final audio amplifier stage which drives the speaker. The illustration depicted in Figure 1-7 shows a typical FM receiver block diagram. The antenna feeds the RF amplifier stage. Both the RF amplifier and local oscillator are fed into the mixer. The signal from the mixer is next sent to the IF amplifier stage. From the IF amplifier stage the signal is next sent to the FM demodulator section, which feeds the signal to the voltage amplifier and then the signal is fed to the final audio amplifier stage and on to the speaker. Note the feedback path between, i.e. the AGC or automatic frequency control from the FM demodulator back to

Amateur stations operating at 1900-2000 kHz must not cause harmful interference to the radiolocation service and are afforded no protection from radiolocation operations.

General, Advanced and Amateur Extra licensees may use the following five channels on a secondary basis with a maximum effective radiated power of 50 W PEP relative to a half wave dipole. Only upper sideband suppressed carrier voice transmissions may be used. The frequencies are 5330.5, 5345.5, 5355.5, 5371.5 and 5403.5 kHz. The occupied bandwidth is limited to 2.8 kHz centered on 5332, 5345, 5355, 5373 and 5405 kHz respectively.

† Phone and image modes are permitted between 7075 and 7100 kHz for FCC licensed stations in ITU Regions 1 and 3 and by FCC licensed stations in ITU Region 2 West of 130 degrees West longitude or South of 20 degrees North latitude. See sections 97.305 (c) and 97.307 (f)(11). Novice and Technician Plus licensees outside ITU Region 2 may use CW only between 7050 and 7075 kHz. See Section 97.301(e). These exemptions do not apply to stations in the continental US.

Maximum power on 30 meters is 200 watts PEP output. Amateurs must avoid interference to the fixed service outside the US.

Novice, Advanced and Technician Plus Allocations

New Novice, Advanced and Technician Plus licenses are no longer being issued, but *existing* Novice, Technician Plus and Advanced class licenses are unchanged. Amateurs can continue to renew these licenses. Technician who pass the 5 wpm Morse code exam *after* that date have Technician Plus privileges, although their license says Technician. They must retain the 5 wpm Certificate of Successful Completion of Examination (CSCE) as proof. The CSCE is valid indefinitely for operating authorization, but is valid only for 365 days for upgrade credit.

Novices and Technician Plus Licensees are limited to 200 watts PEP output on 10 meters.

Novices are limitted to 25 watts PEP output from 222 to 225 MHz.

Novices are limited to 5 watts PEP output from 1270 to 1295 MHz.

US AMATEUR POWER LIMITS

At all times, transmitter power should be kept down to that necessary to carry out the desired communications. Power is rated in watts PEP output. Unless otherwise stated, the maximum power output is1500 W. Power for all license classes is limited to 200 W in the 10,100-10,150 kHz band and in all Novice subbands below 28,100 kHz. Novices and Technicians are restricted to 200 W in the 28,100-28,500 kHz subbands. In addition, Novices are restricted to 25 W in the 222-225 MHz band and 5 W in the 1270-1295 MHz subband.

E = AMATEUR EXTRA
A = ADVANCED
G = GENERAL
P = TECHNICIAN PLUS
T = TECHNICIAN
N = NOVICE

*Technicians who have passed the 5 wpm Morse code exam are indicated as "P".

**Geographical and power restrictions apply to all bands with frequencies above 420 MHz. See *The ARRL FCC Rule Book* for more information about your area.

***219-220 MHz allocated to amateurs on a secondary basis for fixed digital message forwarding systems only and can be operated by all licensees except Novices.

All licensees except Novices are authorized all modes on the following frequencies:
2300-2310 MHz
2390-2450 MHz
3300-3500 MHz
5650-5925 MHz
10.0-10.5 GHz
24.0-24.25 GHz
47.0-47.2 GHz
76.0-81.0 GHz
122.225-123.0 GHz
134-141 GHz
241-250 GHz
All above 275 GHz

the local oscillator. Finally, the shortwave radio block diagram is illustrated in the diagram in Figure 1-8. The antenna line is fed to the RF amplifier section. Both the local oscillator and the RF amplifier are fed to a filter section, which is in turn sent to the IF amplifier section. The output signal from the IF amplifier section is next sent to the product detector. A BFO or beat frequency oscillator signal is sent to the product detector, this is what permits SSB reception. The signal from the product detector is next sent to the audio amplifier and then on to the speaker. The receivers shown are the most common types of receivers. There are in fact many different variations in receiver designs including receivers made to receive special digital signals, which we will not discuss here.

Next, we will move our discussion to identifying electronics components and reading schematics and learning how to solder before we forge ahead and begin building some fun radio receiver projects.

Chapter 2

Identifying Components and Reading Schematics

Identifying electronic components

If you are a beginner to electronics or radio, you may want to take a few minutes to learn a little about identifying electronic components, reading schematics, and installing electronic components on a circuit board. You will also learn how to solder, in order to make long-lasting and reliable solder joints.

Electronic circuits comprise electronic components such as resistors and capacitors, diodes, semiconductors and LEDs, etc. Each component has a specific purpose that it accomplishes in a particular circuit. In order to understand and construct electronic circuits it is necessary to be familiar with the different types of components, and how they are used. You should also know how to read resistor and capacitor color codes, recognize physical components and their representative diagrams and pin-outs. You will also want to know the difference between a schematic and a pictorial diagram. First, we will discuss the actual components and their functions and then move on to reading schematics, then we will help you to learn how to insert the components into the circuit board. In the next chapter we will discuss how to solder the components to the circuit board.

The diagrams shown in Figures 2-1, 2-2 and 2-3 illustrate many of the electronic components that we will be using in the projects presented in this book.

Types of resistors

Resistors are used to regulate the amount of current flowing in a circuit. The higher the resistor's value or resistance, the less current flows and conversely a lower resistor value will permit more current to flow in a circuit. Resistors are measured in ohms (Ω) and are identified by color bands on the resistor body. The first band at one end is the resistor's first digit, the second color band is the resistor's second digit and the third band is the resistors's multiplier value. A fourth color band on a resistor represents the resistor's tolerance value. A silver band denotes a 10% tolerance resistor, while a gold band denotes a 5% resistor tolerance. No fourth band denotes that a resistor has a 20% tolerance. As an example, a resistor with a brown, black, and red band will represent the digit (1), the digit (0), with a multiplier value of (00) or 1000, so the resistor will have a value of 1k or 1000 ohms. There are a number of different styles and sizes of resistor. Small resistors can be carbon, thin film or metal. Larger resistors are made to dissipate more power and they generally have an element wound from wire.

A potentiometer (or pot) is basically a variable resistor, generally having three terminals and fitted with a rotary control shaft which varies the resistance as it is rotated. A metal wiping contact rests against a circular carbon or wire wound resistance track. As the wiper arm moves about the circular resistance, the resistance to the output terminals changes. Potentiometers are

commonly used as volume controls in amplifiers and radio receivers.

A trimpot is a special type of potentiometer which, while variable, is intended to be adjusted once or only occasionally. For this reason a control shaft is not provided but a small slot is provided in the center of the control arm. Trimpots are generally used on printed circuit boards.

A light-dependent resistor (LDR) is a special type of resistor that varies its resistance value according to the amount of light falling on it. When it is in the dark, an LDR will typically have a very high resistance, i.e. millions of ohms. When light falls on the LDR the resistance drops to a few hundred ohms.

Types of capacitors

Capacitors block DC current while allowing varying or AC current signals to pass. They are commonly used for coupling signals from part of a circuit to another part of a circuit, they are also used in timing circuits. There are a number of different types of capacitor as described below.

Polyester capacitors use polyester plastic film as their insulating dielectric. Some polyester capacitors are called greencaps because they are coated with a green or brown color coating on the outside of the component. Their values are specified in microfarads or (µF), nanofarads, (nF), or picofarads (pF) and range from 1 nF up to about 10 µF. These capacitors do not have polarity and have fixed values.

MKT capacitors are another type of capacitor, but they are rectangular or (block) in shape and are usually yellow in color. One of the major advantages of these capacitors is a more standardized lead spacing, making them more useful for PC board projects. The components can generally be substituted for polyester types.

Ceramic capacitors use a tiny disk of ceramic or porcelain material in their construction for a dielectric

and they range in value from 1 pF up to 2.2 µF. Those with values above 1 nF are often made with multiple layers of metal electrodes and dielectric, to allow higher capacitance values in smaller bodies. These capacitors are usually called 'multilayer monolithics' and distinguished from lower value disk ceramic types. Ceramic capacitors are often used in RF radio circuits and filter circuits.

Electrolytic capacitors use very thin film of metal oxide as their dielectric, which allows them to provide a large amount of capacitance in a very small volume. They range in value from 100 nF up to hundreds and thousands of microfarads (µF). They are commonly used to filter power supply circuits, coupling audio circuits and in timing circuits. Electrolytic capacitors have polarity and must be installed with respect to these polarity marking. The capacitor will have either a white or black band denoting polarity with a plus (+) or minus (–) marking next to the color band.

Variable capacitors are used in circuits for (trimming) or adjustment, i.e. for setting a frequency. A variable capacitor has one set of fixed plates and one set of plates which can be moved by turning a knob. The dielectric between the plates is usually a thin plastic film. Most variable capacitors have low values up to a few tens of picofarads (pF) and a few hundreds of microfarads for larger variable capacitors.

Diodes

A diode is a semiconductor device which can pass current in one direction only. In order for current to flow the anode (A) must be positive with respect to the cathode (K). In this condition, the diode is said to be forward biased and a voltage drop of about .6 volt appears across its terminals. If the anode is less than .6 volt positive with respect to the cathode, negligible current will flow and the diode behaves as an open circuit.

Types of transistors

Transistors are semiconductor devices that can be used either as electronic switches or to amplify signals. They have three leads, called the Collector, Base, and Emitter. A small current flowing between base and emitter (junction) causes a much larger current to flow between the emitter and collector (junction). There a two basic types of transistors, PNP and NPN styles.

Field Effect Transistors, or FETs, are a different type of transistor, which usually still have three terminals but work in a different way. Here the control element is the “gate” rather than the base, and it is the “gate” voltage which controls the current flowing in the “channel” between the other terminals—the “source” and the “drain.” Like ordinary transistors FETs can be used either as electronic switches or as amplifiers; they also come in P-channel and N-channel types, and are available in small signal types as well as power FETs.

Power transistors are usually larger than the smaller signal type transistors. Power transistors are capable of handling larger currents and voltages. Often metal tabs and heatsinks are used to remove excess heat from the part. These devices are usually bolted to the chassis and are used for amplifying RF or audio energy.

Integrated circuits

Integrated circuits, or ICs, contain all, or most, of the components necessary for a particular circuit function, in one package. Integrated circuits contain as few as 10 transistors or many millions of transistors, plus many resistors, diodes and other components. There are many shapes, styles and sizes of integrated circuits: in this book we will use the dual-in-line style IC, either 8, 14 or 16 pin devices.

Three-terminal regulators are special types of integrated circuits, which supply a regulated or constant and accurate voltage from output regardless (within limits) of the voltage applied to input. They are most often used in power supplies. Most regulators are designed to give specific output voltages, i.e. a ‘LM7805” regulator provides a 5 volt output, but some IC regulators can provide adjustable output based on an external potentiometer which can vary the output voltage.

Heatsinks

Many electronic components generate heat when they are operating. Generally heatsinks are used on semiconductors like transistors to remove heat. Overheating can damage a particular component or the entire circuit. The heatsink cools the transistor and ensures a long circuit life by removing the excess heat from the circuit area.

Light-emitting diodes

Light-emitting diodes, or LEDs, are special diodes which have a plastic translucent body (usually clear, red, yellow, green or blue in color) and a small semiconductor element which emits light when the diode passes a small current. Unlike an incandescent lamp, an LED does not need to get hot to produce light. LEDs must always be forward biased to operate. Special LEDs can also produce infrared light.

LED displays consist of a number of LEDs together in a single package. The most common type has seven elongated LEDs arranged in an "8" pattern. By choosing which combinations of LEDs are lit, any number of digits from "0" through "9" can be displayed. Most of these "7-segment" displays also contain another small round LED which is used as a decimal point.

Types of inductors

Inductors or "coils" are basically a length of wire, wound into a cylindrical spiral (or layers of spirals) in order to increase their inductance. Inductance is the ability to store energy in a magnetic field. Many coils are wound on a former of insulating material, which may also have connection pins to act as the coil's terminals. The former may also be internally threaded to accept a small core or "slug" of ferrite, which can be adjusted in position relative to the coil itself to vary the coil inductance.

A transformer consists of a number of coils of windings of wire wound on a common former, which is also inside a core of iron alloy, ferrite of other magnetic material. When an alternating current is passed through one of the windings (primary), it produces an alternating magnetic field in the core and this in turn induces AC voltages in the other (secondary) windings. The voltages produced in the other winding depend on the number of turns in those windings, compared with the turns in the primary winding. If a secondary winding has fewer turns than the primary, it will produce a lower voltage, and be called a step-down transformer. If the secondary winding has more windings than the primary, then the transformer will produce a higher voltage and it will be a step-up transformer. Transformers can be used to change the voltage levels of AC power and they are available in many different sizes and power handling capabilities.

Microphones

A microphone converts audible sound waves into electrical signals which can be then amplified. In an electret microphone, the sound waves vibrate a circular diaphragm made from very thin plastic material which has a permanent charge in it. Metal films coated on each side form a capacitor, which produces a very small AC voltage when the diaphragm vibrates. All electret microphones also contains FET which amplifies the very small AC signals. To power an FET amplifier, the microphone must be supplied with a small DC voltage.

Loudspeakers

A loudspeaker converts electrical signals into sound waves that we can hear. It has two terminals which go to a voice coil, attached to a circular cone made of either cardboard or thin plastic. When electrical signals are applied to the voice coil, its creates a varying magnetic field from a permanent magnet at the back of the speaker. As a result the cone vibrates in sympathy with the applied signal to produce sound waves.

Relays

Many electronic components are not capable of switching higher currents or voltages, so a device called a relay is used. A relay has a coil which forms an electromagnet, attracting a steel "armature" which itself pushes on one or more sets of switching contacts. When a current is passed through the coil to energize it, the moving contacts disconnect from one set of contacts to another, and when the coil is de-energized the contacts go back to their original position. In most cases, a relay needs a diode across the coil to prevent damage to the semiconductor driving the coil.

Switches

A switch is a device with one or more sets of switching contacts, which are used to control the flow of current in a circuit. The switch allows the contacts to be controlled by a physical actuator of some kind—such as a press-button toggle lever, rotary or knob, etc. As the name denotes, this type of switch has an actuator bar which slides back and forth between the various contact positions. In a single-pole, double throw, or "SPDT" slider switch, a moving contacte links the center contact to either of the two end contacts. In contrast, a double-pole double throw (DPDT) slider switch has two of these sets of contacts, with their moving contacts operating in tandem when the slider is actuated.

Wire

A wire is simply a length of metal conductor, usually made from copper since its conductivity is good, which means its resistance is low. When there is a risk of a wire touching another wire and causing a short, the copper wire is insulated or covered with a plastic coating which acts as an insulating material. Plain copper wire is not usually used since it will quickly oxidize or tarnish in the presence of air. A thin metal alloy coating is often applied to the copper wire; usually an alloy of tin or lead is used.

Single or multi-strand wire is covered in colored PVC plastic insulation and is used quite often in electronic applications to connect circuits or components together. This wire is often called “hooku” wire. On a circuit diagram, a solid dot indicates that the wires or PC board tracks are connected together or joined, while a “loop-over” indicates that they are not joined and must be insulated. A number of insulated wires enclosed in an outer jacket is called an electrical cable. Some electrical cables can have many insulated wires in them.

Semiconductor substitution

There are often times when building an electronic circuit, it is difficult or impossible to find or locate the original transistor or integrated circuit. There are a number of circuits shown in this book which feature transistors, SCRs, UJTs, and FETs that are specified but cannot easily be found. Where possible many of these foreign components are converted to substitute values, either with a direct replacement or close substitution. Many foreign parts can be easily converted directly to a commonly used transistor or component. Occasionally an outdated component has no direct common replacement, so the closest specifications of that component are attempted. In some instances we have specified replacement components with substitution components from the NTE brand or replacements. Most of the components for the projects used in this book are quite common and easily located or substituted without difficulty.

When substituting components in the circuit, make sure that the pin-outs match the original components. Sometimes, for example, a transistor may have bottom view drawing, while the substituted value may have a drawing with a top view. Also be sure to check the pin-outs or the original components versus the replacement. As an example, some transistors will have EBC versus ECB pin-outs, so be sure to look closely at possible differences which may occur.

Reading electronic schematics

The heart of all radio communication devices, both transmitters and receivers, all revolve around some type of oscillator. In this section we will take a look at what is perhaps the most important part of any receiver, and that is the oscillator. Communication transmitters, receivers, frequency standards and synthesizers all use some type of oscillators circuits. Transmitters need oscillators for their exciters, while receivers most often use local oscillators to mix signals. In this section you will see how specific electronics components are utilized to form oscillator circuits. Let’s examine a few of the more common types of oscillator designs and their building considerations. In this section, you will also tell the difference between a schematic diagram and a pictorial diagram. A schematic diagram illustrates the electronic symbols and how the components connect to one another, it is the circuit blue-print and pretty much universal among electronic enthusiasts. A pictorial diagram, on the other hand, is a “picture” of how the components might appear in an actual circuit on a circuit board of one type or another. Take a close look at the difference between the two types of diagram, and they will help you later when building actual circuits. Our first type of oscillator shown below is The Hartley.

Hartley oscillator

The Hartley RF oscillator, illustrated in Figure 2-4, is centered around the commonly available 2N4416A FET transistor. This general purpose VFO oscillator operates around 5100 kHz. The frequency determining components are L1, C1, a 10 pF trimmer and capacitors C2, C3, C4, C5 and C6. Note capacitor C6 is a 10-100 pF variable trimmer type. Capacitor C7 is to reduce the loading on the tuned circuit components. Its value can be small but be able to provide sufficient drive to the succeeding buffer amplifier stage. You can experiment using a small viable capacitor trimmer, such as a 5-25 pF.

The other components, such as the two resistors, silicon diode at D1 are standard types, nothing particularly special. The Zener diode at D2 is a 6.2 volt type. Capacitor C8 can be selected to give higher/lower output to the buffer amplifier. Smaller C6 values give lower output and conversely higher values give larger output.

In order to get the circuit to work properly, you need to have an inductive reactance for L1 of around about 180 ohms. At 5 MHz this works out at about 5.7 uH. The important consideration, is that the feedback point from the source of the JFET connects to about 25% of the windings of L1 from the ground end. An air cored inductor is shown in the diagram. It could be, for example, 18-19 turns of #20 gauge wire on a 25.4 mm (1″) diameter form spread evenly over a length of about 25.4 mm (1″). The tap would be at about 4½ turns. Alternatively, with degraded performance, you could use a T50-6 toroid and wind say 37 turns of #24 wire (5.48 µH) tapping at 9 turns.

So to have the oscillator operate at around 5 MHz, we know the LC is 1013 and if L is say 5.7 µH then total C for resonance (just like LC Filters eh!) is about 177 pF. We want to be able to tune from 5000 to 5100 kHz, a tuning ratio of 1.02, which means a capacitance ratio of 1.04 (min to max).

Colpitts oscillators

Colpitts oscillators are similar to the shunt fed Hartley oscillator circuit except the Colpitts oscillator, instead of having a tapped inductor, utilizes two series capacitors in its LC circuit. With the Colpitts oscillator the connection between these two capacitors is used as the center tap for the circuit. A Colpitts oscillator circuit is shown at Figure 2-5, and you will see some similarities with the Hartley oscillator.

The simplest Colpitts oscillator to construct and get running is the “series tuned” version, more often referred to as the “Clapp Oscillator.” Because there is no load on the inductor, a high “Q” circuit results with a high L/C ratio and of course much less circulating current. This aids drift reduction. Because larger inductances are required, stray inductances do not have as much impact as perhaps in other circuits.

The total capacitive reactance of the parallel combination of capacitors depicted as series tuning below the inductor in a series tuned Colpitts oscillator or “Clapp oscillator” should have a total reactance of

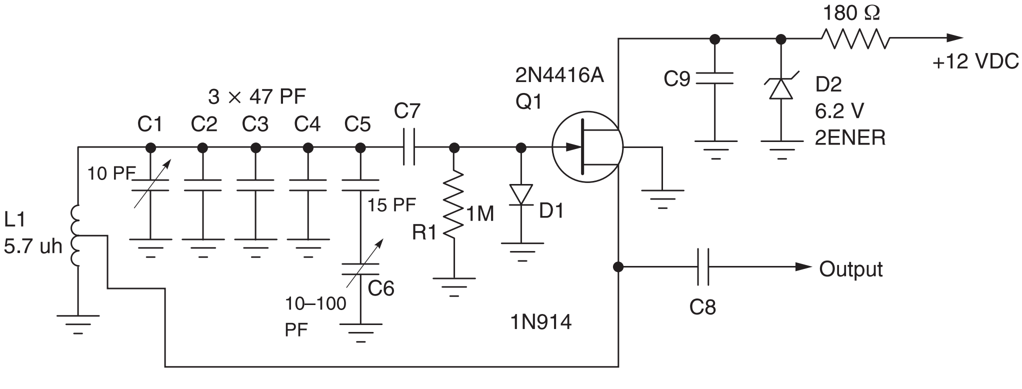

Figure 2-4 *Hartley oscillator circuit*

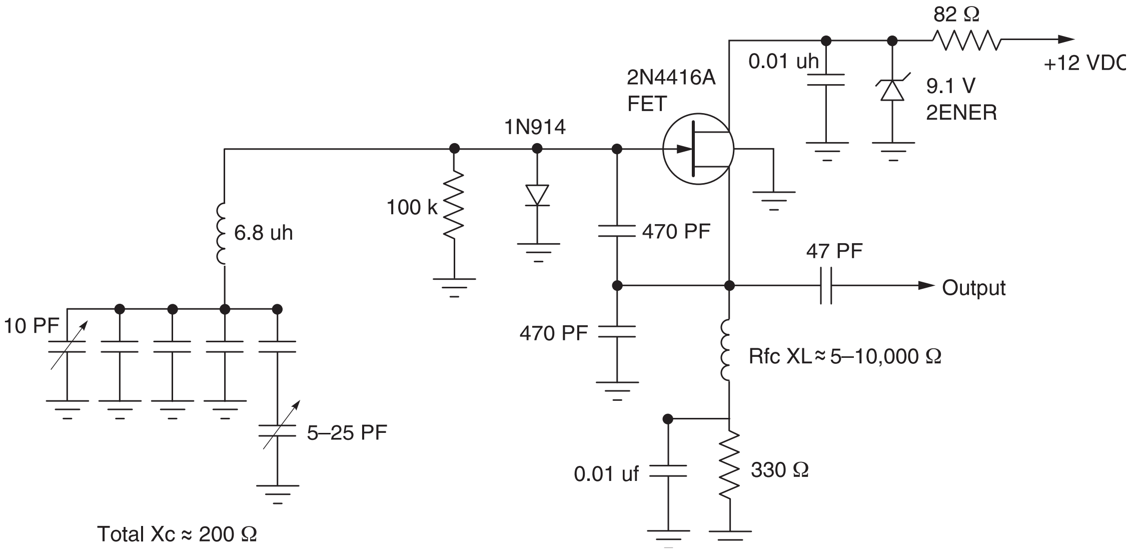

Figure 2-5 *Series tuned Colpitts oscillator circuit*

around 200 ohms. Not all capacitors may be required in your particular application. Effectively all the capacitors are in series in a Colpitts oscillator, i.e. they appear as parallel connected but their actual values are in fact in series.

Ideally, your frequency determining components L1 and the parallel capacitors should be in a grounded metal shield. The FET used in the Colpitts oscillator is the readily available 2N4416A. Note, the metal FET case is connected to the circuit ground. The output from the Colpitts oscillator is through output capacitor 47 pF; this should be the smallest of values possible, consistent with continued reliable operation into the next buffer amplifier stage.

Crystal oscillators

Crystal oscillators are oscillators where the primary frequency determining element is a quartz crystal. Because of the inherent characteristics of the quartz crystal the crystal oscillator may be held to extreme accuracy of frequency stability.

Crystal oscillators are, usually, fixed frequency oscillators where stability and accuracy are the primary considerations. For example, it is almost impossible to design a stable and accurate LC oscillator for the upper HF and higher frequencies without resorting to some sort of crystal control. Hence the reason for crystal oscillators.

The crystal oscillator depicted at Figure 2-6 is a typical example of an RF or radio frequency crystal oscillators which may be used for exciters or RF converters. Transistor Q1, can be any transistor which will operate up to 150 MHz, such as a 2N2222A.

The turns ratio on the tuned circuit depicts an anticipated nominal load of 50 ohms. This allows a theoretical 2.5k ohms on the collector, so typically a 7:1 turns ratio for T1 would be used. Use the: L * C = 25330 / $F0^2$ formula for determining L and C in the tuned circuits of crystal oscillator. Personally I would make L a reactance of around 250 ohms. In this case, I'd make C1 a smaller trimmer capacitor. The crystal at X1 could be an overtone type crystal for the crystal, selecting a L * C for the odd particular multiple of overtone wanted in your crystal oscillators. Typically the output of the crystal oscillator would be followed by a buffer circuit. A pictorial diagram of the crystal controlled oscillator circuit is shown in Figure 2-7. Note that the components in this diagram are illustrated as component blocks as they might actually look placed on the circuit, rather than as electronic symbols in a circuit diagram or schematic.

Ceramic resonator VFO oscillator

The ceramic resonator VFO, or variable frequency oscillator circuit shown in Figure 2-8, illustrates a 7MH oscillator with a variable crystal oscillator (VXO). The VXO oscillator is extremely stable, but allows only a small variation in frequency, as compared with a conventional VFO. In contrast, a VFO with an LC resonant circuit can be tuned over a range of several hundred kHz, but its frequency stability will depend upon its construction, and is never as good as a crystal oscillator. The use of a ceramic resonator as a frequency determining component fulfills both requirements. The VXO oscillator is very stable yet it can vary the frequency, so the oscillator can be tuned. The range of a VXO oscillator circuit is not as wide as an LC oscillator but it offers a tuning range of 35 kHz with good frequency stability. The somewhat unusual resonant LC circuit at the collector of Q1 has two functions. It improves the shape of the output signal and also compensates for the amplitude drop starting at approx. 7020 kHz. Transistor Q1 is a readily obtainable 2N3904 and the ceramic resonator is a Murata SFE 7.02 M2C type or equivalent. Inductor L1 consists of two coils on a T50-2 powered iron toroid. The primary coil is 8-turns, while the secondary coil is 2-turns.

The diagram shown in Figure 2-9 depicts the ceramic resonator as a pictorial diagram, where the components look as a components block that might be placed in a circuit rather than an actual schematic diagram.

Voltage controlled oscillator (VCO)

A voltage controlled oscillator, or VCO, is an oscillator where the main variable tuning capacitor is a varactor diode. The voltage controlled oscillator is tuned across the “band” by a well regulated Dc voltage applied to the varactor diode, which varies the net capacitance applied to the tuned circuit. The voltage controlled oscillator, shown in Figure 2-10, illustrates a VCO which operates in the amateur radio band between 1.8 and 2.0 MHz.

Buying quality variable capacitors today is often quite expensive, so VCOs are an extremely attractive alternative. As an alternative, all you need is an extremely stable and clean source of Dc power, a varactor diode and a high quality potentiometer—usually a 10 turn type. Note that circuit “Q” tends to be somewhat degraded by using varactor diodes instead of variable capacitors.

When a reverse voltage is applied to a diode, it exhibits the characteristics of a capacitor. Altering the voltage alters the capacitance. Common diodes such as

1N914 and 1N4004 can be used, but more commonly a special diode known as a varactor diode is specifically manufactured for VCO use, such as Motorola's MVAM115.

The variable capacitor in this circuit is replaced by a varactor diode as a tuning diode, in series with capacitor C2. Note, the two, diodes back-to-back in series. Although this in effect divides total varactor diode capacitance by two, it eliminates RF energy present in the tank circuit driving a single diode into conduction on peaks which will increase the bias voltage; this also gives rise to harmonics.

Inductor L is wound on a toroid, an Amidon T50-2 type which would require about 55 turns of #26 wire, or even the T68-2 type requiring about 51 turns of #24 wire. Both gauges mentioned are those which will conveniently fit around the core. The inductor should have a value of about 15 µH. Capacitor C2 should have around180 pF, and the total capacitance of C1 a/b should be 390 pF. C4 is used to reduce the loading of the tuned circuit components. Its value can be small but be able to provide sufficient drive to the succeeding buffer amplifier stage. You can experiment using a small viable capacitor trimmer, such as a 5-25 pF.

The 10K potentiometer is a 10 turn "quality" potentiometer for tuning; the upper and lower trim pots (set and forget) allow you to adjust the voltage range of your choice that your tuning potentiometer will see. Use "quality" trimpots for these potentiometers, since they will affect the stability of the tuning of the circuit. The 100K resistor and the two 0.1 µF capacitors are further filtering. The diagram in Figure 2-11 depicts a pictorial diagram of the voltage controlled oscillator circuit. The circuit is shown as the components might appear rather than as symbols in a schematic diagram. The pictorial diagram often reflects an actual layout or parts placement and how the parts may appear on a circuit board.

Now that you can identify electronics components and you understand how they function in an electronics circuit, as well how electronics circuits are drawn, we can move on to the how-to-soldering section. In the next chapter, you will learn how to install components and how to solder the components onto a circuit board.

Chapter 3

Electronic parts installation and soldering

Before we discuss mounting the components to the printed circuit board we should take a few minutes to discuss the resistor and capacitor codes which are used to help identify and install these components. Table 3-1 lists the resistor color code information. Resistors generally have three or four color bands which help identify the resistor values. The color band will start from one edge of the resistor body; this is the first color code which represents the first digit, and the second color band depicts the second digit value, while the third color band is the resistor's multiplier value. The fourth color band represents the resistor tolerance value. If there is no fourth band then the resistor has a 20% tolerance; if the fourth band is silver, then the resistor has a 10% tolerance value, and if the fourth band is gold then the resistor has a 5% tolerance value. Therefore, if you have a resistor with the first band having a brown color, the second band with a black color and a third band with an orange color and a fourth with gold, then one (1) times zero (0) multiplied by a value of (1000), so the resistor will have a 10,000 ohm or 10k ohm value with a 5% tolerance.

Now let's move to identifying various capacitors. When identifying and installing the ceramic, mylar or poly capacitors, you will need to refer to Table 3-2, which lists capacitor (code) values vs. actual capacitor values. Most large capacitors, such as electrolytic types, will have their actual value printed on the body of the capacitor. But often with small capacitors they are just too small to have the actual capacitor values printed on them. An abbreviated code was devised to mark the capacitor, as shown in the table. A code marking of (104) would therefore denote a capacitor with a value of .1 µF (microfarads) or 100 nF (nanofarads). Once you understand how these component codes work, you can easily identify the resistors and capacitor and proceed to mount them on the printed circuit board.

Before we begin building actual electronic radio receiver circuits, you will need to understand how to prepare the electronic components before installing them onto the circuit board. First, you will need to know how to "dress" or prepare resistor leads, which is shown in Figure 3-1. Resistor leads are first bent to fit the PC board component holes, then the resistor is mounted to the circuit board. Figure 3-2 depicts how capacitor leads are bent to fit the PC board holes. Once, the capacitor leads are prepared, the capacitor can be installed onto the circuit board. The diagram shown in Figure 3-3 illustrates how to prepare diode leads before mounting them to the PB board. Finally, Figure 3-4 depicts transistor lead preparation, while Figure 3-5 shows how integrated circuit leads are prepared for installation.

Learning how to solder

Everyone working in electronics needs to know how to solder well. Before you begin working on a circuit, carefully read this chapter on soldering. In this section you will learn how to make good solder joints when soldering point-to-point wiring connections as well as for PC board soldering connections.

In all electronics work, the wiring connections must be absolutely secure. A loose connection in a radio results in noise, scratching sounds, or no sound at all. In a TV, poor connections can disrupt the sound or picture. The safe operation of airplanes and the lives of astronauts in flight depend on secure electronics connections.

Table 3-2

Capacitor code identification information

This table is designed to provide the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Most capacitors actually have the numeric values stamped on them; however, some are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

Soldering joins two pieces of metal, such as electrical wires, by melting them together with another metal to form a strong, chemical bond. Done correctly, it unites the metals so that electrically they act as one piece of metal. Soldering is not just gluing metals together. Soldering is tricky and intimidating in practice, but easy to understand in theory. Basic supplies include a soldering iron, which is a prong of metal that heats to a specific temperature through electricity, like a regular iron. The solder, or soldering wire, often an alloy of aluminum and lead, needs a lower melting point than the metal you're joining. Finally, you need a cleaning resin called flux that ensures the joining pieces are incredibly clean. Flux removes all the oxides on the surface of the metal that would interfere with the molecular bonding, allowing the solder to flow into the joint smoothly. You also need two things to solder together.

The first step in soldering is cleaning the surfaces, initially with sandpaper or steel wool and then by melting flux onto the parts. Sometimes, flux is part of the alloy of the soldering wire, in an easy-to-use mixture. Then, the pieces are both heated above the melting point of the solder (but below their own melting point) with the soldering iron. When touched to the joint, this precise heating causes the solder to "flow" to the place of highest temperature and makes a chemical bond. The solder shouldn't drip or blob, but spread smoothly, coating the entire joint. When the solder cools, you should have a clean, sturdy connection.

Many people use soldering in their field, from electrical engineering and plumbing to jewelry and crafts. In a delicate procedure, a special material, called solder, flows over two pre-heated pieces and attaches them through a process similar to welding or brazing. Various metals can be soldered together, such as gold and sterling silver in jewelry, brass in watches and clocks, copper in water pipes, or iron in leaded glass stained windows. All these metals have different melting points, and therefore use different solder. Some "soft" solder, with a low melting point, is perfect for wiring a circuit board. Other "hard" solder, such as for making a bracelet, needs a torch rather than a soldering iron to get a hot enough temperature. Electrical engineers and hobbyists alike can benefit from learning the art and science of soldering.

Solder

The best solder for electronics work is 60/40 rosin-core solder. It is made of 60% tin and 40% lead. This mixture melts at a lower temperature than either lead or tin alone. It makes soldering easy and provides good connections. The rosin keeps the joint clean as it is being soldered. The heat of the iron often causes a tarnish or oxide to form on the surface. The rosin dissolves the tarnish to make the solder cling tightly. Solders have different melting points, depending on the ratio of tin to lead. Tin melts at 450°F and lead at 621°F. Solder made from 63% tin and 37% lead melts at 361°F, the lowest melting point for a tin and lead mixture. Called 63-37 (or eutectic), this type of solder also provides the most rapid solid-to-liquid transition and the best stress resistance. Solders made with different lead/tin ratios have a plastic state at some temperatures. If the solder is deformed while it is in the plastic state, the deformation remains when the solder freezes into the solid state. Any stress or motion applied to "plastic solder" causes a poor solder joint.

The 60-40 solder has the best wetting qualities. Wetting is the ability to spread rapidly and bond materials uniformly; 60-40 solder also has a low melting point. These factors make it the most commonly used solder in electronics.

Some connections that carry high current can't be made with ordinary tin-lead solder because the heat generated by the current would melt the solder. Automotive starter brushes and transmitter tank circuits are two examples. Silver-bearing solders have higher melting points, and so prevent this problem. High-temperature silver alloys become liquid in the 1100°F to l200°F range, and a silver-manganese (85-15) alloy requires almost 1800°F.

Because silver dissolves easily in tin, tin bearing solders can leach silver plating from components. This problem can greatly reduced by partially saturating the tin in the solder with silver or by eliminating the tin. Tin-silver or tin-lead-silver alloys become liquid at temperatures from 430°F for 96.5-3.5 (tin-silver), to 588°F for 1.0-97.5-1.5 (tin-lead-silver). A 15.080.0-5.0 alloy of lead-indium-silver melts at 314°F.

Never use acid-core solder for electrical work. It should be used only for plumbing or chassis work. For circuit construction, only use fluxes or solder-flux combinations that are labeled for electronic soldering.

The rosin or the acid is a flux. Flux removes oxide by suspending it in solution and floating it to the top. Flux is not a cleaning agent! Always clean the work before soldering. Flux is not a part of a soldered connection—it merely aids the soldering process. After soldering, remove any remaining flux. Rosin flux can be removed with isopropyl or denatured alcohol. A cotton swab is a good tool for applying the alcohol and scrubbing the excess flux away. Commercial flux-removal sprays are available at most electronic-part distributors.

The soldering iron

Soldering is used in nearly every phase of electronic construction so you'll need soldering tools. A soldering tool must be hot enough to do the job and lightweight enough for agility and comfort. A temperature controlled iron works well, although the cost is not justified for occasional projects. Get an iron with a small conical or chisel tip. Soldering is not like gluing; solder does more than bind metal together and provide an electrically conductive path between them. Soldered metals and the solder combine to form an alloy.

You may need an assortment of soldering irons to do a wide variety of soldering tasks. They range in size from a small 25-watt iron for delicate printed-circuit work to larger 100 to 300-watt sizes used to solder large surfaces. If you could only afford a single soldering tool when initially setting up your electronics workbench than, an inexpensive to moderately priced pencil-type soldering iron with between 25 and 40-watt capacity is the best for PC board electronics work. A 100-watt soldering gun is overkill for printed-circuit work, since it often gets too hot, cooking solder into a brittle mess or damaging small parts of a circuit. Soldering guns are best used for point-to-point soldering jobs, for large mass soldering joints or large components. Small "pencil" butane torches are also available, with optional soldering-iron tips. A small butane torch is available from the Solder-It Company. Butane soldering irons are ideal for field service problems and will allow you to solder where there is no 110 volt power source. This company also sells a soldering kit that contains paste solders (in syringes) for electronics, pot metal and plumbing. See the Appendix for the address information.

Keep soldering tools in good condition by keeping the tips well tinned with solder. Do not run them at full temperature for long periods when not in use. After each period of use, remove the tip and clean off any scale that may have accumulated. Clean an oxidized tip by dipping the hot tip in sal ammoniac (ammonium chloride) and then wiping it clean with a rag. Sal ammoniac is somewhat corrosive, so if you don't wipe the tip thoroughly, it can contaminate electronic soldering. You can also purchase a small jar of "Tip Tinner," a soldering iron tip dresser, from your local Radio Shack store. Place the tip of the soldering iron into the "Tip Tinner" after every few solder joints.

If a copper tip becomes pitted, file it smooth and bright and then tin it immediately with solder. Modern soldering iron tips are nickel or iron clad and should not be filed. The secret of good soldering is to use the right amount of heat. Many people who will have not soldered before use too little heat dabbing at the joint to be soldered and making little solder blobs that cause unintended short circuits. Always use caution when soldering. A hot soldering iron can burn your hand badly or ruin a tabletop. It's a good idea to buy or make a soldering iron holder.

Soldering station

Often when building or repairing a circuit, your soldering iron is kept switched "on" for unnecessarily long periods, consuming energy and allowing the soldering iron tip to burn and develop a buildup of oxide. Using this soldering-iron temperature controller, you will avoid destroying sensitive components when soldering.

Buying a lower wattage iron may solve some of the problems, but new problems arise when you want to solder some heavy-duty component, setting the stage for creating a "cold" connections. If you've ever tried to troubleshoot some instrument in which a cold solder joint was at the root of the problem, you know how difficult such defects are to locate. Therefore, the best way to satisfy all your needs is to buy a temperature controller electronics workbench.

A soldering station usually consists of a temperature controlled soldering iron with an adjustable heat or temperature control and a soldering iron holder and cleaning pad. If you are serious about your electronics hobby or if you have been involved with electronics building and repair for any length of time, you will eventually want to invest in a soldering station at some point in time. There are real low cost soldering station for hobbyists, for under $30, but it makes more sense to purchase a moderately price soldering station such as the quality Weller series. A typical soldering station is shown in Figure 3-6.

Soldering gun

An electronics workbench would not be complete without a soldering gun. Soldering guns are useful for soldering large components to terminal strips, or splicing wires together or when putting connectors on coax cable. There are many instances where more heat is needed than a soldering iron can supply. For example, a large connector mass cannot be heated with a small soldering iron, so you would never be able to "tin" a connector with a small wattage soldering iron. A soldering gun is a heavy duty soldering device which does in fact look like a gun. Numerous tips are available for a soldering gun and they are easily replaceable using two small nuts on the side arm of the soldering gun. Soldering guns are available in two main heat ranges.

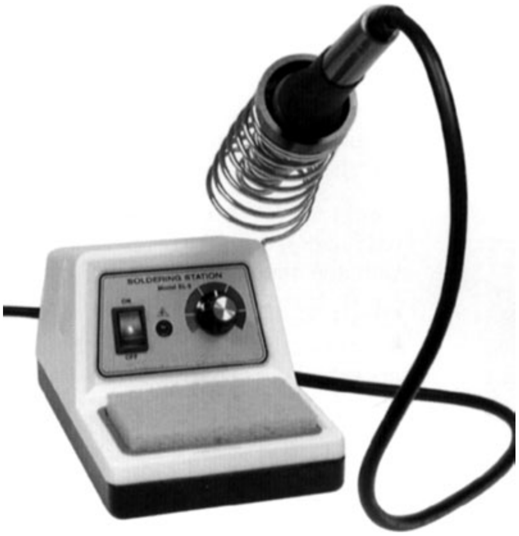

Figure 3-6 *Temperature controlled soldering station*

Most soldering guns have a two-step "trigger" switch which enable you to select two heat ranges for different soldering jobs. The most common soldering gun provides both a 100 watt setting when the "trigger" switch is pressed to its first setting, and as the "trigger" switch is advanced to the next step, the soldering gun will provide 150 watts, when more heat is needed. A larger or heavy-duty soldering gun is also available, but a little harder to locate is the 200 to 250 watt solder gun. The first "trigger" switch position provides 200 watts, while the second switch position provides the 250 watt heat setting. When splicing wires together either using the "Western Union" or parallel splice or the end splice, a soldering gun should be used especially if the wire gauge is below size 22 ga. Otherwise the solder may not melt properly and the connections may reflect a "cold" solder joint and therefore a poor or noisy splice. Soldering wires to binding post connections should be performed with a soldering gun to ensure proper heating to the connection. Most larger connectors should be soldered or pre-tinned using a soldering gun for even solder flow.

Preparing the soldering iron

If your iron is new, read the instructions about preparing it for use. If there are no instructions, use the following procedure. It should be hot enough to melt solder applied to its tip quickly (half a second when dry, instantly when wet with solder). Apply a little solder directly to the tip so that the surface is shiny. This process is called "tinning" the tool. The solder coating helps conduct heat from the tip to the joint face, the tip is in contact with one side of the joint. If you can place the tip on the underside of the joint, do so. With the tool below the joint, convection helps transfer heat to the joint. Place the solder against the joint directly opposite the soldering tool. It should melt within a second for normal PC connections, within two seconds for most other connections. If it takes longer to melt, there is not enough heat for the job at hand. Keep the tool against the joint until the solder flows freely throughout the joint. When it flows freely, solder tends to form concave shapes between the conductors. With insufficient heat solder does not flow freely; it forms convex shapes-blobs. Once solder shape changes from convex to concave, remove the tool from the joint. Let the joint cool without movement at room temperature. It usually takes no more than a few seconds. If the joint is moved before it is cool, it may take on a dull, satin look that is characteristic of a "cold" solder joint. Reheat cold joints until the solder flows freely and hold them still until cool. When the iron is set aside, or if it loses its shiny appearance, wipe away any dirt with a wet cloth or sponge. If it remains dull after cleaning, tin it again.

Overheating a transistor or diode while soldering can cause permanent damage. Use a small heatsink when you solder transistors, diodes or components with plastic parts that can melt. Grip the component lead with a pair of pliers up close to the unit so that the heat is conducted away. You will need to be careful, since it is easy to damage delicate component leads. A small alligator clip also makes a good heatsink to dissipate from the component.

Mechanical stress can damage components, too. Mount components so there is no appreciable mechanical strain on the leads.

Soldering to the pins of coil forms male cable plugs can be difficult. Use suitable small twist drill to clean the inside of the pin and then tin it with resin-core solder. While it is still liquid, clear the surplus solder from each pin with a whipping motion or by blowing through the pin from the inside of the form or plug. Watch out for flying hot solder, you can get severe burns. Next, file the nickel tip. Then insert the wire and solder it. After soldering, remove excess solder with a file, if necessary. When soldering to the pins of plastic coil-forms, hold the pin to be soldered with a pair of heavy pliers to form a heatsink. Do not allow the pin to overheat; it will loosen and become misaligned.

Preparing work for soldering

If you use old junk parts, be sure to completely clean all wires or surfaces before applying solder. Remove all enamel, dirt, scale, or oxidation by sanding or scraping the parts down to bare metal. Use fine sandpaper or emery paper to clean flat surfaces or wire. (Note, no amount of cleaning will allow you to solder to aluminum. When making a connection to a sheet of aluminum, you must connect the wire by a solder lug or a screw.)

When preparing wires, remove the insulation with wire strippers or a pocketknife. If using a knife, do not cut straight into the insulation; you might nick the wire and weaken it. Instead, hold the knife as if you were sharpening a pencil, taking care not to nick the wire as you remove the insulation. For enameled wire, use the back of the knife blade to scrape the wire until it is clean and bright. Next, tin the clean end of the wire. Now, hold the heated soldering-iron tip against the under surface of the wire and place the end of the rosin-core solder against the upper surface. As the solder melts, it flows on the clean end of the wire. Hold the hot tip of the soldering iron against the under surface of the tinned wire and remove the excess solder by letting it flow down on the tip. When properly tinned, the exposed surface of the wire should be covered with a thin, even coating of solder.

How to solder

The two key factors in quality soldering are time and temperature. Generally, rapid heating is desired, although most unsuccessful solder jobs fail because insufficient heat has been applied. Be careful; if heat is applied too long, the components or PC board can be damaged, the flux may be used up and surface oxidation can become a problem. The soldering-iron tips should be hot enough to readily melt the solder without burning, charring or discoloring components, PC boards or wires. Usually, a tip temperature about 100°F above the solder melting point is about right for mounting components on PC boards. Also, use solder that is sized appropriately for the job. As the cross-section of the solder decreases, so does the amount of heat required to melt it. Diameters from 0.025 to 0.040 inches are good for nearly all circuit wiring.

Always use a good quality multi-core solder. A standard 60% tin, 40% lead alloy solder with cores of non-corrosive flux will be found easiest to use. The flux contained in the longitudinal cores of multi-core solder is a chemical designed to clean the surfaces to be joined of deposited oxides, and to exclude air during the soldering process, which would otherwise prevent these metals coming together. Consequently, don't expect to be able to complete a joint by using the application of the tip of the iron loaded with molten solder alone, as this usually will not work. Having said that, there is a process called tinning where conductors are first coated in fresh, new solder prior to joining by a hot iron.

Solder comes in gauges like wire. The two most common types of solder, are 18 ga., used for general work, and the thinner 22 ga., used for fine work on printed circuit boards.

A well-soldered joint depends on

1. Soldering with a clean, well-tinned tip.
2. Cleaning the wires or parts to be soldered.
3. Making a good mechanical joint before soldering.
4. Allowing the joint to get hot enough before applying solder.
5. Allowing the solder to set before handling or moving soldered parts.

Making a good mechanical joint

Unless you are creating a temporary joint, the next step is to make a good mechanical connection between the parts to be soldered. For instance, wrap the wire carefully and tightly around a soldering terminal or soldering lug, as shown in Figure 3-7. Bend wire and make connections with long-nosed pliers. When connecting two wires together, make a tight splice before soldering. Once you have made a good mechanical contact, you are ready for the actual soldering.

The next step is to apply the soldering iron to the connection, soldering the connection as shown.

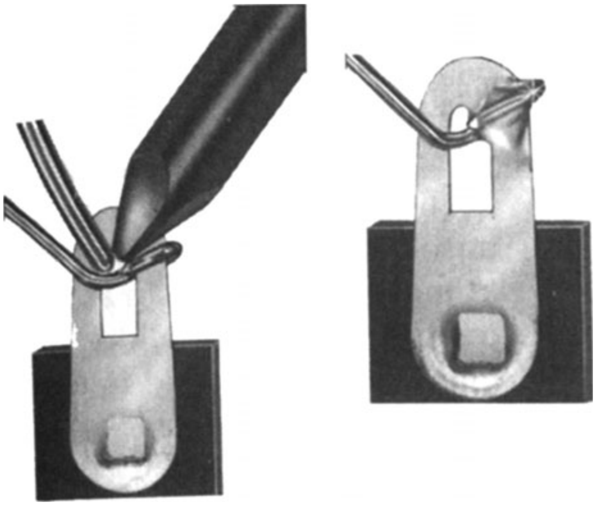

Figure 3-7 *Wire to lug soldering joint*

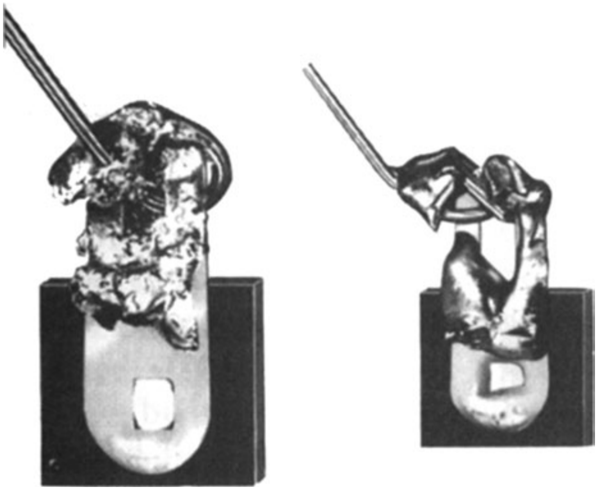

Figure 3-8 *Inferior wire to lug solder joint*

In soldering a wire splice, hold the iron below the splice and apply solder to the top of the splice. If the tip of the iron has a bit of melted solder on the side held against the splice, heat is transferred more readily to the splice and the soldering is done more easily. Don`t try to solder by applying solder to the joint and then pressing down on it with the iron. Be sure not to disturb the soldered joint until the solder has set. It may take a few seconds for the solder to set, depending upon the amount of solder used in making the joint. Now take a good look at the joint. It should have a shiny, smooth appearance—not pitted or grainy. If it does have a pitted, granular appearance as seen in Figure 3-8. reheat the joint, scrape off the solder, and clean the connection. Then start over again. After the solder is well set, pull on the wire to see if it is a good, tight connection. If you find that you made a poor soldering job don't get upset, be thankful you found it and do it over again. A quick reference solder check list is shown in the listing in Table 3-3.

Soldering printed circuit boards

Most electronic devices use one or more printed circuit (PC) boards. A PC board is a thin sheet of fiberglass or phenolic resin that has a pattern of foil conductors "printed" on it. You insert component leads into holes in the board and solder the leads to the foil pattern. This method of assembly is widely used and you will probably encounter it if you choose to build from a kit. Printed circuit boards make assembly easy. First, insert component leads through the correct holes in the circuit board. Mount parts tightly against the circuit board unless otherwise directed. After inserting a lead into the board, bend it slightly outward to hold the part in place.

When the iron is hot, apply some solder to the flattened working end at the end of the bit, and wipe it on a piece of damp cloth or sponge so that the solder forms a thin film on the bit. This is tinning the bit.

Table 3-3
Soldering check list

1. Prepare the joint. Clean all surfaces and conductors thoroughly with fine steel wool. First, clean the circuit traces, then clean the component leads.
2. Prepare the soldering iron or gun. The soldering device should be hot enough to melt solder applied to the tip. Apply a small amount of solder directly to the tip, so that the surface is shiny.
3. Place the tip in contact with one side of the joint, if possible place the tip below the joint.
4. Place the solder against the joint directly opposite the soldering tool. The solder should melt within two seconds; if it takes longer use a larger iron.
5. Keep the soldering tool against the joint until the solder flows freely throughout the joint. When it flows freely the joint should form a concave shape; insufficient heat will form a convex shape.
6. Let the joint cool without any movement, the joint should cool and set-up with in a few seconds. If the joint is moved before it cools the joint will look dull instead of shiny and you will likely have a cold solder joint. Re-heat the joint and begin anew.
7. Once the iron is set aside, or if it loses its shiny appearance, wipe away any dirt with a wet cloth or wet sponge. When the iron is clean the tip should look clean and shiny. After cleaning the tip apply some solder.

Melt a little more solder on to the tip of the soldering iron, and put the tip so it contacts both parts of the joint. It is the molten solder on the tip of the iron that allows the heat to flow quickly from the iron into both parts of the joint. If the iron has the right amount of solder on it and is positioned correctly, then the two parts to be joined will reach the solder's melting temperature in a couple of seconds. Now apply the end of the solder to the point where both parts of the joint and the soldering iron are all touching one another. The solder will melt immediately and flow around all the parts that are at, or over, the melting part temperature. After a few seconds remove the iron from the joint. Make sure that no parts of the joint move after the soldering iron is removed until the solder is completely hard. This can take quite a few seconds with large joints. If the joint is disturbed during this cooling period it may become seriously weakened.

The most important point in soldering is that both parts of the joint to be made must be at the same temperature. The solder will flow evenly and make a good electrical and mechanical joint only if both parts of the joint are at an equal high temperature. Even though it appears that there is a metal-to-metal contact in a joint to be made, very often there exists a film of oxide on the surface that insulates the two parts. For this reason it is no good applying the soldering iron tip to one half of the joint only and expecting this to heat the other half of the joint as well.

It is important to use the right amount of solder, both on the iron and on the joint. Too little solder on the iron will result in poor heat transfer to the joint, too much and you will suffer from the solder forming strings as the iron is removed, causing splashes and bridges to other contacts. Too little solder applied to the joint will give the joint a half finished appearance: a good bond where the soldering iron has been, and no solder at all on the other part of the joint.

The hard cold solder on a properly made joint should have a smooth shiny appearance and if the wire is pulled it should not pull out of the joint. In a properly made joint the solder will bond the components very strongly indeed, since the process of soldering is similar to brazing, and to a lesser degree welding, in that the solder actually forms a molecular bond with the surfaces of the joint. Remember it is much more difficult to correct a poorly made joint than it is to make the joint properly in the first place. Anyone can learn to solder, it just takes practice.

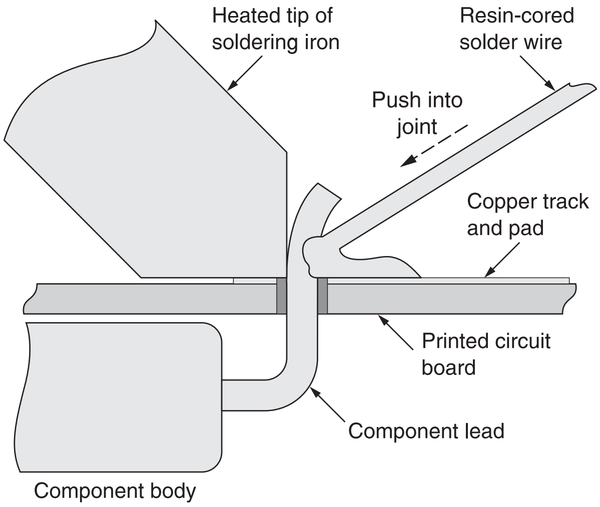

Figure 3-9 *Proper technique for soldering components on PC board*

The diagram in Figure 3-9 shows how to solder a component lead to a PC board pad. The tip of the soldering iron heats both the lead and the copper pad, so the end of the solder wire melts when it's pushed into the contact. The diagram illustrated in Figure 3-10 shows how a good solder joint is obtained. Notice that it has a smooth and shiny "fillet" of solder metal, bonding all around to both the component lead and the copper pad of the PC board. This joint provides a reliable electrical connection.

Try to make the solder joint as quickly as possible because the longer you take, the higher the risk that the component itself and the printed circuit board pad and track will overheat and be damaged. But don't work so quickly that you cannot make a good solder joint.

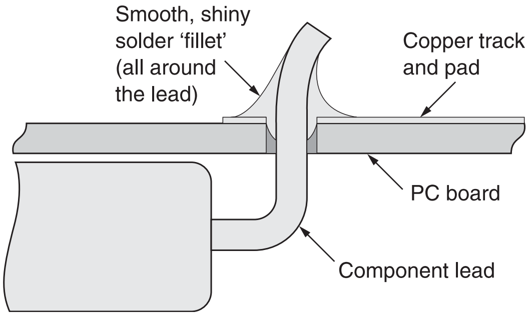

Figure 3-10 *Excellent solder joint*

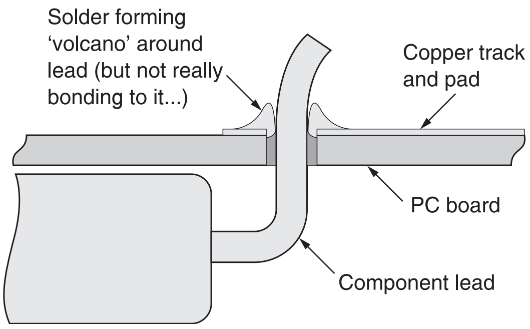


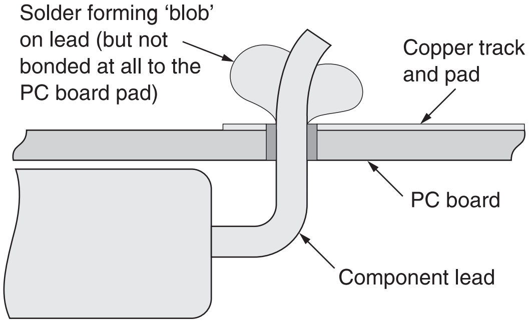
Solder forming 'volcano' around lead (but not really bonding to it...)
Copper track and pad
PC board
Component lead

Figure 3-11 *Inferior solder joint: Example 1*

Having to solder the joint over again always increases the risk of applying too much heat to the PCB.

As the solder solidifies, take a careful look at the joint you have made, to make sure there's a smooth and fairly shiny metal "fillet" around it. This should be broadly concave in shape, showing that the solder has formed a good bond to both metal surfaces. If it has a rough and dull surface or just forms a "ball" on the component lead, or a "volcano" on the PCB pad with the lead emerging from the crater, you have a "dry joint." If your solder joint looks like the picture shown in Figure 3-11, you will have to re-solder the joint over again. Figure 3-12 shows another type of dry solder joint which would have to be re-soldered. These types of "dry" solder joints if now redone will cause the circuit to be unreliable and intermittent.

For projects that use one or more integrated circuits, with their leads closely-spaced pins, you may find it easier to use a finer gauge solder, i.e. less than 1 mm in diameter. This reduces the risk of applying too much solder to each joint, and accidentaly forming "bridges" between pads to PC "tracks."



Solder forming 'blob' on lead (but not bonded at all to the PC board pad)
Copper track and pad
PC board
Component lead

Figure 3-12 *Inferior solder joint: Example 2*

The finished connection should be smooth and bright. Reheat any cloudy or grainy-looking connections. Finally, clip off the excess wire length, as shown in Figure 3-13.

Occasionally a solder "bridge" will form between two adjacent foil conductors. You must remove these bridges; otherwise a short circuit will exist between the two conductors. Remove a solder bridge by heating the bridge and quickly wiping away the melted solder with a soft cloth. Often you will find a hole on the board plugged by solder from a previous connection. Clear the hole by heating the solder while pushing a component lead through the hole from the other side of the board. Good soldering is a skill that is learnt by practice.

How to un-solder

In order to remove components, you need to learn the art of de-soldering. You might accidentally make a wrong connection or have to move a component that you put in an incorrect location. Take great care while un-soldering to avoid breaking or destroying good parts. The leads on components such as resistors or transistors and the lugs on other parts may sometimes break off when you are un-soldering a good, tight joint. To avoid heat damage, you must use as much care in un-soldering delicate parts as you do in soldering them. There are three basic ways of un-soldering. The first method is to heat the joint and "flick" the wet solder off. The second method is to use a metal wick or braid to remove the melted solder. This braid is available at most electronics

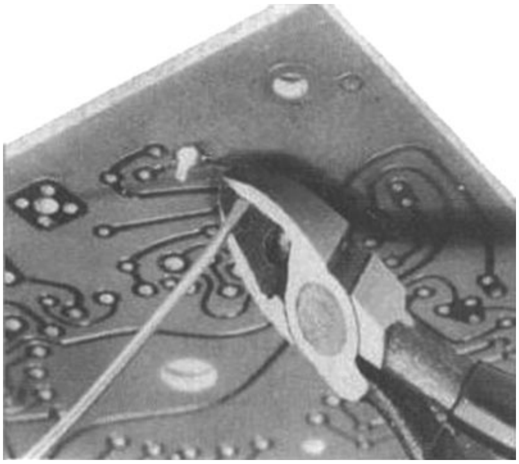


Figure 3-13 *Trimming excess component leads*

parts stores; use commercially made wicking material (braid). Place the braid against the joint that you want to un-solder. Use the heated soldering iron to gently press the braid against the joint. As the solder melts, it is pulled into the braid. By repeating this process, you can remove virtually all the solder from the joint. Then re-heat the joint and lift off the component leads. Another useful tool is an air-suction solder remover.

Most electronics parts stores have these devices. Before using a de-solder squeeze bulb, use your soldering iron to heat the joint you want to un-solder until the solder melts. Then squeeze the bulb to create a vacuum inside. Touch the tip of the bulb against the melted solder. Release the bulb to suck up the molten solder. Repeat the process until you've removed most of the solder from the joint. Then re-heat the joint and gently pry off the wires. This third method is easy, and is the preferred method, since it is fast and clean. You can use a vacuum device to suck up molten solder. There are many new styles of solder vacuum devices on the market that are much better than the older squeeze bulb types. The new vacuum de-soldering tools are about 8 to 12 inches long with a hollow Teflon tip. You draw the vacuum with a push handle and set it. As you re-heat the solder around the component to be removed, you push a button on the device to suck the solder into the chamber of the de-soldering tool.

De-soldering station

A de-soldering station is a very useful addition to an electronics workshop or workbench, but in many cases they just cost too much for most hobbyists. De-soldering stations are often used in production environments or as re-work stations, when production changes warrant changes to many circuit boards in production. Some repair shops used de-soldering stations to quickly and efficiently remove components.

Another useful de-soldering tool is one made specifically for removing integrated circuits. The specially designed de-soldering tip is made the same size as the integrated circuit, so that all IC pins can be de-soldered at once. This tool is often combined with a vacuum suction device to remove the solder as all the IC pins are heated. The IC de-soldering tips are made in various sizes; there are 8 pin, 14 pin and 16 pin versions, which are used to uniformly de-solder all IC pins quickly and evenly, so as not to destroy the circuit board. The specialized soldering tips are often used in conjunction with vacuum systems to remove the solder at the same time.

Remember these things when un-soldering:

1. Be sure there is a little melted solder on the tip of your iron so that the joint will heat quickly.
2. Work quickly and carefully to avoid heat damage to parts. Use long-nosed pliers to hold the leads of components just as you did while soldering.
3. When loosening a wire lead, be careful not to bend the lug or tie point. Use pieces of wire or some old radio parts and wire. Practice until you can solder joints that are smooth, shiny, and tight. Then practice un-soldering connections until you are satisfied that you can do them quickly and without breaking wires or lugs.

Caring for your soldering iron

To get the best service from your soldering iron, keep it cleaned and well tinned. Keep a damp cloth on the bench as you work. Before soldering a connection, wipe the tip of the iron across the cloth, then touch some fresh solder to the tip. The tip will eventually become worn or pitted. You can repair minor wear by filing the tip back into shape. Be sure to tin the tip immediately after filing it. If the tip is badly worn or pitted, replace it. Replacement tips can be found at most electronics parts stores. Remember that oxidation develops more rapidly when the iron is hot. Therefore, do not keep the iron heated for long periods unless you are using it. Do not try to cool an iron rapidly with ice or water. If you do, the heating element may be damaged and need to be replaced or water might get into the barrel and cause rust. Take care of your soldering iron and it will give you many years of useful service.

Remember, soldering equipment gets hot! Be careful. Treat a soldering burn as you would any other. Handling lead or breathing soldering fumes is also hazardous. Observe these precautions to protect yourself and others!

Ventilation

Properly ventilate the work area where you will be soldering. If you can smell fumes, you are breathing them. Often when building a new circuit or repairing a “vintage” circuit you may be soldering continuously for a few hours at a time. This can mean you will be breathing solder fumes for many hours and the fumes can cause you to get dizzy or lightheaded. This is dangerous because you could fall down and possibly hurt yourself in the process. Many people highly allergic are also allergic to the smell of solder fumes. Solder fumes can cause sensitive people to get sinus infections. So ventilating solder fumes is an important subject. There are a few different ways to handle this problem. One method is to purchase a small fan unit housed with a carbon filter which sucks the solder fumes into the carbon filter to eliminate them. This is the most simple method of reducing or eliminating solder fumes from the immediate area. If there is a window near your soldering area, be sure to open the window to reduce the exposure to solder fumes. Another method of reducing or eliminating solder fumes is to buy or build a solder smoke removal system. You can purchase one of these systems but they tend to be quite expensive. You can create your own solder smoke removal system by locating or purchasing an 8 to 10 foot piece of 2 inch diameter flexible hose, similar to your vacuum cleaner hose. At the solder station end of the hose, you can affix the hose to a wooden stand in front of your work area. The other end of the hose is funneled into a small square “muffin” type fan placed near a window. Be sure to wash your hands after soldering, especially before handling food, since solder contains lead; also try to minimize direct contact with flux and flux solvents.

Chapter 4

AM, FM, and Shortwave Crystal Radio Projects

Parts list

Simple Crystal Radio

L1 150 turns of 24 ga. enameled wire on 4″ × 2″ dia tube

C1 365 pF tuning capacitor (old radio)

D1 1N34 germanium diode (not a silicon diode)

C2 .005 µF, 35 volt disk capacitor

H1 high impedance headphones (crystal or 2000k type)

ANT 80–100 foot long wire antenna

GND cold water pipe or ground rod

Misc wood block, coil tube, hardware, screws, clips, washers, Krylon spray, wire, etc.

FM Crystal Radio Set

R1 47k ohm ¼ watt, 5% resistor

C1 82 pF capacitor

C2 80 pF air variable capacitor

C3 18 pF capacitor

D1 1N34 or rock crystal diode

L1 5 turns AWG #18 bare copper or silver wire, 12 mm inside diameter, tapped at 2.5 turns

H1 high impedance headphones (crystal type of 2k ohm type)

Ant antenna- 7″ of #18 bare copper wire

Misc wood block, wire, hardware, clips, etc.

Supersensitive AM/Shortwave Crystal Radio

L1 11 turns, 22 ga. enameled wire on 2⅞″ cardboard form

L2 (AM) 54 turns, 22 ga. enameled wire on 3″ air-core form

Taps are brought out at 40T, 27T, 15T and 6T

L2 (SW) 15 turns, 22 ga. enameled wire on 3″ air-core form

Taps are brought out at 12T, 9T, 6T and 3T

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

D1	germanium diode or galena crystal w/”cat’s whisker”
C1	500 pF turning capacitor
C2	.001 µF, 35 volt disk capacitor
S1	single-pole – 5-position rotary switch
S2	single-pole - 6-position rotary switch
H1	crystal headphone or 2k headphones (Baldwin, Brandes)
ANT	80–100 foot long wire antenna
GND	cold water pipe or ground rod
Misc	wood block, hardware, wire, clips, screws, Krylon, etc.

A crystal radio is the simplest form of AM (amplitude modulation) receiver ever invented. It has great potential for experimentation and usually requires no source of power for its operation other than the radio signal itself, and costs little. Most people do not realize that crystal radios can be built to pickup shortwave as well as FM radio signals. Did you know that you can build very sensitive and selective crystal radios far better than most commercial AM radios! Ever thought of building a crystal radio? Building a crystal radio will give you immense satisfaction, and the results are sure to please.

Crystal sets date back to the earliest days of wireless (pre-W.W.I) and an enormous variety of circuit designs have been produced over the years. Their popularity has been variable as developments in other more elaborate forms of reception have taken place. However, fascination with this crystal radio design, building and experimentation, is still very strong today with national and international organizations and clubs offering competitions.

So how does a crystal radio work? An AM transmitter sends out its broadcast in the form of an electromagnetic wave that radiates from its transmitting antenna. The AM transmitter sends out a fixed frequency carrier wave. When sound is present in the program material, the strength, or amplitude, of these waves is made to vary in response to the audio content of the program. The resulting wave is called an amplitude modulated wave. See Figure 4-1.

The purpose of a simple AM or crystal radio receiver is to pick up these AM waves and extract the audio signal so that it can be heard by the listener. It does this by a process called “detection.” The detection process utilizes a device called a detector which effectively strips off either the upper half or lower half of the AM wave. It only remains to filter out the carrier wave to leave the audio signal and the job is done! The following diagram shows how the detector and filter work together to “recover” the original audio signal. The strength of the recovered audio signal is small but, given the right conditions, it can be large enough to drive a pair of headphones; all without any power source other than the signal itself.

The diagram shown in Figure 4-2 illustrates a basic crystal radio. In its simplest form, a crystal radio is composed of just our main components. A good antenna, a detector, a filter capacitor and pair of headphones. The basic diagram shows the input section at (A), the rectifier section at (B), the filter section at (C) and finally the headphones at section (D).

The antenna consists of a length of wire suspended above the ground, while the ground or earth connection could be a metal spike driven into the ground. When a

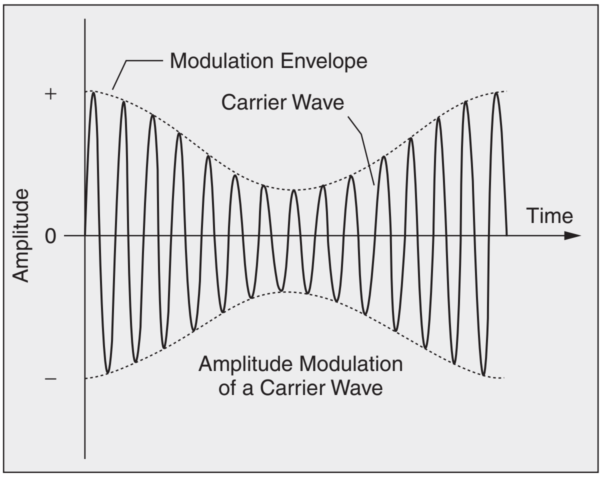

Figure 4-1 *Amplitude modulation*

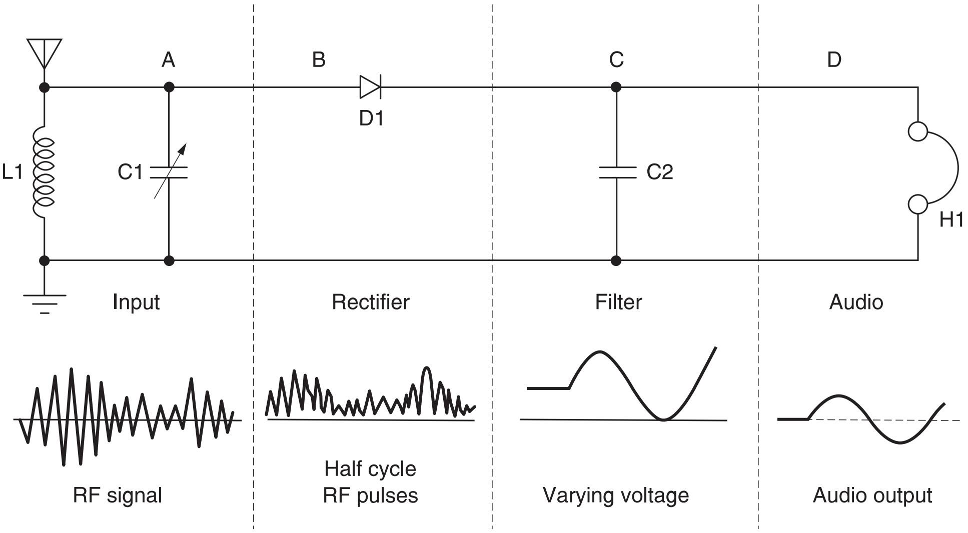

Figure 4-2 *Basic crystal radio*

capacitor is connected in parallel with an inductor and an alternating voltage applied across the combination, alternating current will flow. The amount of current that flows depends upon the frequency of the applied voltage. At a particular frequency, called the resonant frequency, almost no current flows. For frequencies above or below the resonant frequency, significant current will flow. In Figure 4-2, capacitor C1 plus the aerial capacitance forms the capacitor of our tuned circuit, while L1 forms the inductor. At the resonant frequency of the tuned circuit, almost no current flows to earth through L1 or C1, leaving virtually all of it free to flow through the detector. Alternating currents at broadcast frequencies either above or below the resonant frequency will tend to flow through C1 or L1 to earth. Thus we have added selectivity to the receiver. Notice that C1 is adjustable, as signified by the arrow. By varying C1 we can tune the receiver to select specific broadcast frequencies.

The main requirement for a detector is that it should act as a non-return "valve" or one-way "switch" to the alternating currents of the AM wave. If you could look at the alternating current in a circuit you would see it flowing back and forth, first one way and then the other. A detector placed in such a circuit allows the alternating current to flow easily in one direction but not in the other. Certain naturally occurring minerals were found to have this property and these became some of the earliest forms of detectors. One such mineral, the crystalline form of galena (lead sulphide), was found to be particularly good at detection, and became very popular for building crystal radios. The detector consists of galena in a small cup or tin. A small coil of wire, with one free end was called the "cat's whisker" which was used to make contact with the crystal.

The remaining uni-directional current is filtered by the combined effect of the headphone impedance and the capacitor at C2 and only the desired audio signal current passes on through to the headphones at H1. One drawback with the very simple circuit shown is that it has little selectivity. That is, it picks up all AM broadcast signals with similar efficiency and often close together. So as time passed more advanced, more sensitive and more selective receivers were born.

Let's construct a simple crystal radio. In order to build the crystal radio shown in Figure 4-3, you will need to secure some tools and supplies. First you will need to find a clean well lit work bench or table to spread out all your tools, charts, diagrams and components. You will also need to secure a soldering iron, some 60/40 rosin core solder and a small jar of "Tip Tinner," a soldering iron tip cleaner/dresser, obtainable from your local Radio Shack store. You will also want to locate some small tools such a pair of end-cutters, a pair of needle-nose pliers, a magnifying glass and a set of Phillips and flat-blade screwdrivers for this project. Grab the crystal radio schematic, see Figure 4-2, and the resistor and capacitor identification charts, and place them in front of you, so we can get started building the project. The resistor identification chart in Table 4-1 will help you

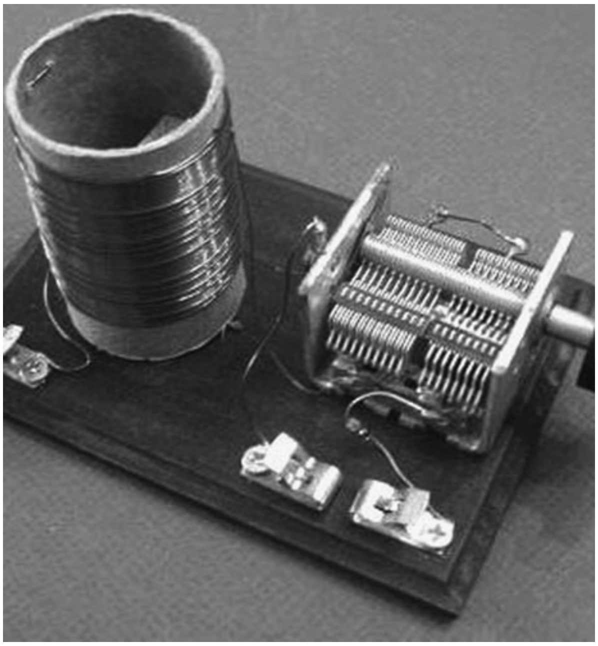

Figure 4-3 *AM crystal radio*

identify resistors needed for the some of the projects in this chapter. Each resistor will have three or four colored bands on the body of the resistor. These colors identify the resistor's value. The color bands start at one end of the resistor, the first colored band is the first digit of the resistor's value, while the second resistor represents the resistor's second digit of the value. The third colored band is the resistor's multiplier value. For example, a resistor whose first color band is yellow represents a digit four (4), while a second color band which is violet is seven (7). If the third color band is orange, then the multiplier would be (000) or one thousand, so the value would be 47,000 or 47k ohms. Resistors usually have a fourth colored band which represents the resistor's tolerance value. A silver band denotes a 10% tolerance value, while a gold band denotes a 5% tolerance resistor. No color band represents a tolerance value of 20%.

Our crystal radio projects in this chapter all utilize capacitors of some sort. Capacitors usually are available in two major classifications, polarized and non-polarized. The project in this chapter will utilize only non-polarized capacitors. Non-polarized capacitors can often be physically very small and not have their actual value printed on the body of the capacitor, so a chart was developed to help identify a capacitor using a three-digit code. See Table 4-2.

As this project will not require a circuit board, we will build the crystal radio on a 6″ × 6″ × ¾″ wood block base. You can elect to use an additional piece of wood at a right angle to the base as a front panel to secure the tuning capacitor as shown in Figure 4-3.

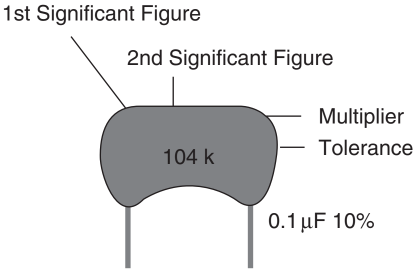
Table 4-1
Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000	
Blue	6	6	1,000,000 (M)	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No color				20%

Table 4-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.



CSGNetwork.Com 6/4/92

Value	Type	Code	Value	Type	Code
1.5 pF	Ceramic		1,000 pF /.001 µF	Ceramic / Mylar	102
3.3 pF	Ceramic		1,500 pF /.001 5µF	Ceramic / Mylar	152

820 pF	Ceramic	821	2	Mylar	205

Next, you will need to locate a plastic or cardboard tube approximately 3½ to 4″ long by 2″ in diameter on which to wind your coil. Punch a hole at both ends of the tube about ½″ from the actual end of the tube. Start winding the coil at one end of the tube using #24 ga. enameled wire, leave about 6″ of wire free at the first hole to allow connection to the circuit. Wind the coil with each winding touching the previous winding but not overlapping the prior winding. Wind about 150 turns of wire across the length of the tube. After winding about 150 turns take the free end of the remaining wire and put it through the last punched hole, leave about 6″ of wire so you can connect the coil to the circuit. When you are finished winding the coil, you can varnish the coil winding or just spray Krylon around the coil to keep the winding close to the coil, so they won't spread out or come loose. Fasten the coil to a 6″ × 6″ wood block; you can mount the coil upright as shown in Figure 4-3, or you can lay the coil down near one edge of the wood block and secure it to the block with some brackets or clips. You will have to use a knife and scrape off the enameled insulation of the two coil wires before you can fasten or solder them to the tuning capacitor. Now fasten the tuning capacitor to the wood block near the coil assembly, and wire the coil in parallel with the tuning capacitor. Next locate a germanium diode; make sure you use only a germanium diode and not the more common silicon diode. Remember to observe the correct polarity when connecting the diode in the circuit, the black to white colored band is the cathode lead. The cathode end of the diode points to the headphone in the circuit diagram. The anode side of the diode connects to one end of the "tank" or coil/capacitor and the cathode side of the diode connects to capacitor C2 and one end of the high impedance headphones. The free end of the headphones connects to the remaining end of the capacitor at C2 which connects to the free end of the "tank" circuit. You can connect the headphones via a terminal strip, a Fahnestock clip or headphone jack mounted on the wood block. Crystal radios generally require high impedance headphones, so you must use either a small crystal headphone or a pair of older high impedance (2000) ohm headphones; these are still available through EBAY or from Antique Electronics.

You could elect to build the radio using a galena crystal, with a "cat's whisker" instead of the germanium diode to give the radio an "old-time" look if desired: see the Appendix for Antique Radio Supply.

Connect an antenna and a ground wire to rod in the ground or an electrical ground in your house and your crystal radio will be ready to test out. The ground wire can be attached to a metal cold water pipe, or to a metal rod stuck a couple of feet into the earth. Do not attach it to a line carrying gas or electricity. The crystal radio will operate forever without a power supply, but you do need a good antenna to make the radio work well. The simplest outdoor antenna for receiving signals is a horizontal wire with the lead-in wire to the set connected on one end. An insulated wire 50 to 100 feet long placed as high and clear of surrounding objects as possible works best: see Figure 4-4. Both ends of the antenna should have insulators and rigid support. Tree branches are not good because they sway in the wind. If you use a tree trunk, have slack in the wire so it can move without pulling the wire. Keep the antenna wire far away from chimneys, metal roofs, gutters, drain pipes, telephone, and especially power lines. The antenna and lead-in should be one continuous piece of wire. Use stranded copper wire, with only the lead-in extending beyond the insulator. A lightning arrestor and ground wire should also be used to avoid a direct hit by lightning.

A crystal radio will generally be able to detect radio signals within 25 to 35 miles, during the day and often much further at night. A simple crystal radio is not very selective, if there are many local AM radio stations that are close in frequency, then you may have some trouble tuning them in, and you may have to build a more selective radio, such as the All-Wave model below. The crystal radio project above is a great project for demonstrating the principles of AM radio and the fun and excitement of building a crystal radio or "free-power" radio.

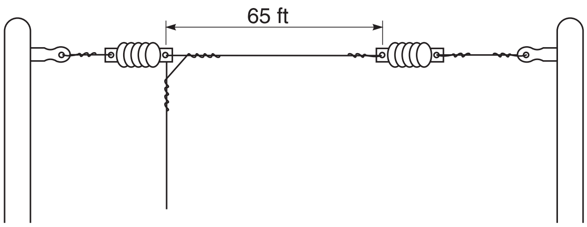

Figure 4-4 *Basic long-wire antenna*

FM radio crystal radio

Believe it or not, you can actually create a simple FM radio crystal radio. An FM crystal receiver is depicted in Figure 4-5. The key to understanding how this simple circuit can decode FM signals is to understand what happens when an FM signal is coupled to a tuned circuit. A good tuned circuit (one with a high "Q factor") will attenuate signals that are not near its resonant frequency. If you apply an FM signal to a good tuned circuit, as the frequency of the FM signal moves away from the resonant frequency of the tuned circuit, the tuned circuit will attenuate that signal. As the frequency of the FM signal moves toward the resonant frequency of the tuned circuit, the tuned circuit will let more of the signal pass through. Thus, a tuned circuit will impose amplitude changes on an FM radio signal that match the frequency changes. A crystal diode is sensitive to amplitude changes, so it converts the amplitude changes into a signal that the listener can hear through headphones.

Using a tuned circuit to induce amplitude changes onto an FM signal, then converting the amplitude changes to sound frequencies, is called slope detection. "Slope" refers to the slope of the tuned circuits' attenuation curve. If you have an AM receiver you can listen to an FM signal by using the *slope* of the tuned circuits in the receiver. This *slope tuning* method gives you none of the real advantages of FM. For instance, FM is noted for its immunity to static. An AM receiver used to slope detect will hear static. The only real advantage to slope detection is that is can be cheap and convenient. When tuning in an FM signal with an AM receiver, the clearest sound occurs when the FM center frequency is offset from the center frequency of the receiver's tuned circuits. If the FM signal is at the receiver's center frequency, then frequency deviations both up and down produce downward amplitude changes. When the FM signal is off center frequency, up and down frequency changes create up and down amplitude changes in the receiver.

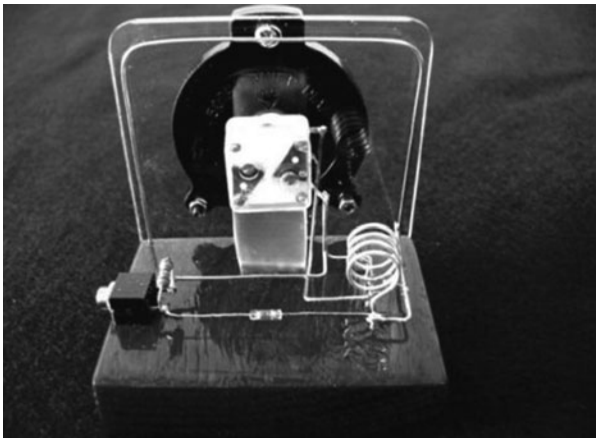

Figure 4-5 *FM crystal radio*

The FM crystal receiver circuit, shown in Figure 4-6, looks almost identical to a classic AM crystal circuit; but look closely, there are a few major changes. The FM crystal radio is relatively easy to build and can be built on a small block of wood as shown. The components values for the "tank" or resonant circuit were reduced to resonate at higher frequencies in the FM band. This was done by experimenting with smaller and smaller coils and capacitors values. The antenna is also much reduced in size (from that of AM crystal radio) to resonate at higher frequencies. The antenna is actually a 7″ long bare copper wire. The coil at L1 is just four turns #18 copper or silver wire, 12 mm inside diameter, tapped at 2.5 turns, The coil was wrapped around a "magic marker," then slipped off and expanded. As you can see, this is far different than the 150 turn coil for the AM crystal radio. The detector diode, once again, is a 1N34 germanium diode and not a silicon diode, or you could use a galena crystal as a detector if you desire. Capacitor C3 is 18 pF, but is not critical and can be 10 to 50 pF. Resistor R1 is a 47k ohm, ¼ watt, 5% carbon composition type. The air variable capacitor, used in the prototype, was an 80 pF variable type and it had two trimmers in it which should be adjusted for best reception.

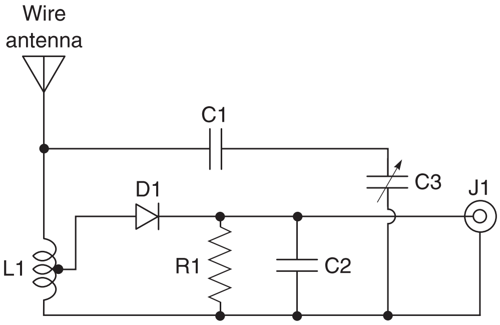

Figure 4-6 *Simple FM crystal radio*

Commonly available vernier dial and knob will fit the tuning capacitor and will work nicely. When building the FM crystal radio it is important to keep the components physically close together and the wiring short as possible. You can build the FM crystal radio in an open style format on a wood or Lucite plastic sheet. You can make your receiver a work of art, and impress your friends with an FM crystal radio built from scratch. Note that you will have to use high impedance headphones for this receiver. A detected FM signal is converted to AM due to an effect called slope detection that modulates amplitude.

This FM crystal radio works best near the transmitter, reception seems fine up to 15 miles away. Secondly, the sound level is not very loud; a quiet room is best for listening. One must be willing to move the set around to find a location for the best reception of signals. If desired, you could connect the audio output of the FM set directly to an audio amplifier's fed to a small speaker.

Supersensitive AM/Shortwave crystal radio

There are several characteristics that make the difference between a good and a great receiver. One of these characteristics is sensitivity. Great receivers can pick up weak signals and amplify them into a useful output. A second characteristic is selectivity. Great receivers can separate signals so that only one is heard at a time. The third and final thing that separates good receivers from great receivers is fidelity. Great receivers not only pick up weak signals but can reproduce a signal without distortion. The last project in this chapter is the All-Wave, AM/Shortwave crystal radio. This All-Wave design takes the crystal radio concept a little further and provides a more sensitive and more selective radio for you to build and enjoy.

The All-Wave Crystal Radio is a supersensitive and selective AM and shortwave receiver; see Figure 4-7. The design of the All-Wave radio has been around since the early 1930s and is still a very efficient receiver design that is fun to build and use. The receiver will tune from below the AM broadcast band to around the 40 meter band, so you will be able to pickup international shortwave reception quite well. You will be surprised how well it performs with a good pair of high impedance headphones.

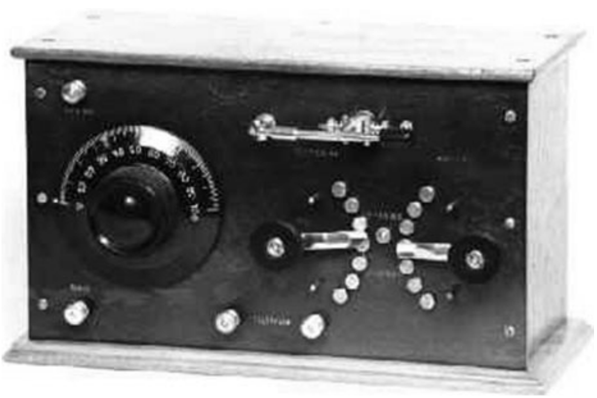

Figure 4-7 *Shortwave crystal radio*

The key to this efficient receiver's design lies with the two coils, L1 and L2, which are shown in the schematic at Figure 4-8. Coil L2 is a multi-tapped plug-in coil based on the band selected. For the AM radio band, L2 is the 54 turn multi-tapped coil, with tapped from the ground end at 6T, 15T, 27T and at 40T. The shortwave version of the L2 coil is a 15 turn multi-tapped coil with tapped at 3T, 6T, 9T, and 12 turns. Depending upon the band chosen, you simply plug in the AM or shortwave coil. The AM and shortwave coils (L2) were wound on a 3″ cardboard tube, but you could use a plastic form instead. The untuned primary coil (L1) was wound a slightly smaller 2 ⅞ form, so that it can be slipped inside of the L2 coil at the ground side of the coil assembly. The interchangeable coils (L2) were mounted on a non-metallic carrier, a piece of phenolic board with five pin-plugs secured to the carrier board. The coil form for L2 was glued to the phenolic carrier board which forms the plug-in coil assembly. The wire tapes are brought out to the five pin-plugs on the carrier board, so that the coil (L2) assembly can be plugged into sockets on the radio's wood base plate, see Figure 4-9. This will allow either the AM coil or the shortwave coil to be plugged into the crystal receiver. You could elect to build a fixed coil version of the crystal radio for either AM or shortwave reception if you desire, making the receiver a bit easier to build.

The detector for the All-Wave Crystal Radio can be either a 1N34 germanium diode or you could elect to

build the radio more like the "original" version by using a galena crystal with a "cat's whisker." The galena crystal and "cat's whisker" are still available, see Appendix. Be careful to install the diode or galena crystal with the proper orientation.

The original All-Wave receiver used a 500 pF tuning capacitor at C1, but you could also use a 365 pF type which are easier to locate from sources such as Antique Radio Supply. Mount the tuning capacitor to the wood block base using standoff and screws. The ceramic disk capacitor at C2 acts as an audio filter, ahead of the high impedance headphones.

The All-Wave receiver needs to be used with either a crystal earphone or a pair of dual high impedance (2K) headphones such as the old Baldwin or Brandes headphones which are still available via EBAY or from Antique Radio Supply, see Appendix.

Switches S1 and S2 are used to select the taps between the antenna and the detector. The two switches are labeled **Right** and **Left** as shown in the diagram. The same station may come in on several taps, but use the one which places the station lowest on the turning capacitor setting for the loudest signals. Move the **Right** (S2) forward or clock-wise, one to three taps before advancing the **Left** switch (S1). The efficiency of this radio seems to lie partly in the low loss coils, but mostly in the one basic change in the circuit, in which the detector is connected permanently to the last turn of L2 towards ground.

The All-Wave Crystal radio is just about completed and you now have only to connect a good antenna and ground for the receiver to spring-to-life! The All-Wave Crystal Radio should be connected to a good ground such as a cold water pipe or 6 to 8 foot copper ground rod pounded into the ground. The All-Wave receiver will perform best with an 80 to 100 foot insulated long-wire antenna placed up-in-the-air outdoors away from metal objects. An alternate antenna might be a 50 to 60 foot insulated wire strung around your attic, away from any metal objects. You will be amazed at how well this receiver will work with a good antenna and a good pair of high impedance headphones.

In the event that your new All-Wave Crystal Radio fails to work, you will have to re-check a few details. First check the diode and how it was oriented in the circuit, you may have placed it backward and this will prevent the receiver from functioning. You will also need to check the coil connections and placement of L1 with respect to coil L2. There is no polarity regarding coil L1, but its placement at the ground end of L2 is important in order for the receiver to work properly. Also check the connections to L2, you may have reversed two end wires of the coil, and this will prevent the radio from working as well. Try the receiver once more, hopefully all of the connections are right now and the receiver should work fine. Reconnect up your ground and antenna, put on your high impedance headphones and you'll be ready to listen to your new All-Wave receiver. You may want to have a "log" book close to your new radio to log down the far away stations you will receive with this radio. During nighttime hours, you will be able to receive stations much further away, and when the shortwave coil is plugged in you will hear international shortwave stations from all around the world on your new All-Wave receiver. Have fun with your new All-Wave crystal radio.

Chapter 5

TRF AM Radio Receiver

Parts list

TRF AM Radio Project

R1 120k ohm, ¼ watt, 5% resistor

R2 2.7k ohm, ¼ watt, 5% resistor

R3 10k ohm potentiometer (volume)

R4 10k ohm potentiometer (trim)

R5 820 ohm, ¼ watt, 5% resistor

R6,R9,R13 10k ohm, ¼ watt, 5% resistor

R7,R8 22k ohm, ¼ watt, 5% resistor

R10 150k ohm, ¼ watt, 5% resistor

R11,R12 4.7k ohm, ¼ watt, 5% resistor

C1 10 nF, 35 volt polyester capacitor

C2 500 pF tuning capacitor (variable)

C3 100 nF, 35 volt polyester capacitor

C4,C5 2.2 µF, 35 volt electrolytic capacitor

C6 33 µF, 35 volt electrolytic capacitor

C7 220 µF, 35 volt electrolytic capacitor

C8 2200 µF, 35 volt electrolytic capacitor

L1 220 µH coil; see text (Ocean State-LA-540)

D1,D2,D3,D4,D5,D6 1N4148 silicon diodes

Q1 BC108B-NTE123A transistor

Q2 BC109C-NTE123AP transistor

Q3 BC179C-NTE234 transistor

U1 ZN414 or MK484 - TRF Radio IC

U2 LM741 Op-amp IC

S1 SPST power switch

B1 9-volt transistor radio battery

SPK 8-ohm speaker or headphone

Misc PC board, chassis, battery holder, battery clip, wire, hardware

AM radio is the name given for the type of radio broadcasting used in the medium wave band in all parts of the world and in the long wave band in certain areas, notably Europe. Medium wave frequencies in the US range from 540 to 1710 kHz with 10 kHz spacing. The letters AM stand for amplitude modulation,

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

the technique by which speech and music are impressed on the radio waves. The sound waves from the studio are converted into electrical signals by the microphones, and these electrical signals are used to vary the amplitude, or the distance from 'peak' to 'trough' of the main constant frequency carrier wave generated at the transmitting station. As a result, the signal radiated by the station varies in amplitude in step with the variations in the loudness and pitch of the sound in the studio. In the receiver, the amplitude variations of the radio signal are separated from the carrier wave by a process known as demodulation, and after further amplification are fed to the loudspeaker.

Amplitude modulation is also used by international broadcasting stations operating in the shortwave band, and for some professional communications such as air traffic control, ship-to-shore traffic, and some mobile radio services.

AM radio stations in the medium wave or AM radio band can provide a service over an area the size of a town or of a whole continent, depending upon the power of the transmitter which can vary from less than a hundred watts to hundreds of kilowatts. Long wave AM radio stations cover even larger areas. Normally, all radio waves travel only in straight lines, which would limit a radio station to an area of only about 40 miles (65 km) in diameter—as far as the horizon. Medium and long wave stations can actually cover much larger areas because their signals are bent round the curvature of the Earth by the ionosphere (an electrically charged layer in the upper atmosphere which can reflect radio waves). In the US, where AM radio stations are operated on a commercial basis, coverage is generally and deliberately limited to one city and its environs. Major cities such as New York are served by large numbers of stations, each radiating a different program. AM radio stations in the US generally operate with omni-direction patterns during the day. In the evening many AM broadcasters switch to directional antenna beam patterns, and their broadcasts go much further due to ionospheric bending. This is why you can hear AM broadcast stations more distant in the evening.

AM radio first began with the experimental broadcast in 1906 by Reginald Fessenden, and was used for small-scale voice and music broadcasts up until World War I. The great increase in the use of AM radio came the following decade. The first licensed commercial radio services began on AM in the 1920s (the first licensed American radio station was started by Frank Conrad: KDKA in Pittsburgh, Pennsylvania). Radio programming boomed during the "Golden Age of Radio" (1920s–1950s). Dramas, comedy and all other forms of entertainment were produced, as well as broadcasts of news and music.

The quality of reproduction on AM radio is not as good as FM radio because of limitations in the amplitude modulation technique itself and because of overcrowding and subsequent interference in the medium wave band. Interference is particularly serious at night because the nature of the ionosphere alters after sunset, so that it can then reflect medium wave signals back to Earth a long way beyond their normal service area. Here, they interfere with other stations, producing whistles and other unwanted noises.

The AM method is still used for most popular broadcasting. Although the alternative FM radio system gives better quality, it is more difficult to receive, and is less suitable than AM for use in inexpensive transistor portables and car radios.

The most important concept in any communications system is the ability to send information from one place to another via a transmitter to a receiver, see Figure 5-1. This means you have to find a way to impress the audio signal information on the radio wave in such a way that it can be recovered at the other end. This process is known as modulation. In order to modulate a radio wave, you have to change either or both of the two basic characteristics of the wave: the amplitude or the frequency.

If you change the amplitude, or strength, of the signal in a way corresponding to the information you are trying to send, you are using a modulation system called amplitude modulation, or AM. The earliest means of radio communications was by Morse code, and the code key would turn the transmitter on and off. The amplitude went from nothing to full power whenever the key was pressed, a basic form of AM.

Modern AM transmitters vary the signal level smoothly in direct proportion to the sound they are transmitting. Positive peaks of the sound produce maximum radio energy, and negative peaks of the sound produce minimum energy.

The main disadvantage of AM is that most natural and man made radio noise is AM in nature, and

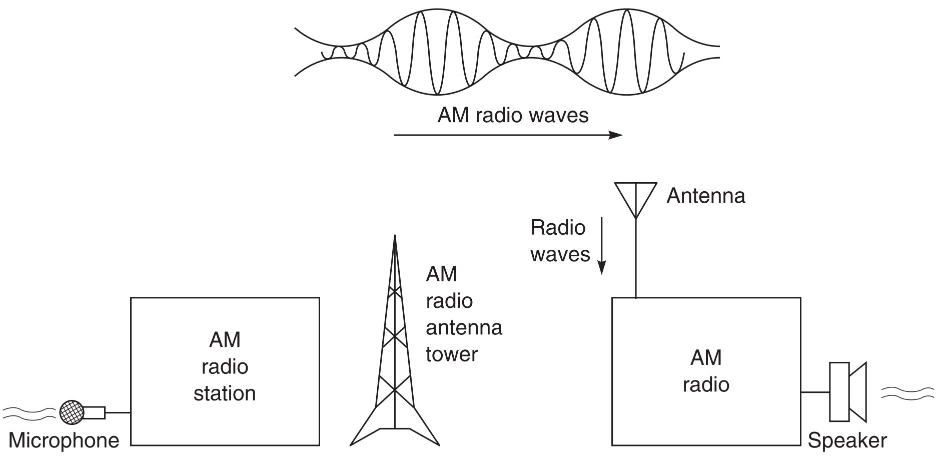

Figure 5-1 *AM broadcast system block diagram*

AM receivers have no means of rejecting that noise. Also, weak signals are (because of their lower amplitude) quieter than strong ones, which requires the receiver to have circuits to compensate for the signal level differences.

An AM radio station takes a low-frequency audio signal such as people talking or music (2500 Hz) and mixes it or superimposes on a high-frequency carrier wave (540 kHz), see Figure 5-2. It sends this radio signal out into the air as electromagnetic waves using a tall antenna. The electromagnetic wave travels through the air, going in all directions. At home, your AM radio takes this incoming signal, in a process called detection. With amplitude modulation it is simple. All you need to do is to rectify the signal, through a rectifier which removes the bottom half of every cycle. Essentially you are throwing away the high-frequency or carrier part, but keeping the low-frequency or audio part. At the output of the detector the original audio information is sent to the speaker in your radio. You then "hear" whatever was broadcast at the radio station.

The AM radio project that we are going to build in this chapter is called a TRF or tuned radio frequency type AM radio, see Figure 5-3. The TRF AM Radio design was at the forefront of radio design in the early 1920s. It utilized a tuned front end which allowed only RF energy of interest to be amplified by the RF amplifier, the signal was then passed on to the detector

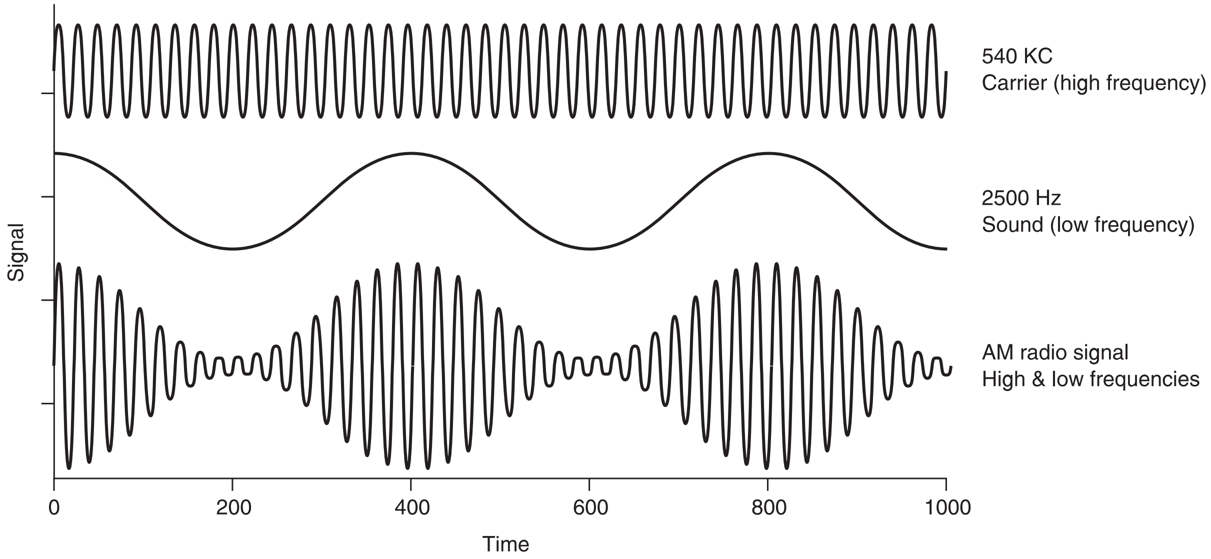

Figure 5-2 *AM carrier and modulation signals*

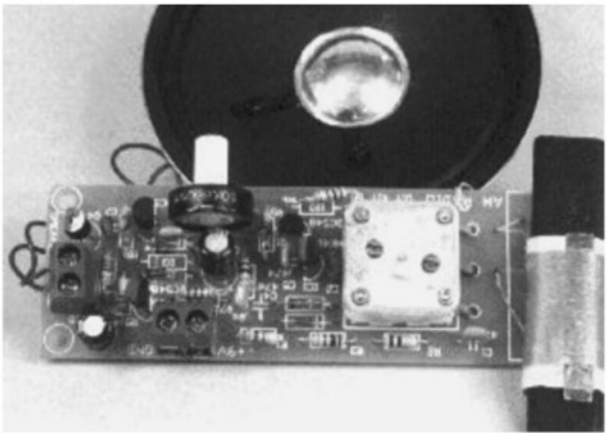

Figure 5-3 *AM TRF receiver*

followed by an audio amplifier to drive headphones. Early TRF radios had up to three controls for tuning the receiver, but later all three controls were consolidated into "tuning" control. Our modern day TRF receiver shown in the block diagram in Figure 5-4 illustrates the three major components of the AM TRF receiver. The first block consists of the tuned RF front-end resonant coil/capacitor, the second block consists of the MK484 IC, an integrated circuit RF amplifier and detector, and finally the third block, which is an audio amplifier.

The TRF AM radio project was designed around the popular MK484 TRF integrated circuit module, shown in Figure 5-5. This receiver covers the medium wave band or (AM) radio band from approximately 540 to 1700 kHz. The TRF front end consists of two components, the ferrite aerial coil and the tuning capacitor and the MK484 TRF IC. The important word is tuned, since this AM radio is called a TRF, or tuned RF radio All the AM signals reaching the radio are very weak. Only that signal which matches the TRF frequency is magnified by resonance so that it stands out at a very much higher level of signal strength. The original ZN414 IC, has now been replaced by the MK484, which is considerably easier to locate. The integrated circuit is a 3-pin, tuned radio frequency circuit, and incorporates several RF stages, automatic gain control and an AM detector. The receiver front-end is easily overloaded and the operating voltage of the IC is somewhat critical to achieve good results, but all-in-all the receiver is a great little radio for AM reception. The TRF radios were some of the first radios on the scene when the dawn of radio appeared in the early 1920s.

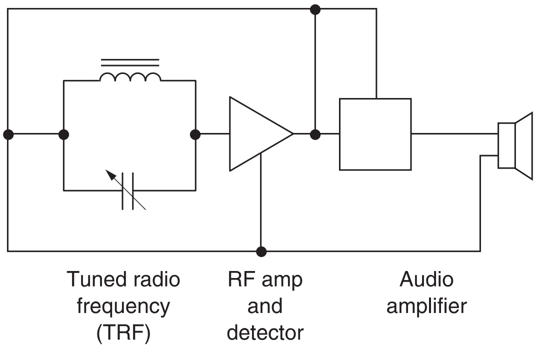

Figure 5-4 *TRF AM radio block diagram*

The front-end of the TRF receiver as mentioned consists of a tuned circuit composed of the ferrite inductor, a tuning capacitor and the TRF radio chip. A small square plastic 0-200 pF tuning capacitor was used for this radio project, but you could locate any suitable tuning capacitor within the range and it will work equally well. Often these small tuning capacitors will have additional on-board trimmer capacitors, but we used only the main tuning capacitor in the center of the device.

The second critical component of the TRF receiver is the coil at L1, which is wound on a ferrite bar. First, let's begin winding the coil at L1. The coil needs approximately 65 turns of #28 gauge enameled Litz wire on a 2½″ long ferrite rod. The windings should measure approximately 25 mm wide. Start winding the coil, close to one end, by securing the enameled wire by a piece of insulating tape. Leave approximately 100 mm for connection. The quality of reception is dependent upon the care taken in winding the antenna coil.

The signal reception will vary, dependent upon location, and is better away from large buildings that can distort the signal. Wind the wire tightly around the ferrite rod, taking care to keep the coil together and not to overlap the windings. To help hold the windings in place a piece of double-sided tape can be placed on the ferrite rod. Before soldering the antenna coil to the circuit board, you will need to scrape off the enamel coating from the ends of the wire. The two components L1 and C2 are connected in parallel to form an LC network. The Litz wire coil and the ferrite bar give the LC network a high "Q" or quality factor. This is important to the selectivity of the receiver, that is the ability to tune into one radio station at a time.

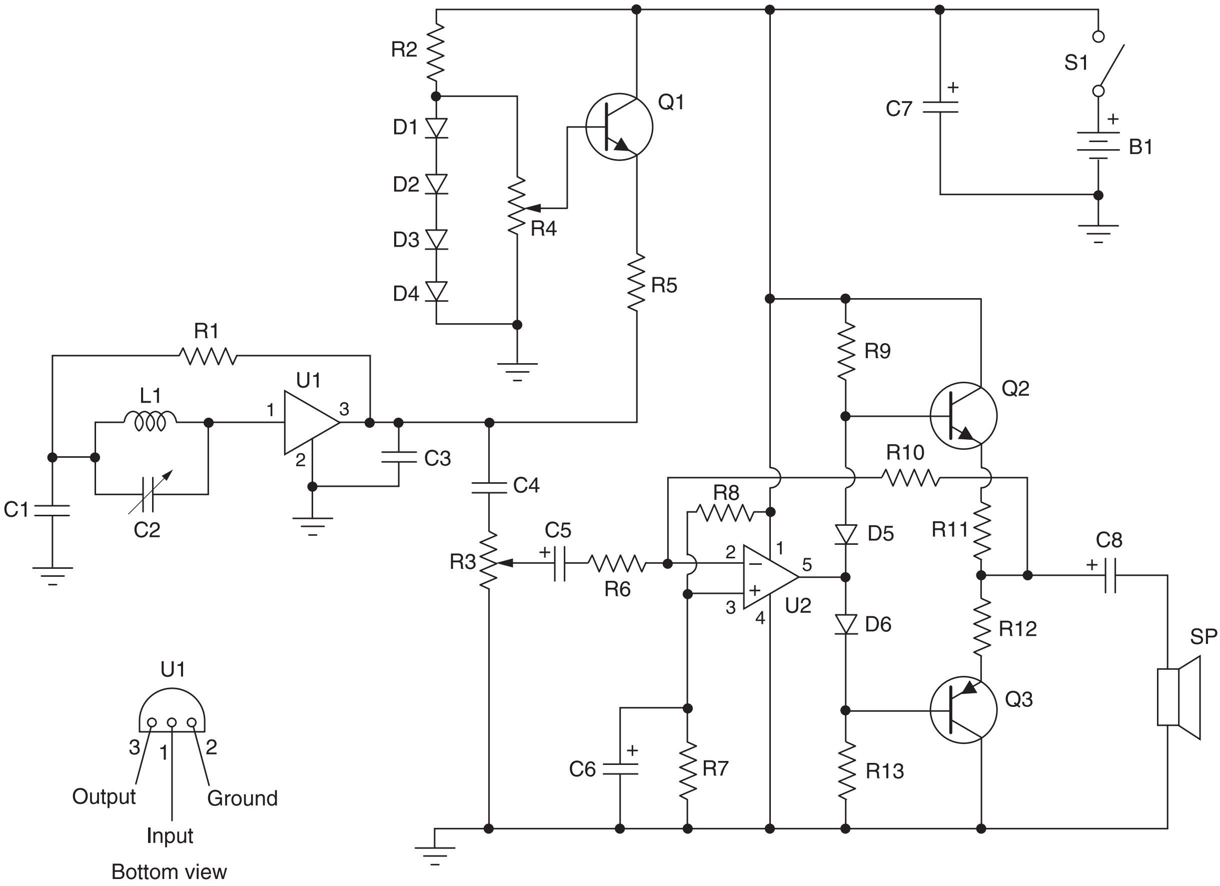

Figure 5-5 *TRF AM receiver broadcast band receiver*

The coil winding and the ferrite bar act as an efficient wire antenna, as no additional antenna is required. The only disadvantage is that the tuned circuit is directional and depends on the orientation of the bar with respect to the originating broadcast station. The coil winding and the ferrite bar act as an efficient wire antenna. No additional external antenna is needed. The only disadvantage is that the tuned circuit is directional. Signal strength depends on the orientation of the bar with respect to the origin of the signal. The coil and tuning capacitor may be taken from an old AM radio to save time, if desired.

The third main component of the TRF radio front-end is the TRF integrated circuit. The MK484 is a Japanese copy of the original ZN414. It contains an RF amplifier, active detector and automatic gain control (AGC to improve sensitivity) all in a 3-pin package. The input impedance is typically 4 M ohm. It operates over a range of 150 kHz to 3 MHz. DC supply of 1.1 V to 1.8 V and 0.3 mA current drain makes it ideal for battery operation. The output is typically 40–60 mV of audio signal. It is important to realize that the radio IC does not create any sounds by itself. It can only take the RF signal provided from the TRF circuit, amplify it, separate the audio signal from the RF (called detection) and pass the audio signal on to be amplified. It has no selective or rejection components contained in it. (This is in contrast to superhetrodyne receivers.)

In this circuit, a small voltage regulator is built around the BC108B transistor, four 1N4148 diodes, the 2.7k and 10k preset resistor and the 820 ohm resistor. The 10k pot acts as a selectivity control for the whole receiver, controlling the operating voltage for the ZN414 (or MK484). If you live in an area that is permeated with strong radio signals, then the voltage may need to be decreased. I found optimum performance with a supply of around 1.2 volts.

The audio amplifier is built around an inverting 741 op-amp amplifying circuit. Extra current boost is provided using the BC109C/BC179 complementary transistor pair to drive an 8 ohm loudspeaker. The voltage gain of the complete audio amplifier is around 15. The audio output of the complete receiver is really quite good and free from distortion. I used a small wooden enclosure and the complete tuning assembly from an old radio.

Before we begin the AM radio project, you will want to locate a well lit and well ventilated work space. You will want a large work table or work bench to spread out all you components, diagrams and tools. Locate a small pencil tipped 27 to 33 watt soldering iron and a roll of 60/40, 22 ga. tin/lead rosin core solder. If you don't have a jar of "Tip Tinner," a soldering iron tip conditioner/dresser, then you will want to go to a local Radio Shack store and purchase one. Place all the component parts in front of you along with the necessary project diagrams, so it will be easy to work with everything in front of you. Grab a few small tools, such as a pair of end-cutters, a pair of needle-nose pliers, a pair of tweezers, a magnifying glass, a small flat-blade, and small Phillips screwdriver. Once everything is right in front of you we can begin building the AM radio project. Warm up your soldering iron and we will begin. It is a good idea to use a circuit board for this project, since circuit boards provide a more reliable method used to build circuits: you could elect to use prototype construction or point-to-point wiring on a perf-board as an alternative.

Refer to the chart in resistor color chart in Table 5-1 and the capacitor code chart in Table 5-2. Resistors used in this project will be mostly carbon composition type resistors and potentiometers. Each resistor will have three or four color bands on the body of the resistor. The first band closest to one edge will be the first color which represents the first value. For example, a brown color band will signify the first digit as a one (1). The second color band represents the second digit value. So if the second color is red, then the value of the second digit would be two (2). The third color band is the multiplier value. So, if the third color is orange then the multiplier value would be (000), so the resistor value would be 12,000 or 12k ohms. Often there is a fourth color band which represents the tolerance value. No fourth band denotes a resistor with a 20% tolerance, a silver band denotes a 10% tolerance value, and a gold band represents a 5% tolerance value. Now refer the capacitor code chart. Many small capacitors are too small to have their full value marked on the body of the capacitor, so a three-digit code is used to represent the value.

Let's begin installing the project resistors now; find and identify a couple of resistors at a time. Once you are

Table 5-1
Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%

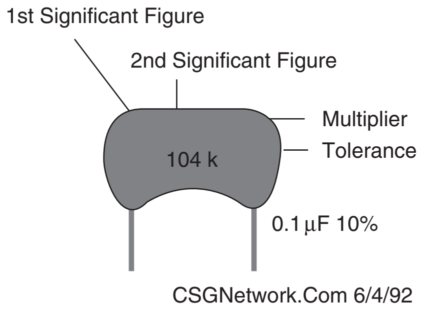
Silver			0.01	10%
No color				20%

Table 5-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.



Value	*Type*	*Code*	*Value*	*Type*	*Code*
1.5 pF	Ceramic		1,000 pF /.001 µF	Ceramic / Mylar	102
3.3 pF	Ceramic		1,500 pF /.0015 µF	Ceramic / Mylar	152

680 pF	Ceramic	681	.56	Mylar	564
750 pF	Ceramic	751	1	Mylar	105
820 pF	Ceramic	821	2	Mylar	205

sure you have correctly identified each resistor, and you know where each resistor is placed on the PC board, you can go ahead and install them on the circuit board. Solder the resistors in place and then trim the excess component leads with your end-cutters. Cut the excess component leads flush to the edge of the circuit board. Install the remaining resistors, solder them in place and remember to trim the excess leads from the board.

Next we will move on to installing the capacitors. This project uses two types of capacitors, small mica or polyester types and electrolytic types. The smaller capacitors may not have their actual value printed on them, but might have a three-digit code on them. Refer to the capacitor code chart to help identify each capacitor before installing them on the PC board. Slowly identify each capacitor and place it in the correct location on the circuit board. Solder these small capacitors in their respective locations after referring to the schematic and parts layout diagrams. This project also utilizes larger electrolytic capacitors. Electrolytic capacitors have polarity and this must be observed if the circuit is to work correctly. Take a look at one of the larger electrolytic capacitors and you will notice that it may have a black or white color band or a plus (+) or minus (–) marking on one side of the capacitor body. When placing these types of capacitors on the circuit board, be sure you have oriented the capacitor correctly. Install the electrolytic capacitors on the circuit board and solder them in place; remember to trim the excess component lead with your end-cutter.

Let's move on to installing the silicon diodes. The AM radio project uses six silicon diodes, and they too have polarity which must be observed. Each diode will have either a white or black band at one end of the diode's body. This band denotes the cathode lead of the particular diode. Refer to the parts layout and schematic diagram when installing the six resistors. Place the diodes on the circuit board and solder them in place on the board. Don't forget to cut the extra lead lengths.

Locate the semiconductor pin-out diagram shown in Figure 5-6. Now, go ahead and identify all three of the transistors for the project and install the transistors on the circuit board. There are two NPN types and one PNP type transistors in the AM radio project. Transistors usually have three leads, a Base lead, a Collector lead and an Emitter lead. The symbol for a transistor is a vertical line which is the Base lead and two lines running at 45°angles with respect to the Base lead. The angled lead with the arrow pointing towards or away from the Base lead is the Emitter lead and the remaining lead is the Collector lead. Be sure you can identify each of the transistor leads before placing them on the circuit board. Solder the transistors in place on

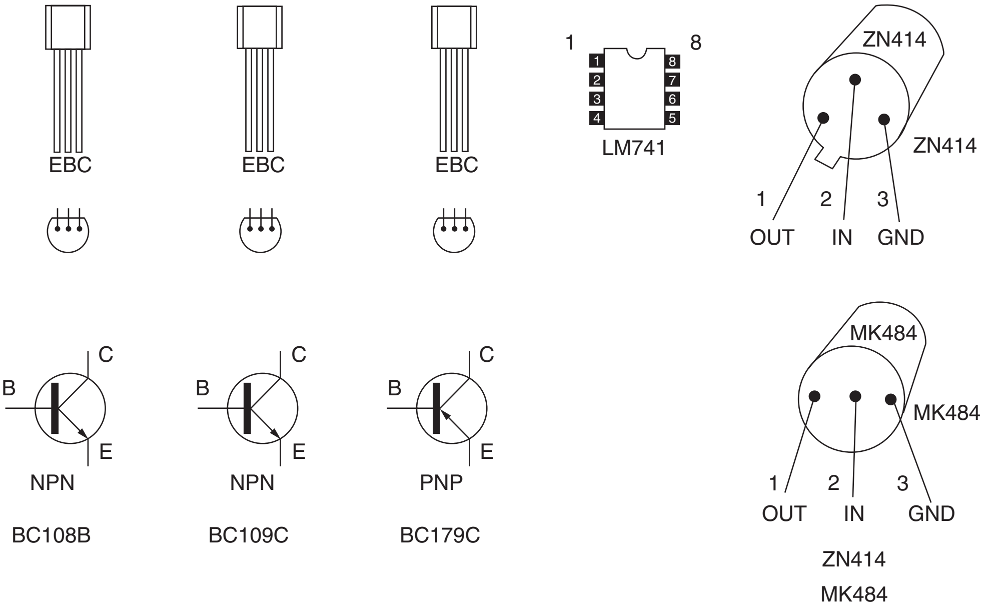

Figure 5-6 *Semiconductor pin-outs*

the circuit board; when finished remember to trim the excess component leads.

The ZN414 or MK484 TRF module looks very much like a common three-lead transistor. Carefully refer to the pin-out diagram for the MK484 before installing, in order to prevent damaging it upon power-up. One lead is the input lead from the tuned circuit. One lead is the ground lead and the remaining lead is the output lead which is directed to the actual circuit.

The AM radio project uses a single dual in-line integrated circuit, an LM471. We elected to use an IC socket as insurance against a possible circuit failure at some point in time. Integrated circuit sockets are inexpensive and make life easier in the event of a circuit problem, since it is much easier to unplug an IC rather than attempting to unsolder a multi-pin integrated circuit. Go ahead and solder-in a good quality IC socket for U2. Take a look at U2 and you will notice that at one end of the plastic package you will find a cut-out, notch or indented circle. Pin 1 of the IC will be just to the left of the notch or cut-out. Be sure to align pin of the IC to pin 1 of the IC socket, pin 1 of U2 is the null offset pin which is not used in this circuit. Note that pin 2 of U2 is the inverting input which is connected to the junction of R6 and R8.

Next locate the ferrite inductor coil or L1; you will notice that it is in parallel with the tuning capacitor C2. The parallel tuned circuit is placed between capacitor C1 and the input of U1, the MK484 TRF IC. These components are best placed at one end of the PC board if possible, or can be placed off the PC board on the front of your enclosure. Now, locate the volume control, the 10k ohm potentiometer; it is a chassis mounted control which can be mounted on the front panel of your enclosure.

Let’s wrap up the project. First you will want to solder the battery clip; note that the black wire of the battery clip will go to the circuit board minus or ground bus and the red battery clip wire will go in series with one post on the on-off switch at S1, the remaining post of the SPST toggle switch will connect to the Collector of Q1. Finally locate two 4″ pieces of #22 ga. insulated hookup wire. Bare both ends of the two wires, solder one end of each wire to the speaker leads. Now take one free wire end and solder it to the common ground of the circuit and then solder the remaining free wire end to the minus end of capacitor C8.

This completes the construction of the AM radio project. Let’s take a well deserved rest and when we return we will check the circuit board for possible “cold” solder joints and possible “short” circuits. Pick up the circuit board with the foil side facing upwards toward you. Look closely at the circuit board, first we will inspect the circuit board for possible “cold” solder joints. The solder joints should all look clean, shiny and bright. If any of the solder joints look dull, dark or “blobby” then you should remove the solder from that joint and re-solder the joint over again. Now pick up the circuit board once again and we will look for possible “short” circuits. “Short” circuits are usually caused from one of two reasons. The first cause of “short” circuits are loose solder “blobs” or solder balls which can sometimes stick to the circuit board. The second cause for “short” circuits is to have “stray” component leads stick to the foil side of the board. Rosin core solder residue can often be sticky and often solder “blobs” or “stray” component leads can bridge across circuit traces causing a “short” circuit. Look over the board and remove anything that looks like it might be bridging any circuit traces. Once the circuit inspection has occurred, you can prepare the circuit for its first test.

Connect up a fresh 9 volt battery to the AM radio circuit. Once the battery is connected to the circuit, you can “flip” the on-off switch to the on position and you should begin to hear some “hiss” from the speaker. If you do not hear anything, turn up the volume control to mid-position. At this point you should begin to hear some sounds from the speaker. Move the tuning capacitor control across the AM radio band and if all goes well you should begin to hear some local stations. Move the ferrite core coil or the circuit board around in a 360° pattern to see where the station is loudest. Hopefully the radio works fine without any further adjustments.

In the event that the AM radio circuit does not work at all, you will have to remove the battery from the circuit and inspect the circuit board one more time, but this time you will be looking for components placed incorrectly. Remember earlier, we talked about certain components have polarity such as diodes, electrolytic capacitors, transistors, etc. Now, you will need to inspect the PC board closely to see if you might have placed a component incorrectly. Its easy to make a mistake and insert a capacitor or diode incorrectly; it happens to professionals too! Another possible cause for failure is that you may have placed an IC incorrectly in the socket! Finally, it's easy to incorrectly install one of the transistors. Look at each transistor carefully, you may want to refer to the manufacturer's specification and/or pin-out information sheets along with the circuit layout and schematic diagram to confirm transistor pin-outs. Once you have inspected the circuit board for misplaced components and have corrected any mistakes, you can reapply power to the AM radio circuit and check out the circuit once again. Have fun listening to your new AM radio, you will have the great satisfaction of listening to the radio that you just built.

Chapter 6

Solid-State FM Broadcast Receiver

Parts list

FM Radio Receiver

R1,R15 4.7k ohm, ¼w, 5% resistor (yellow-violet-red)

R2,R18 1K resistor, ¼w, 5% resistor (brown-black-red)

R3,R16,R17 270 ohm, ¼w, 5% resistor (red-violet-brown)

R4,R11 47k ohm, ¼w, 5% resistor (yellow-violet-orange)

R5,R7,R8,R9,R14 10K, ¼w, 5% resistors (brown-black-orange)

R6 470 ohm, ¼w, 5% resistor (yellow-violet-brown)

R10 2.2k ohm, ¼w, 5% resistor (red-red-red)

R12,R13 10k ohm, potentiometers

R19 2 ohm, ¼w, 5% resistor (red-black-gold)

C1 4.7 or 5 pF, 35v disk capacitor (marked 5 or 5K)

C2,C3,C7,C8,C16,C18, .01 µF, 35v disk capacitor (marked .01 or 103 or 10 nF)

C4,5,15,27 .001 µF, 35v disk capacitor (marked .001 or 102 or 1 nF)

C6,C14 100 pF, 35v disk capacitor (marked 100, 101, or 101K)

C9,C17,C22,C26 4.7 or 10 µF, 35v electrolytic capacitor

C10,C13,C19 100 to 220 µF, 35v electrolytic capacitor

C11,C12 22 pF, 35v disk capacitor (marked 22)

C20,C21,C23,C24,C28,C29 .01 µF, 35v disk capacitor (marked .01 or 103 or 10 nF)

C25 .1 µF, 35v disk capacitor (marked .1 or 104)

FL1 10.7 MHz ceramic filter; Digi-Key Electronics

L1 slug tuned plastic molded coil

L2 10.7 MHz shielded can style IF transformer (421F122)

D1 varactor diode, 33 pF

D2 Zener diode, 6.2 volt

U1 ULN2111 or MC1357 IC

U2 LM386 IC

U3 SA602 IC

Q1,Q3 2N3904 NPN transistor

Q2 2SC2498 or 2SC2570A NPN transistor

B1 9 volt transistor radio battery

Misc PC board, battery holder, battery clip, RCA jacks

⅛″ earphone jack, wire, antenna

The FM broadcast receiver will permit you to listen to your favorite radio shows as well as allow you to tune outside of the standard FM broadcast band to “listen-in” to FM room bugs, FM mikes and other interesting hidden transmitters. The FM receiver could also be connected to an SCA adapter, so that you may listen to ‘MUSAK’ radio show used in stores and restaurants. The FM radio project is just plain fun and will teach you about FM radio theory.

The FM broadcast receiver demonstrates the basics of FM radio theory in one compact, simple circuit! Separate circuits are “sections” of the receiver, making it easy to visualize every function. The latest in IC circuitry is used in the FM receiver, which allows high performance.

The FM receiver project is designed to receive wide-band FM transmissions typical of FM broadcast stations, wireless mikes, and telephone transmitters or “bugs,” rather than Narrow Band FM transmissions (NBFM) as used on police or public service radios.

Why not build your own FM Broadcast receiver like the one shown in Figure 6-1. Not only will you learn how FM receiver works but you will be able to build and utilize your new FM radio. The FM receiver is great for listening to FM broadcasts and news as well as listening-in to commercial SCA—free music, stock quotes, sports, etc. The receiver has an SCA or sub-carrier output which can be fed into an SCA converter to allow this reception of these signals.

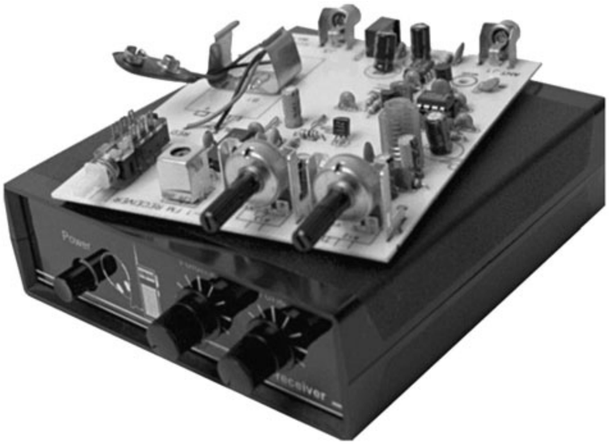

Figure 6-1 *FM receiver*

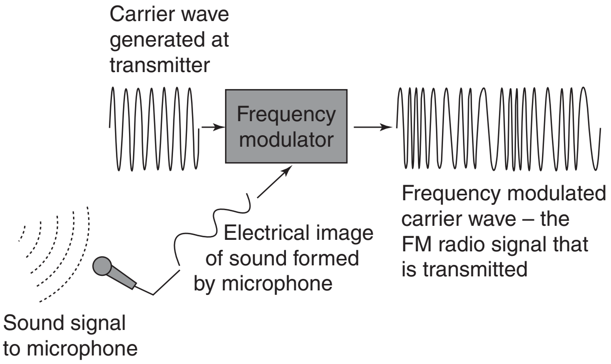
The receiver tunes from 70 to 110 MHz, ideal for tuning in out-of-band FM wireless mikes, “bugs” and other “hidden” transmitters. The FM receiver also features plenty of audio output, and operates from a standard 9 volt battery for truly portable operation.

FM modulation

Frequency modulation (FM) is a form of modulation which represents information as variations in the instantaneous frequency of a carrier wave. Contrast this with amplitude modulation, in which the amplitude of the carrier is varied while its frequency remains constant. In analog applications, the carrier frequency is varied in direct proportion to changes in the amplitude of an input signal. Digital data can be represented by shifting the carrier frequency among a set of discrete values, a technique known as frequency-shift keying. The diagram in Figure 6-2 illustrates the FM modulation scheme, the RF frequency is varied with the sound input rather than the amplitude.

FM is commonly used at VHF radio frequencies for high-fidelity broadcasts of music and speech, as in FM broadcasting. Normal (analog) TV sound is also broadcast using FM. A narrowband form is used for voice communications in commercial and amateur radio settings. The type of FM used in broadcast is generally



Carrier wave generated at transmitter
Frequency modulator
Frequency modulated carrier wave – the FM radio signal that is transmitted
Electrical image of sound formed by microphone
Sound signal to microphone

Figure 6-2 *FM modulation*

called wide-FM, or W-FM. In two-way radio, narrowband narrow-fm (N-FM) is used to conserve bandwidth. In addition, it is used to send signals into space.

Wideband FM (W-FM) requires a wider bandwidth than amplitude modulation by an equivalent modulating signal, but this also makes the signal more robust against noise and interference. Frequency modulation is also more robust against simple signal amplitude fading phenomena. As a result, FM was chosen as the modulation standard for high frequency, high fidelity radio transmission: hence the term "FM radio." FM broadcasting uses a well-known part of the VHF band between 88 and 108 MHz in the USA.

FM receivers inherently exhibit a phenomenon called capture, where the tuner is able to clearly receive the stronger of two stations being broadcast on the same frequency. Problematically, however, frequency drift or lack of selectivity may cause one station or signal to be suddenly overtaken by another on an adjacent channel. Frequency drift typically constituted a problem on very old or inexpensive receivers, while inadequate selectivity may plague any tuner. Frequency modulation is used on the FM broadcast band between 88 and 108 MHz as well as in the VHF and UHF bands for both public service and amateur radio operators.

FM receiver circuit description

The FM receiver block diagram in Figure 6-3 illustrates the fundamentals of FM reception. The schematic diagram of the FM broadcast receiver is depicted in Figure 6-4. FM broadcast signals captured by the whip antenna or from the input jack are applied to the RF amplifier Q2, a high gain, low noise microwave style transistor. Input signals are amplified about 100 times or equivalent to 20 dB. After being boosted, these input signals are routed to the SA602 mixer-oscillator chip for conversion down to the 10.7 MHz Intermediate Frequency (IF). The SA602 is a very popular chip used in a great variety of receivers from cellular telephones to satellite receivers. The reason for its popularity is that it contains most of a receiver's "front end" circuitry on a single, easy-to-use chip. Internal to the SA602 is an oscillator tuned by an external tank circuit; C11, 12, L1 and varactor diode D1. A varactor diode acts like a voltage variable capacitor and the voltage applied across it comes from tuning pot R12. This IF signal is an exact reproduction of the desired signal, but at 10.7 MHz. We then band-pass filter it with ceramic filter FL-1.

The ceramic filter allows only the desired 10.7 MHz signal to pass, rejecting any adjacent channel signals. Transistor Q1 amplifies the IF signal before it is applied to the detector chip U1.

One of the primary advantages of FM is that the program information (modulation) is contained in carrier frequency variations and not in amplitude changes like AM, which would be susceptible to noise and interference. This means that we can limit or clip the signal, thus removing any noise and not affecting the desired information. The first section of U1 performs this limiting function, providing high gain and clipping any amplitude (noise) variations. FM is detected in the second section using a process known as quadrature detection. We'll not get into this too deeply because it requires a knowledge of trigonometry identities—let's just say it extracts the frequency modulated program information. Capacitor C1 and coil assembly L2 comprise a phase shift network that is required by the quadrature detector. Demodulated signals are amplified and sent out through pin 1 to the volume control, AFC circuitry and the SCA buffer amp. The AFC circuitry is used to properly keep the receiver locked on to the tuned-in radio station. Resistor R9 and capacitor C17 filter out any audio voltage variations so that only major frequency changes will shift the tuning voltage to lock the frequency.

Audio signals from the volume control are amplified to speaker levels by U2, an LM-386 audio amplifier chip. Transistor Q3 provides a buffer stage to external SCA devices you may connect up to the receiver. SCA units decode (demodulate, actually) "hidden" audio and data services transmitted over standard FM broadcast channels. These services include stock quotes, sports scores, talk shows and even background music—commercial free!

Circuit assembly

Look for a clean well lit area in which to assembly your shortwave receiver. You will need a 27 to 30 watt pencil tip soldering iron, some 60/40 tin/lead rosin core solder. You will also need a few hand tools including a pair of end-cutters, needle-nose pliers, a few screwdrivers and a pair of tweezers to pick up small parts. You will want to locate a small jar of "Tip Tinner" from your local Radio Shack store. "Tip Tinner" is a soldering iron tip cleaner/dresser which is invaluable when soldering circuit board. Locate the schematic and layout diagrams and we will begin to construct your new shortwave receiver. Place the project circuit board in front of you and we will begin building the receiver.

Locate all of the resistors for the project and place them in front of you. Each resistor has a color code which describes its value. Check the color code against the parts list and schematic before installing them onto the circuit board. Refer to the resistor color chart in Table 6-1. Place about four or five resistors on the PC board and place these resistors in their respective locations carefully making sure each on is in the correct location. Let your soldering iron tip heat both the component lead wire and PC board trace enough so that the wire itself and the foil trace both become hot enough together to melt a bit of solder so that it flows smoothly from the component leads to the PC board trace. Now, go ahead and solder each of the resistors onto the circuit board. Trim off the excess component leads with and small pair of end-cutters. Pick up and identify the next grouping of resistors and install them on the circuit board, follow up by soldering this next batch of resistors to the circuit board, remember to trim the extra lead lengths form the PC board.

Once all the resistors have been installed on to the circuit board, we can move on to identifying all of the capacitors for the project. Note that there will be different looking capacitors for this project, some will be small disks, while others will be larger body devices with minus and plus marking on them. These larger capacitors with polarity marking are electrolytic capacitors and they have polarity which must be observed for the circuit to work correctly. Look through the parts pile and locate the capacitors and place them in front of you. You will notice a number of small disk capacitors, we will install these first. Look closely at each of the disk capacitors at their markings. Sometimes the capacitors are very small and they may not have their actual value printed on them but will instead have some sort of code. Refer to the parts list for these codes or the capacitor code chart Table 6-2. Locate four or five of these small disk capacitors, identify them and install them on the circuit board, while referring to the schematic and layout diagrams.

Table 6-1

Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000	
Blue	6	6	1,000,000 (M)	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No color				20%

After inserting the disk capacitors on to the circuit board, you can go ahead and solder them to the circuit board. Remember to cut the excess component leads. Next, move on and install another grouping of small disk capacitors, then solder them in place on the printed circuit board. Cut the extra component leads after soldering in the capacitors. When you are finished installing the small capacitors we will move on to the larger electrolytic types.

Next, we will identify and install the electrolytic capacitors. Electrolytic capacitors each have polarity markings on them in the form of a black band with either a plus or minus marking, which denotes the polarity of the device. You must pay particular attention to these markings in order for the FM receiver to work properly. Refer to the schematic and parts layout diagrams when installing C9, C17, C22 and C26, which are all 4.7 to 10 µF electrolytic capacitors. Install these four capacitors and solder them to the circuit board. Remember to trim the excess component leads. Cut the excess leads flush to the edge of the PC board with a pair of small end-cutters. Now locate and install electrolytic capacitors C10, C13 and C19, these are all 100 to 200 µF electrolytic types. After placing them on the PC board in their proper location and with respect to polarity marking you can go ahead and solder them to the PC board.

At this time, locate diodes D1, the varactor “tuning” diode and D2, a Zener diode from the parts pile. Install D1, varactor diode. It has a black body with green and red bands. Observe the correct positioning of the banded end by following the silkscreen. The green band is positioned as shown on the silkscreen. Now, install D2, the Zener diode. It has a gray painted glass body with a black band. Orient the band as shown on the layout diagram. A Zener diode acts as a voltage regulator, keeping the voltage across it constant. This keeps frequency drift to a minimum. Once both of the diodes have been placed on the PC board you can solder them in place and then trim the extra lead lengths flush to the edge of the circuit board.

Next, we are going to locate and install the two inductors; see Table 6-3. Locate the slug tuned plastic molded coil, which is coil L1. Once you have located it, you can place it on the PC; remember to check the schematic and parts layout diagram for placement details. Now, locate L2, the 10.7 MHz shielded metal quadrature coil. Notice that it will only go into the PC board one way. Place L2 on the board and now solder both L1 and L2 to the PC board. Trim the excess component leads from the board.

At this time, you can locate FL1, the 10.7 MHz ceramic IF filter. This part looks like a disk capacitor

Table 6-2
Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

L2	10.7 MHz shielded can style IF transformer (red) Part # (421F122) Mouser Electronics.

but has three leads. Amazingly, its function is equal to a small handful of inductors and capacitors hooked up in a bandpass filter configuration. For those techno-types, its bandwidth is 280 kHz centered at 10.7 MHz with an insertion loss of only 6 dB. Go ahead and solder FL1 in now.

Let's locate the transistors for the receiver now! Next, refer to the semiconductor pin-out diagram shown in Figure 6-5. Transistors are three semiconductors which generally have three leads: Base lead, a Collector lead and an Emitter lead. The transistor symbol shows that the Base lead is a vertical line. Both the Collector and Emitter leads are diagonal lines which point to the Base lead. The Emitter lead has a small arrow which points toward or away from the Base lead. Try and locate transistor Q1, a 2N3904 type. Watch placement of its flat side, refer to the parts layout diagram and the schematic for proper placement. Install Q2, 2SC2498 or 2SC2570A NPN transistor. Transistors are VERY critical of correct orientation of their leads. Be sure to pay close attention to the position of the flat side of the transistor. Finally, install Q3, 2N3904 transistor. Be sure to observe flat side orientation of the transistors when mounting them. Now go ahead and solder the transistors in place on the PC board.

Let's take a short break and when we return we will install the integrated circuits and the final components. Before installing the integrated circuits, please consider using integrated circuit sockets as an insurance policy against having to try and un-solder a 14 pin IC from the circuit board which is a difficult task even for the seasoned electronics technician. Integrated circuits DO fail and if one ever does, you can simply unplug it and replace it with a new one. Refer to the schematic and parts layout diagrams when installing the integrated circuits. Solder in the IC sockets in their respective locations and then we will install the actual ICs.

Integrated circuit packages will generally have a cut-out, notch or indented circle at the top end of the IC package. The cut-out or notch will usually be at the top center while if there is an indented circle it will be at the top left of the IC package. Pin 1 of the IC will always be left of the cut-out or notch, so you can easily identify the pin-outs. Using your schematic and parts

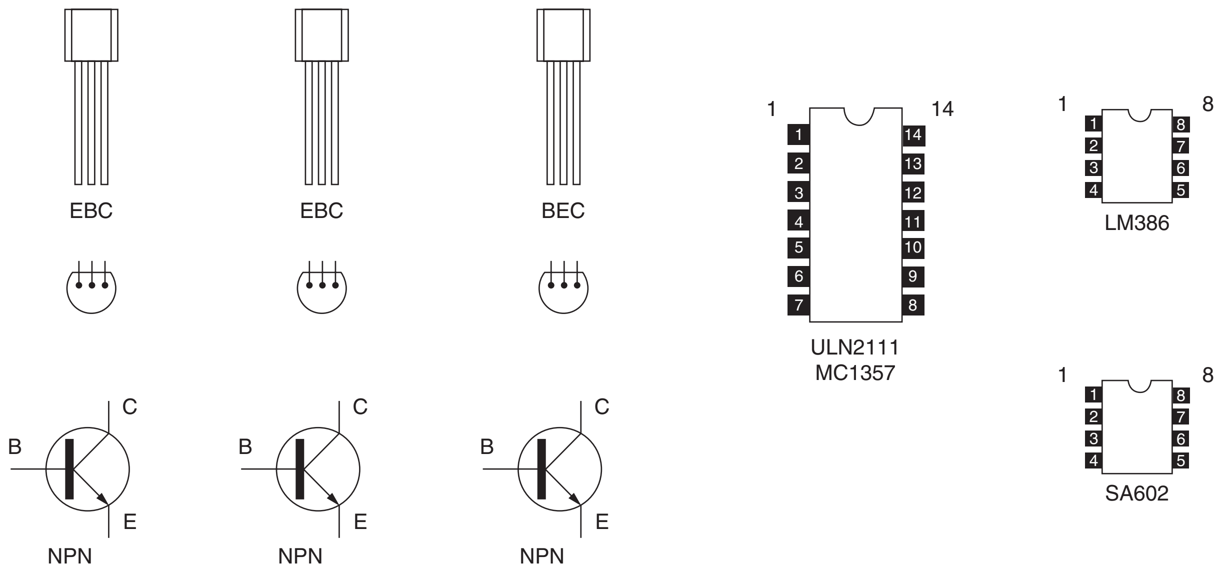

Figure 6-5 *Semiconductor pin-outs*

layout diagrams observe the correct orientation of the integrated circuits before inserting them into the sockets. First locate and install U1, the ULN2111 FM demodulator chip. Since this chip has 14 pins, be especially careful not to bend any pins under as you insert it into the PC board. When you solder the chip, verify that you are soldering all 14 pins. Next, let's install U2, the LM386 audio amplifier IC chip. The LM386 is a very popular part, and with good reason. Tucked inside that little plastic case are about 20 transistors that take a feeble audio signal and amplify it up to room-filling volume! Finally, go ahead and install U3, the SA602 IC mixer-oscillator. The marked end of the IC (band or dot) must face the edge of the PC board. If you wish, install an 8-pin DIP socket, still remembering to orient and install the SA602 correctly. Remember to firmly press the integrated circuits into their sockets.

The receiver project has two potentiometers, R12 is the "tuning" control, while R13 is the volume control. Locate the two 10k ohm potentiometers and install them, being sure to refer to the schematic and parts layout diagrams. Note that both potentiometers are on the front panel of the PC board. Install potentiometer R12, the tuning control. Insert it into the PC board so it seats firmly and is straight and even. Solder the three pins and the two mounting tabs. Next, install potentiometer R13, the volume control in the same manner.

Now locate S1, the on-off push button switch. Solder all six pins firmly. We've installed some "landmark" parts so far just to get us used to soldering our PC board. Finally, we are going to place the panel jacks on the rear portion of the circuit board. Locate and install J1, the RCA antenna jack, solder all four points. Now locate and install J2, the speaker jack, solder all three pins. At last, install J3, the SCA output jack, solder all four points.

There are only a few more components to go before we finish our FM receiver project. Install the 9 volt battery clamp. Use a scrap component lead wire looped through the holes in the clamp and into the holes in the PC board. Solder the wire to the clamp but don't use too much solder as this will prevent you from seating the battery fully into the clamp. Now, go ahead and install the 9 volt battery snap connector. Make sure you put the right color wire into the proper hole on the PC board. At long last, you are all done and ready to listen to tunes from your radio.

Before we apply power to the FM receiver for the first time we should make one last inspection of our work. First you will want to make sure that you have installed the diodes, electrolytic capacitors and the transistors with the correct orientation. Failure to do so may result in a damaged circuit, when power is first applied. Don't forget to check the orientation of the integrated circuits for proper location and orientation. Now we will inspect the PC board for "cold" solder joints. Pick up the PC board with the foil side facing upwards towards you. Take a look at all of the solder connections and make sure that they all look clean, smooth and shiny. If you find a solder joint that looks dirty, dark, dull or "blobby" then un-solder the connection, remove the solder and re-solder the connection once again until it looks good. Finally, we are going to inspect the PC board for possible "short" circuits. Often "cut" components leads can form "bridges" which can "short" out the circuit board traces, thus causing power to flow into the wrong places, and possibly damage the circuit. Also look carefully for any solder blobs that can form "bridges" between circuit traces. Now that you have inspected the PC circuit board, we can move on to testing and aligning your new receiver.

Testing and alignment

A hex head alignment tool is required to tune up your FM receiver. If you do not already have a set of plastic or nylon coil alignment tools and expect to build other radio or transmitter type kits, such tools are well worth having and can be found at any electronics store, including Radio Shack. While a hex style Allen wrench will fit the coil slug, the metal itself will drastically change the coil's inductance while it is in the slug. For this reason you should not use an Allen wrench unless you don't mind the trial and error process of turning the slug, withdrawing the tool, checking tuning, reinserting the tool, re-tuning, checking and so on.

You can fabricate your own non-metallic tuning tool with some patience, a bit of sandpaper and a piece of plastic rod. Try a large wooden matchstick, kebab skewer, or small plastic crochet needle. Carefully sand down the end to a hex shaped form and check for proper fit within the coil slug. It is better to have the tool fit loosely rather than too tight, since a tight tool will cause stress on the delicate slug.

Connect up a fresh 9 volt battery (preferably heavy duty alkaline type), a speaker or earphone, a short length of wire (about two feet) to serve as antenna, or the telescopic whip if the optional matching case and knob set was purchased. Now, set the volume and the tuning controls to the center of their range, then press the power switch "ON," you should hear some rushing noise from your speaker. Next, rotate the volume control and see if it does its job, then slowly turn L2's slug back and forth for maximum noise. This noise should be similar to what you would hear when a regular FM radio is tuned between stations. L2 may be tuned with a regular blade style screwdriver.

Try turning the tuning control, and see if you can receive any stations, but don't be alarmed if nothing is received since we haven't adjusted the oscillator coil yet. The oscillator coil, L1, is adjustable to receive from 70 to 110 MHz. We have to adjust it to cover the frequency range of interest. For alignment purposes we'll work with the understanding that the standard FM 88-108 MHz band is what we wish to receive.

Using an insulated alignment tool, slowly rotate L1's slug gently so that the slug is even with the top of the coil form. (Do not force the slug; if it binds, rotate the slug back and gently "rock it" to-and-fro as you would a thread forming tap. Slugs are by nature very brittle and will crack easily.) Now carefully rotate the slug into the coil form seven turns. The slug will be in about ¼″. Rotate the tune control until you hear an FM broadcast signal. Adjust L2 for best sound. Install R9, 10k ohm (brown, black, orange). R9 adds in AFC voltage to stabilize against drift. Without it your radio may "wander." After a signal is received, rotate the tune control to receive other stations. If the stations seem to "jump away" as you try to tune one in, the coil L1 is adjusted incorrectly and should be re-tuned. The reason for this odd phenomenon is that the AFC circuit is pushing the signal away rather than pulling it in. This is caused by having the oscillator 10.7 MHz below the desired signal rather than 10.7 MHz above it. A similar example of this is closing your eyes, hearing a sound, but not being able to determine if it is in front of, or behind you. Readjusting L1 will correct this situation. Make sure the slug is about three turns from the top of the coil form.

Calibrating the receiver is easy. First tune in a station known to operate at the low end (88 MHz) of the FM broadcast band. Rotate the tune control almost fully counter-clockwise to where that station should logically be located on the dial. Turn L1's slug until that same station is received. The tune control should now tune in the entire FM broadcast band. An easy way of making your own dial is to paste a small rectangle of paper behind the tuning dial knob. Then as you tune in different frequencies, pencil in on the paper the received frequency.

Additional receiver considerations

Your FM receiver was designed for clean, undistorted audio from average FM broadcast stations, while keeping battery current drain low. You may significantly increase the FM radio's audio output by adding a single 10 uF electrolytic capacitor across pins 1 and 8 on the LM-386 audio amplifier IC. The "+" side should connect to pin 1. An easy way of adding this capacitor is to simply "tack" solder it right on the IC pins on the solder side of the PC board. A 50-cent of speaker, lying naked on your workbench, will not give you a fair test of your FM receiver audio quality or volume. Speaker quality and well-designed enclosures have their clear purposes! A reasonable speaker in a box delivers a pleasant listening volume as well as significantly improved fidelity.

Out-of-band operation

Although many people use their receiver for comfortable FM broadcast reception, some James Bond types will want to use it to receive clandestine transmissions from phone bugs, room transmitters, etc. It's a simple matter to re-tune coil L1 to receive the frequency band of interest. First make sure you verify that your receiver receives the FM broadcast band correctly before re-tuning.

SCA output

Many FM broadcast stations now transmit sub-carriers on their signals. Sub-carriers are signals that are modulated on the carrier, just like the normal audio signals, except that they are too high in frequency to be heard. Normal audio signals range in frequency from 20 to 20,000 hertz. Most sub-carriers start at 56,000 hertz (56 kHz). These sub-carriers are themselves modulated, sometimes with audio signals, such as background music, but more and more these days with various forms of data. Some of the information carried on these sub-carrier data services include stock quotes, weather reports, news, sports and even paging signals. There is no limit to the variety of data that can be sent on a sub-carrier signal, and broadcasters are finding new things to send all the time!

The SCA output is a baseband demodulated sub-carrier signal output before any low pass filtering or de-emphasis. It provides a handy connection point for add-on SCA adapters such as the Ramsey SCA-1 kit. You can also connect this output to a receiver capable of receiving 30 to 75 kHz FM signals, or a PLL demodulator you've built yourself. Check out the data sheet from Signetics concerning the NE-565 PLL chip; an SCA demodulator is featured.

Chapter 7

Doerle Single Tube Super-Regenerative Radio Receiver

Parts list

Doerle Receiver – Original #19 Dual Triode

R1 2.2 megohm ½w, 10% resistor

R2 330k ohm ½w, 10% resistor

R3 47k ohm, ½w, 10% resistor

R4 100k ohm, potentiometer panel mount

R5 25 ohm reostat

C1 5–18 pF antenna trimmer capacitor

C2 140 pF main tuning capacitor

C3 .001 mF, 200 volt disk capacitor

C4 100 pF, 200 volt disk capacitor

C5 .1 mF, 200 volt disk capacitor

C6 .005 mF, 200 volt disk capacitor

L1 2.5 mH choke coil - Digi-Key Electronics

L2 “tickler” coil (see text)

L3 main tuning coil (see text)

T1 #19 triode tube – 2.5 volt filaments

B1 Type A filament batteries (6 volts)

B2 Type B battery 90 volt battery pack

HP 200 ohm high impedance headphones

Misc chassis, tuning dial, wire, sockets, standoffs, screws, etc.

Doerle Receiver – 6SN7 Version

R1 2.2 megohm ½w, 10% resistor

R2 1000 ohm, ½w, 10% resistor

R3 470k ohm potentiometer panel mount

R4 100k ohm, ½w 10% resistor

R5 100k ohm potentiometer

C1 8–18 pF trimmer capacitor

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

C2 100 pF main tuning capacitor

C3 50 pF variable tuning control (fine tune)

C4,C5 470 pF, 200 volt disk capacitor

C6 100 pF, 200 volt disk capacitor

C7 .01 mF, 200 volt disk capacitor

C8 .22 mF, 200 volt capacitor

L1 2.5 mH choke coil Digi-Key Electronics

L2 "tickler" coil (see text)

L3 main tuning coil (see text)

T1 6SN7 triode tube

B1 type A battery - 6.3 volt power supply or batteries

B2 type B battery - 150 volt power supply or batteries

HP 200 ohm high impedance headphones

Misc chassis, tuning dial, wire, standoffs, screws, etc.

Old Time Radio lovers will enjoy building this single tube regenerative AM/Shortwave receiver called the Doerle Radio, shown in Figures 7-1 and 7-2. It is a classic radio from around 1934, which was offered as a radio kit that a radio enthusiast could build at home. This very sensitive receiver is a fun-to-build radio which can be powered from batteries as they did in the "old days" or you could construct an AC power supply for it. The original Doerle radio receiver was offered as a kit for $3.00. The early Doerle receiver used a #19 dual triode receiving tube, one section of the tube acted as a regenerative detector and the second section of the tube acted as an audio amplifier. Doerle perfected this receiver design in 1933 when the new #19 tube became readily available.

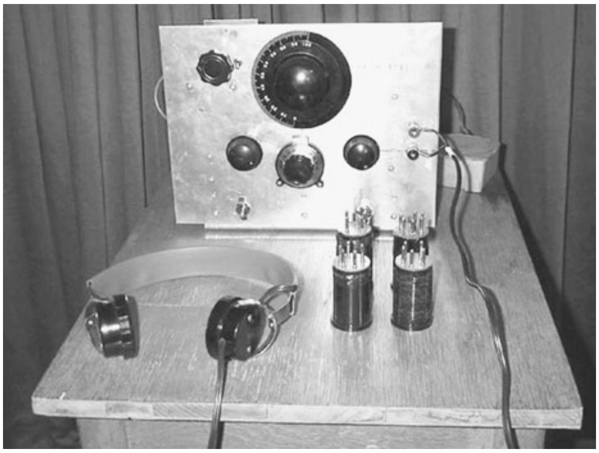

Figure 7-1 *Doerle receiver*

In this chapter we will build a copy of the original Doerle radio and we will also show you how to build the Doerle radio receiver using a more modern tube such as the 6SL7, which may be a lot easier to locate these days. If you are a "purist" you may want to try and locate the original #19 triode tube, which is still actually available. You can build either version, which you can construct to look just like the original radio looked back in the 1930s.

This radio is a study in simplicity, the low parts count kept the original cost down. A single sheet of metal, probably steel, painted in black wrinkle finish became a chassis. The single #19 tube powered by batteries eliminated unnecessary tubes and power supplies. The result is a simple, high-performance shortwave radio that beginners could afford to build and operate during the depths of the Great Depression.

First let's examine the circuit diagram, shown in Figure 7-3 for the original Doerle radio. The antenna is

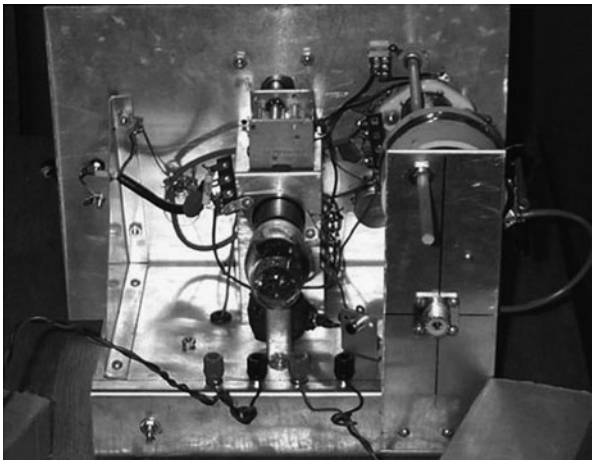

Figure 7-2 *Doerle receiver – inside view*

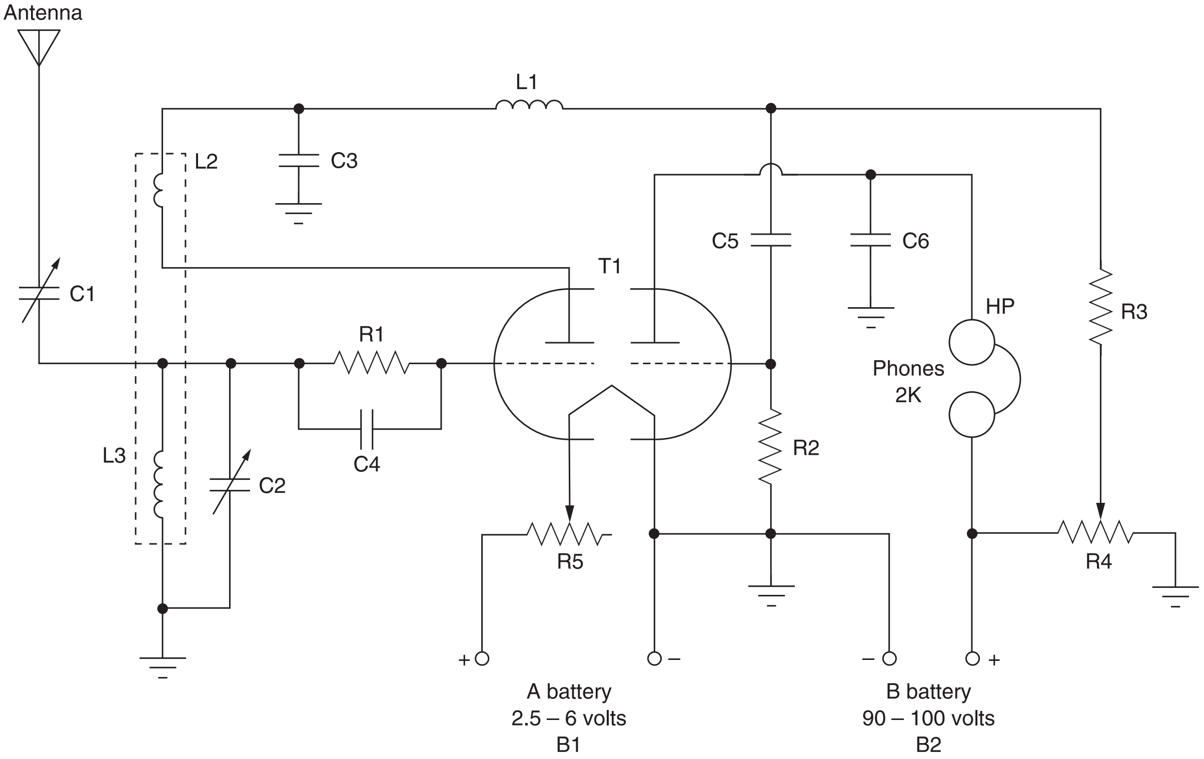

Figure 7-3 *Original #19 dual triode receiver*

coupled through a small 15 pfd screwdriver adjusted variable capacitor to the main tuning coil wound on a four pin form. A 10 pfd variable capacitor across it gives a fairly good trade-off between slow tuning rate and wide tuning range. The signal is fed through a grid leak configuration to one of the grids of the #19 tube. From the plate, the signal goes to the tickler wound on the same four pin coil form. The top side of the tickler coil connects to a 500 pfd capacitor and a 2.1 mH radio frequency choke (RF). The choke allows DC plate voltage into the tickler but prevents the radio frequency (RF) alternating current from getting into the rest of the circuit. The 500 pfd capacitor takes the RF to ground, thereby allowing RF voltage to build up on the tickler winding. Without this 500 pfd capacitor the receiver would probably not regenerate properly.

Variations in the DC voltage delivered to the detector plate feed through a .1 mfd capacitor to the second grid. A 250K, ½ watt resistor pulls the grid to DC ground, to provide the necessary zero bias for this class B amplifier tube, yet the resistance is high enough so that the AC avoids the ground and readily flows into the second grid.

Voltage on the detector plate is changed by a 50K resistor attached to the wiper of a 50K regeneration potentiometer that is connected from the B+ battery to ground. Plate current in the detector flows through these two resistors. Variations in current creates a varying voltage drop across this pair. The varying voltage is the audio signal that is applied to grid of the audio triode.

The B+ voltage source is fed through headphones to the second plate to complete the audio amplifier part of the circuit. The sound that is heard in the headphones comes from the variations in the audio plate current. A .006 mfd capacitor on the plate is large enough to take any stray RF to ground, but is not so large to take audio frequency (AF) voltage to ground. This capacitor aids receiver stability and audio quality.

A 20 ohm rheostat in series with one of the filament legs allows adjustment of the voltage. A rheostat is a low resistance, high wattage potentiometer. In the 1930s, you would have used two No. 6 1.5 volt dry cells (they were about 6″ tall and 2¾″ diameter) as your filament power supply. The rheostat would cut the voltage down to two volts needed by the tube's filament. As the voltage provided by the batteries dropped with use, you would adjust the rheostat to maintain the proper voltage on the filament. In other words, the rheostat allowed you to continue using the filament batteries as their voltage dropped to the point of total failure. Since the filament current for a #19 triode tube is just over 250 mA, so a 20 ohm resistor would allow you to use filament batteries up to 6 volts. And quite frequently that 6 volts was the battery borrowed from the family car.

Building the original Doerle receiver

The first step in building this or any project is getting the parts. In fact, this may be the most difficult step. When it comes to building a replica of an old radio like this, you just cannot go out and buy everything you need. You may have to adapt and use whatever you have on hand or can scavenge. For a project of this type you may want to build the circuit using point-to-point wiring between terminal and components rather than a circuit board to give the radio an "old-time" look. You are probably going to need both a soldering iron and a soldering gun to build this radio. You will also want to consult with the resistor color code chart in Table 7-1 and the capacitor code chart in Table 7-2 in order to identify the correct components.

Building this old radio can be lots of fun, but locating all of these old components can be difficult, and in fact you won't be able to locate the exact same items. You'll get something close. You'll have to mix and match whatever you can find. Most of these components are available at flea markets if you visit enough of them. Many of the components are available new from dealers, such as Antique Radio Supply, see Appendix. But often you'll have to pay substantially higher yet fair prices. The used #19 tube was purchased from a flea market dealer for $5. Yet, that same tube can be obtained brand new from Antique Electronic Supply for about $6, see Appendix. Again, you may have to scrounge, make do, adapt, experiment, and make a few mistakes. But the results are well worth it.

One idea is to build a prototype receiver with whatever components you can find, no matter how new or old, and get it working. Then, over the next few years, visit flea markets, antique radio meets, check out dealers' catalogs, and accumulate the older, more authentic parts. After you accumulate some of those rare, old, beautiful parts from the 20% and 30%, rebuild the receiver. And then a few years later rebuild it again. And every time you rebuild it, add older and more authentic parts, until you get an exact copy of the #19 Doerle receiver. The radio will become more and more of an authentic replica of a receiver from the early days of radio. With patience, practice, and plenty of enjoyment, you can build a fine radio.

Looking at the illustration of the Doerle-1 version, we see in the center a large, slow-motion dial drive

Table 7-1
Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000

Silver			0.01	10%
No color				20%

Table 7-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

Table 7-3
Short-wave band listening frequencies

Shortwave Band	*Shortwave Band*
120 meters = 2300–2495 kHz	25 meters = 11.500–12.160 MHz
90 meters = 3200–3400 kHz	22 meters = 13.570–13.870 MHz
75 meters = 3900–4000 kHz	19 meters = 15.030–15.800 MHz
60 meters = 4750–5060 kHz	17 meters = 17.480–17.900 MHz
49 meters = 5730–6295 kHz	16 meters = 18.900–19.020 MHz
41 meters = 6890–6990 kHz	13 meters = 21.450–21.750 MHz
41 meters = 7100–7600 kHz	11 meters = 25.670–26.100 MHz
31 meters = 9250–9990 kHz	

friction-driven by a small knob at the bottom of the set. This allows fine tuning of stations. To the upper left are the antenna and ground terminals. Just to the right in a hole in the front panel is exposed the screw which adjusts the antenna coupling capacitor. Below left is the filament rheostat knob. At the upper right are the headphone terminals with the regeneration control located at the lower right. Although the receiver as shown in the original drawings may appear complex, it really is not. This is one of simplest receivers that you could build.

The original chassis for the Doerle receiver was an L-shaped piece of sheet metal, most likely steel, and painted with a black wrinkle finish. While the front panel was perfectly rectangular, the base was trapezoidal. Dimples were embossed into the base plate which served as feet.

For our replica Doerle receiver, you can start with an 11″ × 9″ sheet of .063″ (1⁄16″) aluminum to construct the chassis. The most complicated mechanical problems that you may encounter in building the receiver is the mounting #19 dual triode tube up on standoffs, mounting the variable capacitors and building the coils on the coil-form, see Figure 7-4.

The original Doerle model used a simple single bearing variable capacitor. We elected to use a heavy duty Hammarlund tuning capacitor; it is of significantly higher quality and is much heavier, so you will have to support the rear end of the capacitor with a bracket of some type. Once a Z-bracket as fabricated and attached to the breadboard, the prototype dial-drive-capacitor assembly was solid, yet turned smoothly.

Since a solid, rigid mount for the tuning capacitor is essential if you are to achieve frequency stability and eliminate microphonics, you must get this part of the assembly correct. And since your components will need their own custom mounting hardware, you'll need to experiment until you get it right. That's why the breadboard prototype is so useful. Take your time.

In continuing the capacitor assembly, I used a pair of ½″ long 6-32 machine screws in the top and bottom pair of holes on the drive mechanism. In the left-right pair of holes, I used a pair of 1½″ long 6-32 machine screws. The extra length became mounting studs to which an aluminum cross-arm was attached. In the cross-arm was drilled a ⅜″ hole to accommodate the mounting flange of the capacitor.

After the capacitor holes were drilled, the burrs removed, and edges of the panel were rounded and smoothed, I roughed up the surface with fine sandpaper.

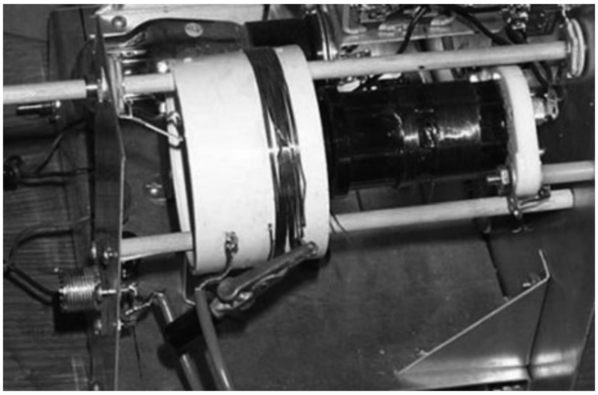

Figure 7-4 *Doerle coil assembly*

Next, the panel was bent into an L shape. You can use an old sheet metal brake, or you can could do the same by clamping the metal between a couple of 1 by 2's or lengths of angle iron held tightly together in a vise or with C-clamps. Since only a single, simple bend is required, you might get by clamping the sheet metal to a table top and by bending the sheet over the edge.

In order to obtain smooth tuning with a large range, you should locate some sort of planetary drive mechanism in front of the main tuning capacitor, such as a used National Velvet Vernier dial drive, which can be removed from an old radio. The first step was to dismantle it into the drive mechanism, the knob, and the dial plate. To mount the actual planetary drive mechanism, I had to cut a ⅝″ hole in the plate with a socket punch. Next, the drive collar was slipped through the ⅝″ hole. With a marker I marked the location of the four mounting holes.

In moving the capacitor and dial drive to the finished receiver, I chose to position the angle mounting bracket vertically as shown in the photos. This made fabrication and installation of a new base bracket much easier, and allowed more clearance for the tube and coil socket as well as for the terminal strip below the dial drive.

When the components are "test" mounted, you can move from the prototype stage to the finished L-shaped panel, if you are happy with the final layout. Then you can spray on a thick coat of fast drying metal primer. Once dry, I wet-sanded it under a stream of water until smooth. Then came the black wrinkle paint. If you wish to try and duplicate the original, you will want to try and create the wrinkle finish. If you are not that concerned about having the radio look exactly like the original radio, you can just paint the chassis with a single coat of black paint. Black Krylon paint is available in a spray can in your local home improvement store. For best results in creating a wrinkle finish, you must put down a heavy layer of paint. It must be heavy so that it can wrinkle up as it dries. If the coat is too light, or if you try to apply a second light coat over the existing layer, you won't get the best results. It might even be shiny where it is supposed to be flat black.

It is recommended that you paint one surface at a time and let it dry. Then reposition the chassis so that another surface is horizontal and then paint that. Of course, it will take four times as long to paint the radio than if you get in a hurry and paint the whole thing at once, but the results will be more predictable. You can bake it in an electric kitchen oven at the lowest possible heat. Nasty smelling solvents are baked out of the paint, so your wife or mother may not be too happy with you!

After mounting the tuning capacitor, the only other assembly of any complexity is the coil socket and antenna trimmer mount. Mounting the other components was fairly easily done. You can use machine screws, spacers of wood, plastic, porcelain, and metal. You can slice wood spacers from hardwood planks, but you'll need a table saw to do a good job. Plastic spacers can be cut from plastic tubing, but just be sure to get the rigid stuff used by plumbers for water supply lines. Porcelain spacers are something, which can be scavenged at a local hamfest or radio flea market. A small trimmer capacitor is mounted on porcelain standoffs in order to insulate both terminals from the chassis. Between the standoffs is a drilled ⅜″ hole in the front panel to allow screwdriver adjustment. That sounds simple enough. But behind the trimmer is the socket that accepts the four-pin lube socket coil form. What I used here were a couple of 2″ 6-32 machine screws cut to the appropriate length with heavy clippers. They were then fed through the coil socket mounting holes and through brake line spacers into the porcelain standoffs. Two soldering lugs were sandwiched between each metal spacer and porcelain standoff. One lug on each side was soldered to a capacitor lead. The other lug on each side became connector for the trimmer. Since the metal spacer pressed tightly against the capacitor lead, it was imperative that the four pin socket be made of insulating material. Here I used an old phenolic wafer socket. A metal socket would short out the capacitor. It sounds complicated but it should be fairly easily understood by studying the photographs.

Wiring was done with some modern plastic covered hookup wire, and with some genuinely old cloth-covered hookup wire salvaged from a piece of old tube gear. Watch for old tube gear with long lengths of cloth-covered wiring at flea markets. New old stock cloth covered wire is around but it is not always easy to find. Sometimes you can look for old wire while scavenging at hamfests.

The coils used in the original circuit were 1½″ dia. by 3″ tall phenolic coil forms. You can use phenolic bases from four prong tubes for the coil forms and they can be purchased from Antique Electronic Supply. The low frequency or main “short-wave” coil is close-wound with about 30 turns of #26 wire. You wind the “tickler” coil, which is 9 or10 turns of #24 ga. wire below the tuning coil, and both coils were covered with clear fingernail polish. The coil covers approximately 2.5 to 4.5 MHz. The exact number of turns you’ll need is going to depend on the tuning capacitor you use and the stray capacitance that results from your particular component layout, among other things. You’ll have to experiment to get the right number of turns.

The original Dorele receiver had plug-in coils for different radio bands. In order to construct an AM radio coil, you will have to wind another main coil along with another “tickler” coil on a second coil form. The main coil will need about 40 turns of #26 ga. wire, with a 9–10 turn “tickler” winding.

Battery terminals can also be purchased at a radio flea market. Using a table saw you could elect to slice a ¼″ strip from an oak 1×6. That gave me a mounting strip of ¾″ × 5 ½″ × 1⁄41″ thick, just right for this radio.

Firing up your original Doerle receiver

Now your #19 Doerle radio receiver is bolted together and wired up. It’s time to try it out. First, check the wiring, then check it again. It’s easy to make stupid wiring errors, sometimes after checking the wiring once or twice! Have a friend look over the circuit before applying power to the circuit for the first time. The coils used in the original drawing look like 1½″ dia. by 3″ tall coil forms. You can use phenolic bases from four prong tubes. They’re not from old tubes but from Antique Electronic Supply.

The low frequency coil is close-wound with about 30 turns of #26 wire. You can wind about 10 turns of tickler below the tuning coil, and cover both coils with clear fingernail polish. The coil covers approximately 2.5 to 4.5 MHz. The exact number of turns you’ll need is going to depend on the tuning capacitor you use and the stray capacitance that results from your particular component layout among other things. You’ll have to experiment to get the right number of turns.

The original ten turns of tickler turned out to be too many, so you may have to improvise to get it right. You’ll discover this problem very quickly if, when you advance the regeneration control, the receiver goes into a deafening howl. You may need to remove one turn of tickler coil at a time until regeneration starts up smoothly near the end of the control clockwise rotation. You should adjust the tickler with the tuning capacitor open, that is, at the receiver’s highest frequency. Here, more regeneration is necessary than at lower frequencies. And you must adjust the antenna trimmer control for the minimum capacity that gives excellent sensitivity. Adjusting the antenna trimmer “couples” or “de-couples” the connection between the receiver and the antenna, and can have a pronounced effect on regeneration adjustment and overall sensitivity.

The #19 tube filaments can be powered by alkaline flashlight batteries. Alkaline batteries should be used rather than cheaper zinc-carbon types since alkaline can deliver higher currents, and because they’ll last much longer. Alkaline batteries will give many more hours of use for your money. You can hook the filament batteries up to the set with the rheostat set to maximum resistance. You can then rotate the rheostat, with a voltmeter connected to the filament leads, in order to allow the meter to show two volts. Then put a reference dot on the panel with a marker pen. You can do something similar to the finished machine. As the batteries age, their voltage will drop making it necessary to adjust the control to maintain the two volts on the filaments.

If you do not want to use flashlight batteries, you may consider nickel-cadmium batteries. They’re inexpensive, each cell delivers about 1.2 volts, so you will need two, three or even four in series, which will deliver as much as 4.8 volts. And when they run down, you can recharge them. But before you go to that trouble: try flashlight batteries. You may be surprised by how long they last. As for a 90 volt B+ battery, you will most likely not be able to find them and if you do they will be expensive. Newark Electronics still had them, the last time I checked their catalog. It is easy enough to build a 90 volt “stack” of batteries. You can build a battery “pack” by buying ten 9 volt transistor radio batteries, and taping them together with electrical tape. When you do this, alternate their terminals so that you can easily wire the batteries in series.

The tube manuals lists the filament current at 260 mA. A voltmeter will show that the filament battery voltage drops about .2 volt over 15 to 20 minutes of operation. The batteries will last quite a long time. As for B+, a "stack" of 9 volt transistor radio batteries produced about 97 volts. With the receiver fired up and properly adjusted, the current draw was only 4 mA, significantly less than what a transistor radio battery is capable of delivering. After several minutes, the B+ battery dropped to 95.9 volts, so you can expect to get long life out of this battery pack. Several changes of filament batteries will be needed before the B+ battery dies.

So how does a Doerle radio receiver perform? For such a simple radio, it performs very well. Just a quick run through the band allowed me to copy amateur CW and marine Morse code. The foreign shortwave broadcasters came blasting-in.

Improvements? Yes, I can think of some. First, a volume control would be useful. I suspect that radio stations today run far more power than they did in the 30s. Therefore, the signals in the headphones are so loud as to be painful. A volume control would be useful to cut some signals down to size. I find the tuning a little too fast. Tuning a single sideband signal in is touchy and difficult in some cases. This could be fixed by going to five pin coils forms where the tuning capacitor could be attached to a tap in the tuning coil. Such a modification, however, changes the Doerle kit which was built for shortwave listeners, not amateurs. If you're a ham, you'll probably want to modify the design so that a ham band is spread out along the whole dial. And the last change that I would make is to improve the antenna trimmer adjustment. Adjusting the trimmer with a screwdriver can be painful after awhile. You don't do it very often, but when necessary it's not a convenient thing.

The 6SL7 Doerle receiver

In 1934, there was only one dual triode available for battery operation, the #19 dual triode! But the 1930s were years of explosive growth in the electronics industry. Just months after the #19 triode was released new metal tubes appeared, and in another ten years, seven and nine pin miniature tubes became available. These new series of tubes offered a variety of new dual triode tubes, many of which were better suited for the Doerle receiver circuit: see the 6SL7 Doerle receiver schematic shown in Figure 7-5.

If you elect to build this modified version of the Doerle, you will need to locate a 6SL7. The 6SL7 is a glass octal high-μ or (hi-gain) twin triode. The μ (mu) of a tube is the amplification factor, or voltage gain. Although the value of what is considered "high μ" has increased over the years, today "high" means a μ of from 60 to 100 or more. That means that the maximum voltage gain possible is 60 to 100, but usually it is significantly less.

High voltage gain tubes usually don't develop very much power. High power tubes usually have lower voltage gain. You can get both in the same tube. The #19 is an audio power tube with a relatively low μ. The 6SL7, on the other hand, has a μ of 70, but delivers little power. If you build both the #19 and 6SL7 versions, you'll immediately hear the increased headphone volume of the latter tube. Headphones don't need much power, so high voltage gain tubes works well, although more gain is usually better. A medium-μ tube like the #19 triode will give great performance. The 6SL7 was very common, and is still available. It is a higher-power, lower-voltage-gain tube with the same pin-out arrangement as the 6SL7.

The only major change introduced into this version of the Doerle is the mechanical layout. In this version, the prototype used an old National ACN dial drive, found at a local hamfest or flea-market, for a couple of dollars. I mounted it on an aluminum face place wrapped around a piece of 1 × 6 oak. The actual planetary drive is identical to that under the phenolic dial plates of the Velvet Vernier used in the model 19 Doerle. The ACN is much larger, 5″ × 7″ overall, and allows the user to mark a paper scale so that the dial becomes direct reading.

The antenna coupling trimmer was replaced by an 8-18 pF air variable stripped from an old radio. A custom bracket was snipped out of aluminum sheet and quickly bent up. By mounting the bracket on the wood base away from other meta components the capacitor electrically "floated" as needed. A knob allows the operator to reach around the side and easily adjust coupling when necessary. But you can take a similar small capacitor and cannibalize it by removing one or more plates to reduce the capacity. Just try get something less than 50 pfd for antenna coupling.

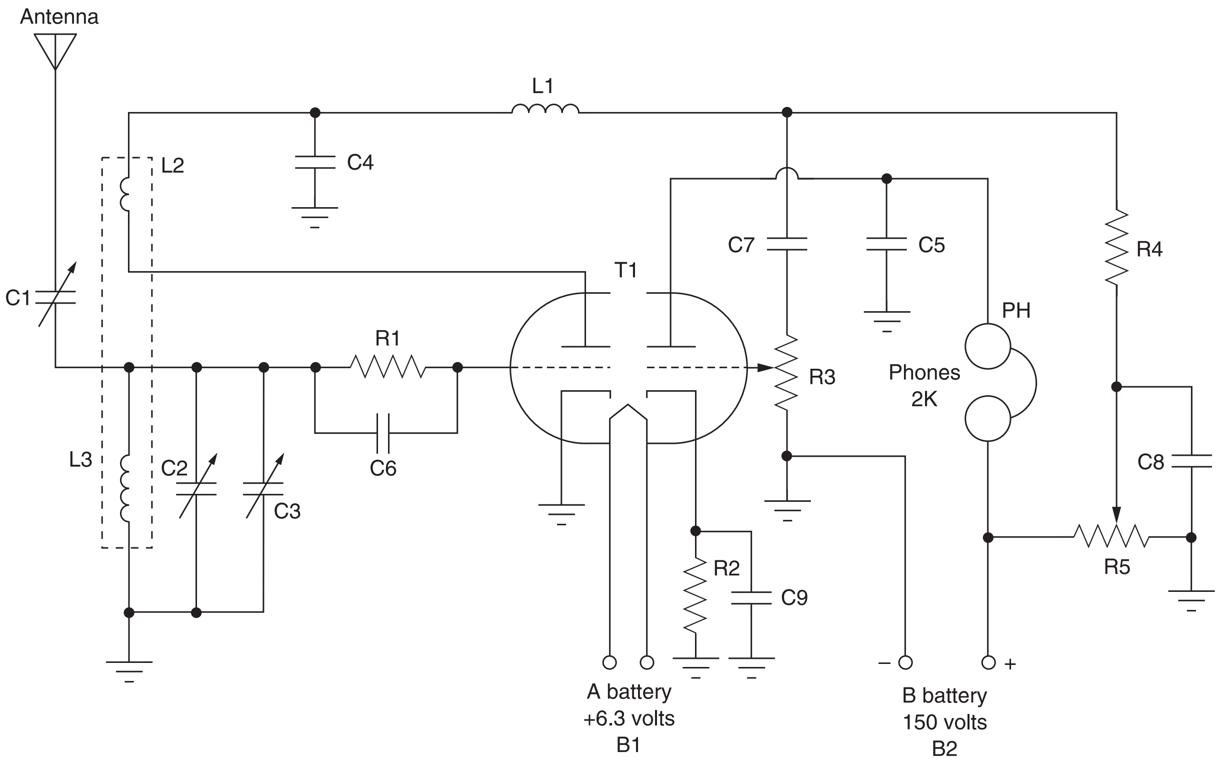

Figure 7-5 *New 6SL7 Doerle received*

A half megohm potentiometer replaced the 330 kilohm grid resistor used in the audio side of the original receiver, by connecting the panel-mounted pot to the rest of the circuit with miniature coaxial cable to reduce AC hum. In the original circuit, the audio grid was biased as before, but now has control over the volume. With a high gain tube like the 6SL7, it is important to reduce the audio output so that you don't destroy your hearing. A one kilohm resistor and a 10 mfd capacitor in parallel are inserted in the cathode lead of the audio triode to provide at least some negative bias to help the tube amplify with less distortion. You may want to increase or decrease the value of the resistor to achieve the necessary grid voltage specified in the tube manual. The voltage you measure across the cathode resistor is your grid bias.

If you compare the original circuit with this version, you'll find that almost all the same components can be used. The few differences are minor. And, again, don't be afraid to substitute. Just about anything within reason will work.

The biggest problem with this version of the Doerle receiver is that you will likely need a power supply, since you have to supply 6.3 volts AC into the filaments. Remember the original Doerle radio had 2.5 volt filaments, and you'll need about 150 volts for the plates on the 6SL7.

Does the 6SL7 version of the Doerle radio work? It sure does! You can use the same coils used in the original version of the Doerle radio for the 6SL7 version of the radio. When powering this version of the Doerle receiver be sure to set the volume control all the way down before applying power, since the audio output is much greater than that of the original radio. Put on a pair of headphones and turn on the 150 volts B+. Remember, you must use high impedance type headphones for this type of radio, not 8 ohm types. The Internet is a good source of the old 2000 ohm high impedance headphones. Bringing up the regeneration and audio controls brought in stations immediately. Many stations appeared across the dial, and they were surprisingly easy to tune in.

One important change in this circuit is the use of two capacitors in the main tuning LC circuit. In the circuit shown, you'll see a 50 pF fixed capacitor is parallel with a 100 pF variable capacitor. Since capacitance in parallel adds, the combination of the two essentially creates a virtual variable capacitor with a range of 50 to 150 pF. The net effect is to slow down the rate of tuning. The amount of band that can be covered by a single coil is reduced, but makes tuning far less “touchy.” This is important when tuning a sideband signal because very slight changes in tuning are needed to clear up the signal. You might want to replace the 50 pF with a 20–150 pF trimmer or something similar. By adjusting the trimmer, you can change the “speed” at which signals are tuned in. More capacitance reduces the speed, but it will also decrease the band of frequencies covered by the coil being used. You might want to replace the 50 pF fixed capacitor with a 140 pF for use as a band-set capacitor and a 35 pF for use as a band-spread capacitor.

Both should be equipped with slow-motion dial drives. You can use just about any dial drive that turns up at a flea market or in a radio parts catalog. You can mix and match components. Many times you’ll need more mechanical skills than you will need electronic skills for building old radios, so dig through your junk box, visit a hamfest and have fun building an old radio!

Chapter 8

IC Shortwave Radio Receiver

Parts list

Shortwave Receiver Project

R1,R5,R20 100k ohm, ¼w 5% resistor [brown-black-yellow]

R2,R4 22k ohm, ¼w, 5% resistor

R3,R7,R9,R10 1k ohm, ¼w 5% resistor [brown-black-red]

R13,R17,R18,R24 1k ohm, ¼w 5% resistor [brown-black-red]

R6,R8,R11,R19,R23 10k ohm, ¼w 5% resistor [brown-black-orange]

R12 1M ohm, ¼w 5% resistor [brown-black-green]

R14,R21 10K potentiometers, 103, or 10nF

R15 2 ohm, ¼w 5% resistor [red-black-gold]

R16,R22,R25 270 ohm, ¼w 5% resistor [red-violet-brown]

R26 100 ohm, ¼w 5% resistor [yellow-violet-orange]

C1,C3,C20,C21,C25 .001 µF, 35 vdc disk capacitor

C2 330 pF, 35 vdc mylar capacitor

C4,C6,C8,C28 .01 µF disk capacitors, 35 vdc (marked .01, 103, or 10nF)

C5,C17 100 pF disk capacitors, 35 vdc (marked 100, 101, or 100K)

C7,C10,C12,C18,C19,C29 1 µF ceramic disk capacitor, 35 vdc (marked .1 or 104)

C9,C24 1 µF, 35 vdc electrolytic capacitor

C11,C22,C23,C27 10 µF, 35 vdc electrolytic capacitor

C13,C14 220 µF, 35 vdc electrolytic capacitor

C15 (see text)

C16 (see text)

C26 1000 µF, 35 vdc electrolytic capacitor

C30 10 pF, 35 vdc mylar capacitor

L1,L2 1 µH molded type inductor (brown-black-gold)-Digi-Key

L3 12 µH molded type inductor (brown-red-black) -Digi-Key

T1,T2 shielded can inductor (42IF-103) Mouser Electronics

T3 shielded can inductor (42IF-123) Mouser Electronics

D1 1N270 diode, glass bead style

D2 Red LED (RSSI)

D3 Varactor diode, transistor style with 2-leads (MVAM108)

Q1,Q2,Q3 2N3904 NPN transistors

U1 LM358 8-pin DIP IC

U2 LM386 8-pin DIP IC

S1 DPDT PC-mount pushbutton switch

J1 RCA-type PC-mount jack

J2 subminiature $^1/_8$ inch PC-mount jack

B1 9 volt transistor radio battery

Misc PC board, battery holder, battery clip, wire, hardware, speaker

Have you ever wanted to listen-in into the fascinating world of radio? The shortwave radio project will allow you to listen to international stations such as the BBC, Radio Canada, Radio Moscow, Radio Sweden. Using just a few feet of wire as you antenna you will be able to reach out and hear the world. Shortwave listening is fun for folks of all ages from 8 to 80 years of age.

The shortwave radio project shown in Figure 8-1 covers the shortwave bands from 4 to 10 MHz. The receiver uses varactor diode for smooth tuning across the band. The superheterodyne shortwave receiver provides both great sensitivity and selectivity. The tuning control as well as the volume and RF gain controls are all located on the front panel for easy operation. The shortwave receiver is powered from a common 9 volt transistor radio battery, so the receiver can be taken virtually anywhere. The receiver would make an ideal scout, school or club project.

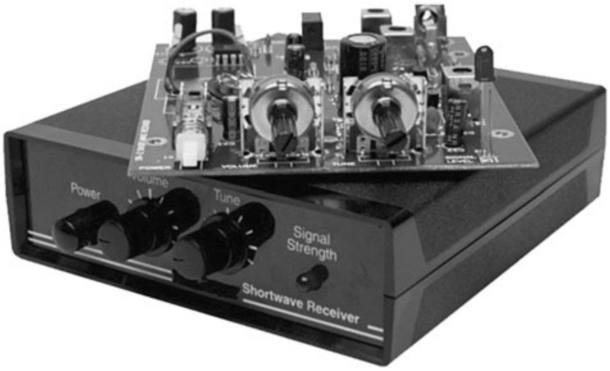

Figure 8-1 *Shortwave radio*

You'll easily tune into broadcasts from many other countries as well. As you become more and more familiar with the world of shortwave broadcasting, you'll be deciding on your own favorite band. You will hear a variety of other "interesting" sounds, but just remember that this receiver is designed for AM only. If a Morse code signal really sounds "good," it is because it is being transmitted in AM tone-modulated form, or perhaps the signal is so close to an AM broadcast carrier that the carrier acts as a "beat-frequency-oscillator" (BFO). Even though this receiver will permit you to tune through several different ham radio bands, the signals are not likely to be intelligible. Reception of CW and SSB signals on an AM receiver requires a BFO. This is not a complicated feature, but it is not a feature of this receiver. Our companion receivers designed for the ham bands will let you tune into these SSB and CW broadcasts.

Shortwave listening as a hobby in itself

Many people worldwide enjoy listening to shortwave broadcasts of all kinds, and they keep written records of what they hear. Almost every nation on Earth has some sort of shortwave broadcast service, though many are much more challenging to tune than the powerful signals of Radio Moscow and the BBC. In addition, these "SWLs" (Shortwave Listeners) listen to ham operators, government and commercial stations and even clandestine operations. Some shortwave listeners enjoy collecting QSL cards from stations which they have logged. Shortwave listening is, for some, a step toward getting a ham radio license. For others, it is a great hobby in itself.

The Shortwave Receiver is a good introductory receiver for this hobby. After you decide exactly what kinds of listening are of the most interest to you, you'll be in a better position to choose a more elaborate receiver.

To learn more about this SWL hobby, look for a copy of *Popular Communications* at newsstands. An inexpensive and interesting general introduction to all kinds of radio listening is the book, *Shortwave Listening Guide* by William Barden, Jr. (1987; Radio Shack Catalog Number 62-1084). To learn more about the hobby of ham radio, write to ARRL (American Radio Relay League), 225 Main Street, Newington, CT 06111.

Circuit description

Take a moment and examine the shortwave receiver block diagram in Figure 8-2. The simplified signal flow of the block diagram shows the basic sections of the receiver. The corresponding components are noted under each main block and can be cross-referenced to the schematic.

The main shortwave receiver diagram is illustrated in Figure 8-3. The receiver circuit begins at the antenna input at J1. RF signals (Fc = carrier frequency) from the antenna are applied to the RF input and filtering allowing only the signals of interest to pass through. The high pass filter helps eliminate unwanted signals picked up by the antenna, so improving the overall reception quality of the radio. After the input signal is filtered, it moves to the mixer stage. Notice on the diagram that there are two inputs to the mixer. We have discussed one of these input signals coming into the mixer but not the other. Now, look down at the local oscillator block. The local oscillator (LO for short) acts as your tuning control for what frequencies you can receive by generating a signal on the board close in value to that which will be used by the mixer. There is a direct relationship between the generated frequency of the local oscillator (LO) and the exact receive frequency (Fc) you want to listen to. This will become clear when we finish discussing the block diagram. The LO section is a Colpitts oscillator that takes advantage of smooth varactor diode tuning. The varactor (D3) forms an L/C (inductor/capacitor) tank circuit with T3. Increasing the voltage on the varactor diode with R21 (tuning pot) increases the capacitance of D3, thus increasing the frequency output of the LO section.

Now that we know the two signals coming into the mixer stage, both the Fc (receive carrier frequency) and the LO (generated local oscillator), we can better cover its operation. The mixer takes these input signals and performs a few very basic operations. The technical explanation of how the mixer combines these

Figure 8-3 *Shortwave receiver schematic. Courtesy of Ramsey Electronics*

signals through Fourier Series is interesting but very drawn out. The point of using the block diagram, however, is to simplify matters. Therefore, the function of the mixer is to obtain the "product" and the "sum" of the input signals. This means you take the input signals and merely "add" and "subtract" their values to determine what you get on the output. The general formulas to use are quite simply, "Fc + LO = Mixer Output" and "Fc – LO = Mixer Output."

The output of the mixer stage unfortunately has other signals besides the ones we want. This brings us to the next stage, Intermediate Frequency Filtering. An Intermediate Frequency (IF) is a signal somewhere between the RF signal Fc we started with and the final audio message we are trying to get. The desired IF we are dealing with is a fixed number, such as 455 kHz. As long as the proper relationship between Fc and the LO exists, the IF value will stay constant. Due to the fact that the IF frequency stays the same all the time, the Intermediate Frequency Filter can be very narrow. The filter will remove any other signals coming from the mixer that are not in the proper pass band and yield a clean signal for further processing.

The next stage is an amplifier with an adjustable gain feedback loop. The gain control is dependent on the amount of signal being received (this Automatic Gain Control "AGC" will be covered in a moment). The amplifier boosts the signal level of the incoming IF and gives us a stronger signal to work with. After the amplifier stage is another Intermediate Frequency Filter. This helps remove any unwanted residual signals still present and cleans up the amplified IF for a high quality signal. At this point the audio signal we are trying to obtain is riding on the IF signal.

The demodulator circuit finally extracts the message from the IF section through a process called envelope detection. Now that we have our message back in the audio realm, it is directed through the audio circuitry to the speaker output. The demodulated audio branches off before the audio circuitry and is used to perform some useful functions. The RSSI LED, Received Signal Strength Indicator Light Emitting Diode, gives us a general signal level feature. The stronger the signal we receive, the brighter the LED will glow. This is great for help pulling in those weak transglobal transmitter signals. The gain of the RSSI circuit is controlled by the value the feedback resistor R17. If you are commonly using a small whip antenna and listening to weak signals, you may need to increase the value of R17 to customize the response indication of D2, the signal strength LED.

The final stage, and the real secret to the sensitivity of the receiver, is the Automatic Gain Control (AGC). The gain control looks at the amount of signal level present at the output of the demodulator and varies the amount of gain the amplifier has accordingly. If there is a strong signal coming through the demodulator the AGC circuit lowers the gain of the amplifier. If the received signal coming through the demodulator is very weak, the AGC circuit increases the gain of the amplifier (Q2) allowing us to receive signals from around the world and listen to them with clarity.

Receiver assembly

Look for a clean well lit area in which to assemble your shortwave receiver. You will need a 27 to 30 watt pencil tip soldering iron, some 60/40 tin/lead rosin core solder, a few hand tools including a pair of end-cutters, a needle-nose pliers, a few screwdrivers and a pair of tweezers to pick up small parts. Locate your schematic and layout diagrams and we will begin to construct your new shortwave receiver. Let your soldering iron tip heat both the component lead wire and PC board trace enough so that the wire itself AND the foil trace BOTH become hot enough TOGETHER to melt a bit of solder so that it flows smoothly from the pin to the PC board trace. Locate the printed circuit board and all the components and we will start.

Before we begin constructing the shortwave receiver, refer to the resistor color code chart in Table 8-1 and the capacitor code chart in Table 8-2. Each resistor will have three or four color bands on them. The first color band will start close to one edge of the resistor body. The first color band will represent the first digit of the resistor value. The second color band will represent the second digit value, while the third color band illustrates

Table 8-1
Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000	
Blue	6	6	1,000,000 (M)	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No color				20%

the resistor multiplier value. The fourth band, if there is one, will represent the resistor's tolerance value. A silver band is a 10% tolerance, while a gold band depicts a 5% tolerance value. No fourth color band notes a resistor with a 20% tolerance. Locate all of the resistors for the project and place them in front of you. Each resistor has a color code which describes its value. Check the color code against the parts list and schematic before installing them onto the circuit board. Place about four or five resistors on the PC board and place these resistors in their respective locations carefully making sure each one is in the correct location. Next solder each of the resistors onto the circuit board. Trim off the excess component leads with a small pair of end-cutters. Pick up and identify the next grouping of resistors and install them on the circuit board, follow up by soldering this next batch of resistors to the circuit board, remember to trim the extra lead lengths form the PC board.

Once all the resistors have been installed onto the circuit board we can move on to identifying all of the capacitors for the project. Note that there will be different-looking capacitors for this project, some will be small disks, while others will be larger body devices with minus and plus marking on them. These larger capacitors with polarity marking are electrolytic capacitors and they have polarity which must be observed for the circuit to work correctly. Look through the parts pile and locate the capacitors and place them in front of you. You will notice a number of small disk capacitors, we will install these first. Look closely at each of the disk capacitors at their markings. Sometimes the capacitors are very small and they may not have their actual value printed on them but will instead have some sort of code. Refer to the parts list for these codes. Locate four or five of these small disk capacitors, identify them and install them on the circuit board, while referring to the schematic and layout diagrams. After inserting the disk capacitors onto the circuit board, you can go ahead and solder them to the circuit board. Remember to cut the excess component leads. Next move on and install another grouping of small disk capacitors, then solder them in place on the printed circuit board. Cut the extra component leads after soldering in the capacitors. When you are finished installing the small capacitors we will move on to the larger electrolytic types.

Capacitors C9 and C24 are 1.0 µF electrolytic capacitors and capacitors, while C11, C22, C23, and C27 are 10 µF electrolytic capacitors. Capacitors C13 and C14 are 220 µF, while C26 is a 1000 µF electrolytic capacitor. When installing these capacitors you must orient them with respect to their polarity. Each electrolytic will have either a plus or minus marking

Table 8-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

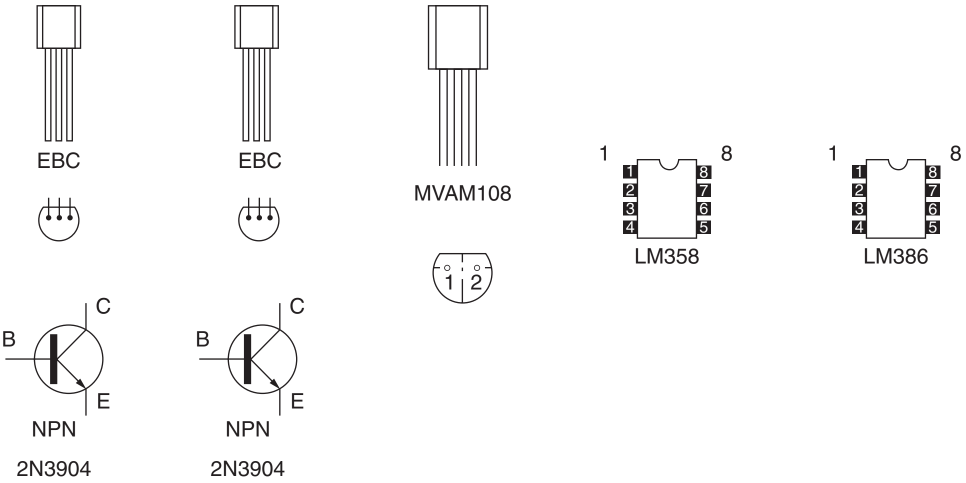

Figure 8-4 *Semiconductor pin-outs*

on them. You must look at the schematic and layout diagram and observe the polarity marking on the diagram match up with the markings on the capacitor when installing them to ensure that the circuit will work. Failure to observe polarity marking may result in damage to the circuit when it is first powered up. Identify these electrolytic capacitors and install on the PC board. Solder them in place and then cut the extra lead lengths flush to the edge of the circuit board.

Take a short break and locate the semiconductor pin-out diagram, shown in Figure 8-4, which illustrates the output pins of the transistors and integrated circuits in the receiver. Next, let's move on to identifying and installing the two diodes; note that diode D2 is the varactor or tuning diode and D1 is a glass bead style diode, while D3 is the red LED RSSI indicator. Diodes have marking on them that denote polarity and it must be observed for the circuit to work correctly. You will notice that a diode will have a small black or white colored band at one end of the diode body. This band denotes the diode's cathode. You will remember that a diode's symbol looks like a triangle pointing to a line. Well, the triangle is the anode and the line corresponds to the black or white band on the diode. Refer to the schematic when installing the two diodes and make sure you have installed them in the correct PC locations before soldering them in place. The RSSI LED is mounted on the front of the PC board near the potentiometers.

Now locate the three NPN transistors and we will install them on the PC board. Remember that transistors each will most likely have three leads, a Base lead, a Collector lead and an Emitter lead. The symbol for a transistor is a vertical line, with two other leads, at 45° angles, pointing to this vertical line. One of these angled leads will have a small arrow pointing towards or away from the vertical line, this lead is the Emitter lead. The vertical lead is the Base lead and the remaining lead is the Collector. Locate and identify these four transistors and install them on the PC board. Be sure you can identify each lead and that each lead goes to the correct PC hole on the board; refer to the layout diagram and schematic before soldering the transistors to the printed circuit board. Don't forget to trim the excess lead from the transistors after the transistors have been soldered to the board.

Now, it's time for a little "destruction"! (If you jumped ahead and installed T3, we've got bad news for you.) Before this, two shielded transformers can be installed, and the internal capacitors need to be removed. Looking at the underside of these two transformers, you'll see a tubular part, probably white with a brown band, somewhat like a resistor. These are brittle and easily crushed with any sharp object that can be pressed against them with mild force (small nail, small screwdriver). You'll find these capacitors will easily disintegrate into particles. DO NOT crush the capacitors in the other two inductors. After crushing the capacitor, install T3. Next locate the remaining inductor cans, i.e. T1 and T2 and install them on the PC board; remember orientation of the inductor cans is important. Now locate the small "resistor like" inductor, i.e. L1, L2 and L3. Solder the inductors to the circuit board and remember to trim the excess leads.

Finally we are going to install the integrated circuits to the circuit board. Consider installing IC sockets, instead of mounting the IC's directly to the PC board. Integrated circuit sockets are good insurance in the event of a possible circuit failure at some later date. It is much easier to unplug an IC rather than trying to unsolder one from a PC board. Mount three IC sockets to the PC boards at the respective locations of U1 and U2. Before installing the ICs we will need to make sure that you can identify the pin-outs on each of the ICs. Have a look at the eight pin integrated circuits, note that at the top of each of them you will see a notch in the center of the device or a small indented circle at the left side at the top of the package. The IC pin to the left of the notch or indented circle is pin one (1). Refer to the schematic and layout diagram to observe where pin one (1) is for each of the integrated circuits before installing them to the PC board. Once you are sure of the pin-outs for each of the ICs and where they go on the PC board, you can insert them into the proper IC socket. If there are any jumpers on the circuit board, you can go ahead and install them now.

Well, we have made quite a bit of progress on building your shortwave receiver. Take a short break and when we return we will mount the remaining final components. At this time look through the remaining parts and look for the two chassis mounted potentiometers R1 and R2. Place the potentiometes at the front of the PC board and solder them in place. Now, locate and install the power on-off switch at S1, and solder it in place on the printed circuit board.

Finally locate and install J1, an RCA chassis jack and J2, the ⅛″ phone jack onto the PC board. Locate the battery clip and solder it to the PC board, where you see the plus and minus markings. The red battery clip wire will go the plus marking on the board, while the black wire will go to the minus marking on the board. Install the battery clamp. Position battery and holder so as not to cover nearby PC board mounting holes. Use the method for securing the clamp that is most convenient for you, such as a (1) wire looped through clamp and PC board holes and soldered, (2) small screws, (3) double-faced adhesive strips or (4) hot-melt glue.

Your shortwave broadcast receiver is now almost finished. Now, you will need to decide what frequency range you would like your receiver to tune, and then select the values for C15 and C16 from the chart, shown in Table 8-3. A suggested configuration would be C15 = 47 pF and C16 = 100 pF. This will give you complete coverage from 6 to 11 MHz by adjusting T3 in or out. This is a very active section of the shortwave band and will provide you with hours of listening enjoyment any time of the day. Select and install C15 and C16.

Table 8-3
Band selection components

C16 = .001	**T3 Slug In**	**T3 Slug out**
C15	6.5–13 MHz	9–18.3 MHz
C15	5.1–7.9 MHz	7.1–10.7 MHz
C15	4.3–5.3 MHz	6–8.3 MHz
C16 = 100 pF	**T3 Slug in**	**T3 Slug out**
C15	8.4–14.2 MHz	11.5–19.5 MHz
C15	6–8.1 MHz	8.5–11 MHz
C15	4.9–6.3 MHz	6.7–8.4 MHz

Finally, you will need to locate an enclosure for the receiver, and then install the circuit board into the enclosure. Place the knobs on the potentiometer shafts, locate a 9 volt transistor radio battery and connect it to the receiver battery clips. Connect up an antenna and you are ready to test out your new receiver.

Before turning on your receiver, double-check that you have correctly oriented all three of the ICs, that you have correctly oriented the transistors, that you have installed the diodes correctly, and that you have installed the electrolytic capacitors correctly.

Finally we will inspect the circuit board for "cold" solder joints and possible "short" circuits. Pickup the PC board with the foil side of the board facing you and inspect the solder connections. You will want to make sure that all of the solder connections look clean, smooth and shiny. If any of the solder joints look dull, dirty or "blobby" then you should un-solder that particular joint and re-solder it over again so that it looks clean, smooth and shiny. Next, let's inspect the CP board for any possible "short" circuits. Often "stray" cut component leads will "bridge" across between circuit traces and "short" out a PC trace. Another possible source of "short" circuits is a solder blob which can "bridge" across a circuit trace. Carefully inspect the PC board for any solder blobs or "stray" wires before connecting up a 9 volt battery.

Initial testing and adjustment

Now, connect up a speaker or headphones, connect up some sort of antenna and install a fresh 9-volt battery and we can begin testing the receiver. We have come to the "moment-of-truth," go ahead and turn the receiver power switch to the "on" position. After adjusting the volume to a pleasant level, you should hear some shortwave stations by turning the Tune Control, no matter how any of the adjustable coils happen to be set. While listening to any kind of station, whether broadcast or Teletype, etc., use a small screwdriver to adjust the slugs in transformers T1 and T2 for the best-sounding reception. The Tuning Control covers varying segments of the bands selected by adjustment of oscillator coil T3. Adjustment of T3 anywhere between the full In position to the full Out position will give the user full range between the minimum and maximum frequency coverage set by C15 and C16.

Both T1 and T2 must be adjusted with a non-metallic alignment tool such as is used in radio-TV service. If you do not have one, a suitable tool can be made by patiently sanding a screwdriver-like blade on the end of a wooden match stick, kebab skewer or small plastic crochet needle. Again, please be aware that a metal screwdriver blade will drastically increase the coil inductance and make adjustment quite difficult. T1 and T2 are simply adjusted for strongest reception of any signal range that is tuned in.

If you do not have any sort of testing or frequency reference equipment whatsoever, the easiest way to begin using the receiver, is to set the Tune Control at its midpoint, slowly tune T3 with your alignment tool as though it were a tuning dial. Stop when you come into the middle of a group or cluster of foreign broadcast stations. Try tuning around these stations with the Tune Control. If you like what you hear, readjust both T1 and T2 for best reception. Eventually, you will get a clue as to what general frequency band you are hearing, because many stations periodically announce their frequencies, particularly at sign-on and sign-off times.

If you like precision, use a frequency counter or calibrated receiver to find the SR2's strong oscillator signal, remembering that there is a 455 kHz IF difference (above or below) between the local oscillator frequency and the broadcast signal you are hearing.

Shortwave antenna ideas

The type of antenna you'll want to use for your shortwave receiver depends on the degree of interest you have in shortwave listening, on whether you are limited to an indoor or balcony antenna. If you cannot use an outdoor antenna, you can make yourself a whip antenna from telescoping radio antenna from your local Radio Shack store. A better antenna would be to throw a 10 to 20 foot piece of insulated wire out the window, secured to a pole or tree away from your window. You could also place a length of wire in your attic to act as an antenna. An even better antenna would be a dipole antenna "cut" for the desired radio band of most interest. In order to construct your own dipole antenna, you can refer to the diagram depicted in Figure 8-5. Simply use the formula: 468 divided by the frequency in Megahertz for example. If you wanted to construct a dipole for 7.410 MHz, you would divide 468 by 7.410. The results would be 63.157 feet, so one-half of that number is 31.5 feet. Each leg of the dipole antenna would then be 31.5 feet. If you do construct your own dipole antenna, you should keep the antenna away from metal objects and use insulated wire and be sure to keep

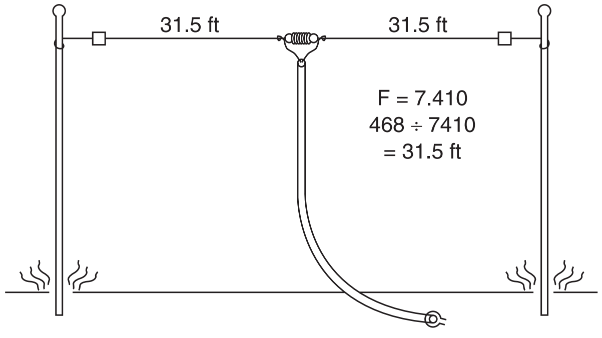

Figure 8-5 *Shortwave dipole antenna*

away from all power lines. The lead-in wire for your dipole antenna to your new receiver can be a length of RG8X min-coaxial cable.

Shortwave listening

Shortwave listening is a fun hobby for young and old alike. Once you have your antenna all set up, it is time to begin listening to your new radio. The chart in Table 8-4 illustrates the most common shortwave bands and their shortwave frequency in Megahertz vs. their wavelength in meters. Many times the shortwave bands are referred to in meters, such as the 40 or 80 meter band, so this chart will help you see the relationship between the two. As a shortwave radio listener, you will want to know what International broadcasters are broadcasting when you have time to listen to your new radio. Most people have spare time in the evening for their hobby. So you will want to know which bands are best for night time use, and who is broadcasting at that time. Refer to the chart in Table 8-5, which illustrates the broadcaster and their frequencies, etc. Usually the best shortwave bands, for evening use are the lower frequency bands such as the 40, 41 and 49 meter bands. Use this chart or check on the Internet for the latest shortwave listings. Have fun!

Table 8-4
Popular shortwave bands

Frequency vs. Meters

Broadcast Frequency – kHz/MHz	*Frequency in Meters*
2300–2495 kHz	120 Meters
3200–3400 kHz	90 Meters
3900–4000 kHz	75 Meters
4750–5060 kHz	60 Meters
5850–6200 kHz	49 Meters
7100–7350 kHz	41 Meters
9400–9900 kHz	31 Meters
11600–12050 kHz	25 Meters
13570–13800 kHz	22 Meters
15100–15800 kHz	19 Meters
17480–17900 kHz	16 Meters
18900–19020 kHz	15 Meters
21450–21850 kHz	13 Meters
25600–26100 kHz	11 Meters

Troubleshooting tips

If you experience difficulty, think of your receiver as consisting of several sections or stages: oscillator-mixer, IF audio and AGC, and final audio output (LM386). The first step in case of problems is to make sure that the tunable oscillator is working, which can be done by listening for its signal on another receiver. After the oscillator circuit is confirmed as working, standard signal tracing procedures should isolate any problem, which will be either an incorrectly installed part, a defective part or a bad solder connection. Correct orientation or polarity of all diodes, transistors, electrolytic capacitors and ICs is essential.

Problem: Strong shortwave broadcast audible throughout tuning range.

Solution: This can occur if your antenna is “too good” or if the RF Gain control is turned up too high. The high sensitivity of the front end is designed for simple antennas, with most reception quite satisfactory with only 25 feet or so of wire.

Problem: Local AM radio station audible throughout tuning range.

Solution: Whether this will even happen depends on how close you are to a local AM station. It is very important that all component leads be as short as possible, since just a bit of wire can help D1 and the several stages of audio amplification give you a free, unwanted “classic crystal radio.” A grounded metal case for the SR2 is one possible solution.

Chapter 9

80/40 Meter Code Practice Receiver

Parts list

80/40 Meter Direct Conversion Receiver Specifications

Sensitivity 3-uV or better

Modes CW, RTTY (FSK), SSB, AM

Audio output 50 mW typical

Frequency coverage Portions of the 80, 75, and 40 meter bands

Power Source 9 volt transistor battery, alkaline preferred

PC Board 4.000″ × 4.700″

80/40 Meter Direct Conversion Receiver

R2 15 ohm, $^{1}/_{4}$w, 5% resistor (brown, green, black)

R3,R8 100 ohm, $^{1}/_{4}$w, 5% resistor (brown, black, brown)

R1 1000 ohm variable potentiometer

C1 8.2 pF ceramic disk (8.2)

C18 100 pF ceramic trimmer capacitor

C19 15-50 pF variable capacitor (main tuning) - see text

C2,C6,C7 .1 μF monolithic (.1 or 104)

C3 see chart below

C4 not used

C5 see chart below

C8,C9,C10 .1 μF monolithic (.1 or 104)

C20 .01 μF ceramic disk (.01 or 103)

C12,C13,C14 1 μF, 35 volt electrolytic capacitor

C16,C17 470 μF, 35 volt electrolytic capacitor

C11,C15 10 μF, 35 volt electrolytic capacitor

U1 SA602 RF Mixer IC, 8-pin DIP

U2 78L05 voltage regulator

U3 LM386 audio amplifier, 8-pin DIP

S1 Power On-off switch

J1 RCA antenna jack

J2 $^{1}/_{8}$″ headphone jack

B1 9 volt transistor radio battery

Misc PC board, IC sockets, chassis, knobs, wire, battery

holder, battery clip, hardware, etc.

80 Meter Band Tuning components

C3,C5 470 monolithic capacitor (471)

L1 6.8 µH variable inductor, shielded

L2 3.3 µH molded choke (orange-orange-gold)

L3 33 µH molded choke (orange-orange-black)

40 Meter Band Turning Components

C3 470 pF monolithic (471)

C5 680 pF monolithic (681)

L1 1.5 µH variable inductor, shielded

L2 1 µH molded choke (brown-black-gold)

L3 10 µH molded choke (brown-black-black)

* Inductors available from Digi-Key Electronics, see Appendix.

Whether you're a novice or an "old-timer," you'll be pleasantly surprised at how this dual band Direct Conversion Receiver performs! The receiver can be constructed to receive either the 80 meter or 40 meter amateur radio bands. You will be able to receive AM, CW and SSB, signals from hams around the world.

Far-away signals are easily copied; and the sensitivity of the 80/40 Meter Direct Conversion Receiver rivals more expensive receivers. This receiver is ideal for practicing and increasing your CW or code efficiency or just having fun listening to shortwave broadcasts or ham radio operators, at home or away. Build the receiver for your favorite band, tuning options allow you to customize the tuning range from full-band to 100 kHz or less. Powered by a common 9 volt transistor battery, it's always ready for action on vacation and camping trips!

Figure 9-1 *80/40 meter code receiver*

The 80/40 Meter Direct Conversion Receiver shown in Figure 9-1, can easily be constructed by a radio neophyte in a few hours with the easy-to-follow instructions.

Circuit description

The circuit diagram shown in Figure 9-2 illustrates the schematic for the 80/40 Meter Direct Conversion Receiver. A dipole or suitable antenna is fed directly to input jack J1, which is coupled to potentiometer R1, which serves as a continuously variable RF attenuator and also serves as the receiver's gain control. Using the RF gain control to set volume is advantageous as it also reduces strong in-band signals that could otherwise overload the receiver front end. Series inductors L2 and L3, and trimmer capacitor C18, provide front-end bandpass filtering, and an impedance match to 50 to 75-ohm antenna systems. IC U1 is an NE602/612 mixer and Local Oscillator (LO) in an 8-pin dip package. The mixer section is an active Gilbert cell design for good conversion gain and low noise figure. The LO section uses heavy capacitive loading to minimize frequency drift. Tuning is capacitive, using a modern Hi-Q miniature plastic variable. The local oscillator (LO) stability is enhanced by a 78L05 voltage regulator.

Since this is a direct conversion receiver, the LO is tuned to the carrier frequency of Single Sideband Signals, or to a difference of 300 to 800 Hz on CW

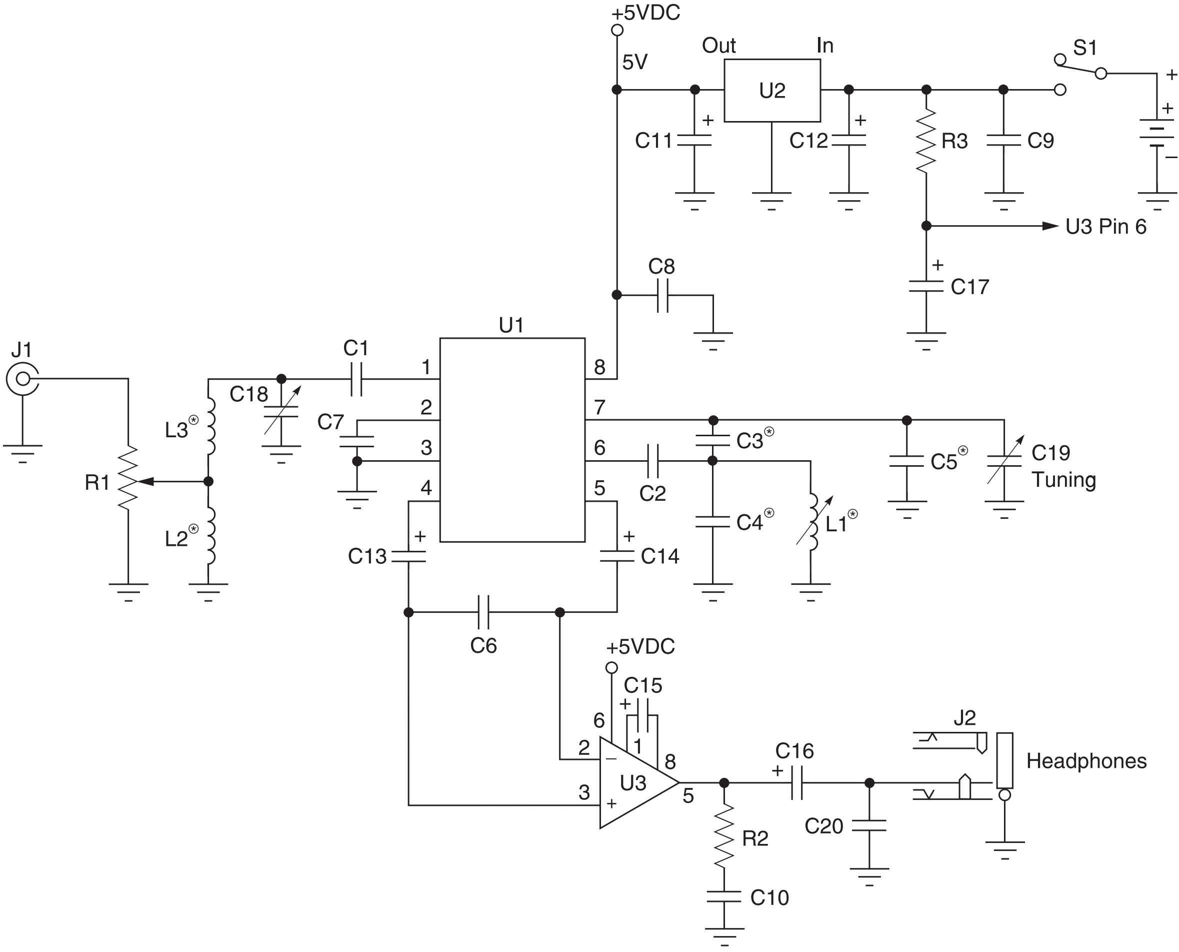

Figure 9-2 *80/40 meter direct conversion amateur radio receiver. Courtesy of Vectronics*

signals, to produce an aural output that is differentially coupled to a LM386 audio IC. The audio amplifier IC is coupled to the headphone jack at J2 by capacitor C16. The receiver circuit is power from a single 9 volt transistor radio battery.

Let's get started! Before we begin building the 80/40 meter receiver, you will need to locate a clean well lit and well ventilated work area. A large table or workbench would be a suitable work surface for your project. Next you will want to locate a small 27 to 33 watt pencil tipped soldering iron, as well as a roll of #22 gauge 60/40 tin/lead solder and a small jar of "Tip Tinner," a soldering iron tip cleaner/dresser, from your local Radio Shack store. You will also want to secure a few hand tools for the project, such as a pair of small end-cutters, a pair of tweezers and a pair of needle-nose pliers. Locate a small Phillips and a small flat-blade screwdriver, as well as a magnifying glass to round out your tool list. Grab the schematic, parts layout diagram as well as the resistor and capacitor identifier charts and we will begin our project. Place all the project components on the table in front of you. The 80/40 direct conversion radio is an RF or radio frequency project and it is best constructed on a printed circuit board with large ground plane areas covering the board for the best RF grounding techniques. Once you have all the parts and PC board in front of you, heat up the soldering iron and we'll get started!

First, find your resistor identifier chart in Table 9-1, which will help you select the resistors from the parts pile. Resistors used in this project are mostly small ¼ watt carbon composition type resistors, which have colored bands along the resistor body. The first color band should be closest to one end of the resistor body. This first color band represents the first digit of the resistor value. For example, resistor R2 has four color bands, the first one is a brown band followed by a green band followed by a black band. The fourth band is gold.

Table 9-1

Resistor color code chart

Color Band	1st Digit	2nd Digit	Multiplier	Tolerance
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000	
Blue	6	6	1,000,000 (M)	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No color				20%

The first band is brown, which denotes a digit one (1), the second band is green, which represents a digit five (5), and the third band is black, which represents a multiplier of zero (0), so the resistor value is 15 ohms with a tolerance value of 5%. Identify the remaining resistors for the project and we can begin "populating" the PC board. Place a few resistors on the board at one time, so as not to confuse the process. Make sure that you place the correct resistor into the correct PC location before soldering it in place. Once you solder a few resistors in place on the PC board you can use your end-cutter to trim the excess component leads. Cut the excess leads flush to the edge of the circuit board. Then place a few more resistors on the PC board and solder them on to the board. Remember to trim the component leads as necessary.

Next we will locate the capacitors for the 80/40 meter receiver. Capacitors are listed as electrolytic and non-electrolytic types. The non-electrolytic types are generally smaller in value and size as compared with the electrolytic types. Non-electrolytic capacitors, in fact, can be so small that their actual value cannot be printed on them, so a special chart was devised as shown in Table 9-2. The chart illustrates the three digit codes which are often used to represent capacitors. For example, a .001 µF capacitor will have (102), while a .01 µF capacitor will have (103) marked on it to represent its true value. Use the chart to identify the small capacitors in the project. Non-electrolytics have no polarity markings on them so they can be installed in either direction on the PC board.

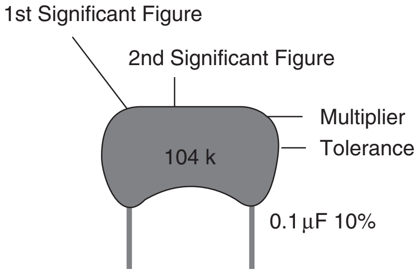
Electrolytic capacitors are usually larger in size and value and they will have a white or black band on the side of the capacitor body or a plus (+) or minus (−) marking on the body of the capacitor near the leads. These markings are polarity markings and that indicate the direction in which the capacitor must be mounted on the PC board. Failure to observe polarity when installing the capacitor may result in damage to the capacitor or to the circuit itself, so pay particular attention to capacitor polarity when placing the capacitors on the board. Note that the receiver can be built for either the 80 meter ham band or the 40 meter ham band. You will need to look at the parts list when deciding which band you want to receive. The inductors L1, L2 and L3 as well as capacitors C3, C4 and C5 determine the band selection.

Let's go ahead and place some of the non-electrolytic capacitors on the PC board. Identify a few small capacitors at a time and place them on the PC board and solder them in place. Trim the component leads after. Go ahead and install the remaining non-electrolytic capacitors after choosing your desired band. Install the capacitors and solder them in place, remember to cut

Table 9-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.



CSGNetwork.Com 6/4/92

Value	*Type*	*Code*	*Value*	*Type*	*Code*
1.5 pF	Ceramic		1,000 pF /.001 µF	Ceramic / Mylar	102

the extra leads flush to the edge of the circuit board. Now, you can go ahead and install the electrolytic capacitors onto the circuit board. Go ahead and solder them in place and trim the leads as necessary.

This receiver project uses a number of small inductors. These small inductors will generally have color bands on them to help identify them. Molded chokes appear, at first glance, to be similar to resistors in both shape and band marking. However, a closer look will enable you to differentiate between the two—chokes are generally larger in diameter and fatter at the ends than resistors. When doing your inventory, separate out any chokes and consult the parts list for specific color-code information. Note, that inductor L1 is an adjustable slug tuned type. Remember that specific chokes are used for each band: see parts list before mounting the chokes. Chokes do not have polarity so they can be mounted in either direction on the PC board.

The 80/40 meter receiver utilizes two integrated circuits and a regulator IC. Take a look at the diagram shown in Figure 9-3, which illustrates the semiconductor pin-outs. When constructing the project it is best to use IC sockets as an insurance against a possible circuit failure down-the-road. Its much easier to unplug an IC rather than trying to un-solder it from the PC board. IC sockets will have a notch or cut-out at one end of the plastic socket. Pin one (1) of the IC socket will be just to the left of the notch or cut-out. Note that pin 1 of U1 connects to C1, while pin one (1) of U2 connects to C15. When inserting the IC into its respective socket make sure you align pin one (1) of the IC with pin one (1) the socket. Failure to install the IC properly could result in damage to the IC as well as to the circuit when power is first applied.

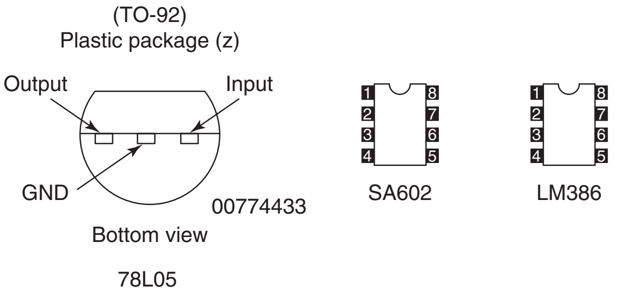

Figure 9-3 *Semiconductor pin-outs*

Let's finish the circuit board by mounting the volume control and the adjustable capacitors. The volume control potentiometer at R1 is a right angle PC board mounted type, which is placed at the edge of the PC board as is the main tuning capacitor. Capacitor C18, which is connected at the junction of L3 and C1, is an 8.2 pF trimmer type; go ahead and solder it to the circuit board using two pieces of bare #22 ga. stiff single conductor wire.

Locate main-tuning capacitor C19, now locate the mounting location for main tuning capacitor C19. The tuning capacitor was mounted on its side using double-sided sticky tape. Remove the protective cover from the double-sided tape, and firmly press the body of capacitor C19 to mount it to the PC board. Firmly press the double-sided tape over the silk-screened outline for the body of C19. You may decide to mount the tuning capacitor in a different way. At the rear of the capacitor: locate the four internal trimmer capacitors, and using a small jeweler's screwdriver or alignment tool, fully open (unmesh) all four trimmers. Note: tuning shaft faces front of board. Bend the two rotor lugs so they are parallel to the front face of the capacitor as shown above. Connect the two rotor lugs to the PC board ground points as shown using scraps of lead wire trimmed from resistors as jumper wires. Cut a 6″ length of 24-AWG insulated hook-up wire in half. Remove about ¼″ of the insulation from each of the cut ends. Solder the jumpers to the capacitor rotor lugs, and to the ground foil run on the bottom of the PC board. Since the tuning capacitor has four sections, you can increase the tuning ranges by paralleling different sections to give a greater tuning range: see Table 9-3. If you used just the 140 pF section, your tuning range would be 190 kHz, but if you combined the 140 pF section with the 40 pF section your tuning range would become 180 pF and so forth. Capacitor jumpers: 180 pF = use 140-pF and 40-pF sections paralleled; 222 pF = use 140-pF and 82-pF sections paralleled; 262 pF = use 140-pF, 82-pF and a 40-pF sections paralleled; 302 pF = use all four capacitor sections in parallel.

The 80/40 meter code practice receiver can be built for either of your favorite ham bands. First you will need to decide which band you are interested in. Then you will have to select the proper components from the chart in Table 9-4, for the band of interest. Note that you will have to select three capacitors and three coils for each band.

Table 9-3
Band tuning range

80 Meter Tuning	
302 pF	350 kHz
262 pF	310 kHz
222 pF	270 kHz
180 pF	230 kHz
140 pF	190 kHz
82 pF	110 kHz
40 pF	55 kHz
40 Meter Tuning Range	
302 pF	N/A
262 pF	N/A
222 pF	N/A
180 pF	310 kHz
140 pF	250 kHz
82 pF	150 kHz
40 pF	75 kHz

Let's take a few minutes for a short well-deserved break, and when we return we will look over the circuit board for any possible "cold" solder joints or "short" circuits. Pick up the circuit board with the foil side facing upwards toward you. First, we will examine the circuit board for "cold" solder joints. Take a look at all of the solder joints on the board, they should look clean, bright and shiny. If you see any solder joints which look dark, dull or "blobby," then you should remove the solder with a solder-sucker and then reapply more solder and re-solder the joint all over again so that it looks good. Next, we will look the board over for any possible "short" circuits which are often caused by "stray" component leads cut from the board or from small solder blobs which may have bridged between circuit traces. Rosin core solder can often leave a sticky residue which will collect component leads and solder blobs, so look the PC board over carefully for any foreign objects on the foil side of the board.

C5 - 680 pF capacitor	C5 - 470 pF capacitor
L1 - 1.5 µH molded coil	L1 - 6.8 µH molded coil
L2 - 1 µH molded coil	L2 - 3.3 µH molded coil
L3 - 10 µH molded coil	L3 - 33 µH molded coil

The 80/40 meter receiver radio prototype was mounted in a metal chassis box on plastic standoffs. The PC board was aligned in the enclosure so that the volume control, and main tuning control and power switch were all mounted at one side of the case. Alight the PC board along the edge of the chassis box, so that you drill holes in the chassis for the volume and tuning controls. The ⅛″ switched headphone jack at J2 was mounted on the front of the chassis, while the antenna input jack at J1 was mounted on the rear of the case. The 9 volt transistor radio battery was mounted in a battery holder which was fastened to the bottom panel of the chassis box.

Your new 80/40 meter direct conversion receiver project is almost completed. Apply the battery clip to the 9 volt battery. Connect up an antenna to the antenna jack, a dipole antenna cut for the band of interest would be the best type of antenna. For test purposes, you could connect a long piece of wire to the antenna jack for a temporary antenna. Plug in an 8 ohm headphone and then, turn on the power switch to the "On" position. Now, adjust the volume control to the mid-position and then turn the main tuning control. If all-goes-well, you should begin to hear some radio stations. You may want to test the radio in the early morning or evening when these two bands are most active for best results. Hopefully you will hear some stations while you tune across the band.

If for some reason, your receiver is DEAD, then you will want to turn off the receiver and remove the battery clip and do another inspection of the circuit board. This inspection is best done by another pair of eyes, someone who is skilled at electronics might be your best choice for inspection. You will want to make sure that you installed the electrolytic capacitors correctly with respect to their polarity. You will also want to make sure that the integrated circuits are aligned correctly in their respective sockets: it's easy to make a mistake. Check to make sure that the regulator IC at U2 was correctly installed with the input of the regulator going to capacitor C12, and the output of the regulator going to capacitor C11. Finally, make sure that you have the battery clip polarity wired correctly. Once you have examined the circuit board once more, you can go ahead and reconnect the battery and antenna and try the receiver again to see if it works now.

If your receiver is now working correctly, we can move on to the alignment of your new receiver. There are two primary methods of aligning the receiver's local oscillator.

Receiver alignment method 1: using an additional receiver

Place your new 80/40 meter receiver next to an amateur or general coverage receiver that covers the band of interest. Connect a short 3 or 4 foot wire antenna to the receiver, route the antenna wire so it passes near the direct conversion receiver PC board. Next, select a tuning tool that properly fits coil L1. The 20 meter kit requires a hex type alignment tool. The other kits require a small blade type tool that matches the slot in the coil core, or use a small jeweler's screwdriver. Now, set coil L1 tuning core to the top of the coil form. At this time, tune the receiver to the lowest operating frequency by turning the tuning capacitor shaft fully CCW (counter clockwise). Next, go ahead and set the monitor receiver to the lowest frequency you wish to receive on the direct conversion receiver. The receiver should be set to a wide filter bandwidth, and if it has a BFO, it should be on. Install a fresh 9 volt alkaline battery to the receiver, and turn it on by depressing the push-action power switch.

Finally, carefully adjust the core in coil L1 until it is heard sweeping across the monitor receiver frequency. Set the coil for zero beat, or strongest S-meter reading on the receiver. Note that metal alignment tools will cause some frequency shift, and interact with the tuning when removed or inserted into the coil. You will have to adjust the coil in small increments, and observe the point where the proper frequency is reached when the tool is removed.

Receiver alignment method 2: using a signal generator

First, set the signal generator to the direct conversion receiver's lowest operating frequency. Set the generator output level for a 30-µV CW signal. Next, connect the generator RF output to the VEC direct conversion antenna jack (J1) using coax cable and the appropriate mating connectors or adapters. Now, connect a speaker or headphones to jack J2 on the receiver. At this point, set the receiver gain fully CW (clockwise) and the tuning knob fully CCW (counter clockwise). Next, select a tuning tool that properly fits coil L1. The 20 meter kit requires a hex type alignment tool. The other kits require a small blade type tool that matches the slot in the coil core. Or, a jeweler's screwdriver may be used. Go ahead and set coil L1 tuning core to the top of the coil form. Now, connect a fresh 9 volt alkaline battery to the receiver, and turn it on using the push-action power switch. Finally, carefully adjust the core in coil L1 until the generator signal is heard. Set the coil for zero beat. Note that metal alignment tools will cause some frequency shift, and interact with the tuning when removed or inserted into the coil. You will have to adjust the coil in small increments, and observe the point where the proper frequency is reached when the tool is removed.

Final alignment

Once the tuning range is set, the RF input stage must be peaked for best sensitivity. This can be done using a signal generator, or on-the-air signals. Find an alignment tool or jeweler's screwdriver that fits trimmer capacitor C18. Use one of the following three methods to peak C18.

1. Using a signal generator, peak C18 for best sensitivity. Reduce the signal generator output, or reduce the R1 Gain control setting, to prevent overload as C18 is brought into resonance.
2. Using off-air signals, adjust C18 until signals are loudest. Reduce the R1 Gain control as C18 is

brought into resonance to prevent overload. Verify that C18 is properly peaked while monitoring a known on-air signal.

3. With an outside antenna connected, peak C18 for maximum atmospheric noise in the headphones or speaker. Verify that C18 is properly peaked while monitoring a known on-air signal.

Antenna considerations

With your new receiver completed and aligned, you can attach a dipole antenna for the chosen band of operation. Direct conversion receivers need good antennas. Using a random length of wire will give poor results. Half-wave dipoles are very effective antennas and are simple to construct. For low-power or QRP work, or for receive only applications, low-cost RG-58 52 ohm coax is fine. The formula for dipole antennas: 234/(frequency in MHz) = ¼-wavelength in feet will give the length of wire needed for each leg of the dipole. For example, if you wanted to build a 40-meter dipole for the CW portion of the band you would divide 234 by 7.040 MHz and the result would be 33.238 feet per leg on either side of the center insulator: see Figure 9-4.

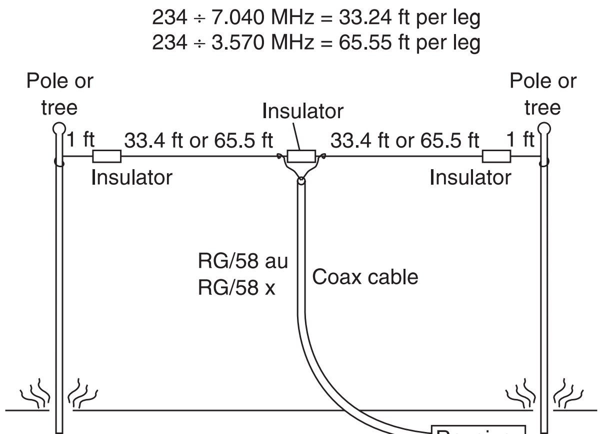

Figure 9-4 *80/40 meter dipole antenna*

Tuning notes

While trying to tune CW stations, you should tune across the band until a CW signal is heard. Set the gain control at R1 for a comfortable listening level. Then, carefully adjust the tuning control until the "beat note," or tone, sounds best for you. Most experienced CW operators prefer a lower beat note of about 300 or 400 Hz.

When trying to tune-in single-side band (SSB) stations, you may need a little practice to tune-in the signal properly. Direct conversion receivers offer no upper or lower sideband rejection, so you will have to slowly tune across the SSB signal until the voices become natural sounding. Use the gain control to prevent overload and to set a comfortable listening level.

In order to tune-in AM stations, you will need to realize that, unlike SSB signals, AM signals have a carrier frequency. That means you will hear a beat note as you tune across an AM signal. Tune the signal so the beat note becomes lower in frequency and stop when "zero beat" (beat note disappears) is reached.

Possible overload problems

An unfortunate fact of life is that low-power amateur signals are surrounded by high-power SW broadcast signals, so there may be a possibility of overload problems. In order to compensate for this possible problem, you may need to lower the gain control. Simply lowering the gain setting will resolve many overload problems. Another approach to an overload problem is to use a **preselector**. A preselector provides protection from strong out-of-band signals. They are most effective when the interfering signal is far from the operating frequency.

A resonant antenna favors signals in the band it was cut for, so when faced with a severe overload problem, you elect to use a resonant antenna. The final approach to solving an overload problem is to change the direction the dipole faces; this may lower unwanted pickup of undesired SW signals. Lowering the antenna will change its angle of pickup; a low antenna may favor local stations over the low-angle of distant broadcast signals. A shorter antenna can also be tried; it will be less efficient and signals will be weaker.

Frequencies are 1.8175, 3.5815, 7.0475, 14.0475, 18.0975, 21.0675, 28.0675 and 147.555 MHz.

Slow Code = practice sent at 5, 7½, 10, 13 and 15 words per minute (wpm).

Fast Code = practice sent at 35, 30, 25, 20, 15, 13 and 10 wpm.

The chart shown in Table 9-5 illustrates the W1AW code practice sessions for Ham Radio operators or those interested in obtaining a Ham Radio license. The 80-meter frequency is 3.5815 MHz and the 40-meter frequency is 7.0475. The Amateur Radio Relay League (ARRL) offers these code practice sessions every day to help amateur radio enthusiasts increase their code speed. The ARRL is a great resource for those interested in Amateur Radio and offers many books, magazines and free literature in including videos to help you understand what Amateur Radio is all about. Take a few minutes and explore their web-site.

Does anybody really know what time it is? The WWV receiver, shown in Figures 10-1 and 10-2, is designed to tune the National Institute of Standards and Technology (NIST) atomic clock for moment by moment time accuracy! This is a great receiver project that actually serves a dedicated purpose. Put one in the boat or on a desk and you'll always know what time it is!

The WWV receiver is quite sensitive, and with a good antenna you should be able to receive time signals most of the time! The receiver features easy tuning and small size, it can be packed up and taken anywhere and runs on a 12 volt DC power supply, or a 12 volt battery for portable operation. An earphone jack is provided for headset operation so you can use it night or day.

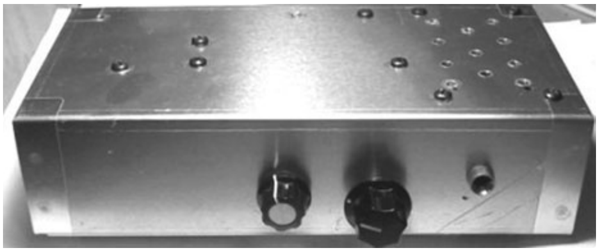

Figure 10-1 *WWV time code received*

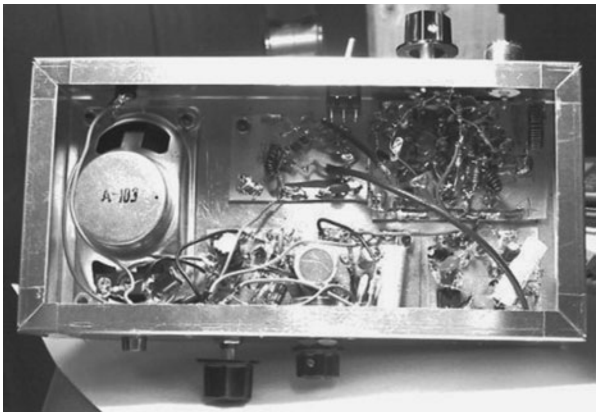

Figure 10-2 *WWV time code received – inside view*

People have always been fascinated with the measurement and properties of time. What happened to that last second that you just spent reading this sentence? Perhaps this is the reason that so many of us have tuned in over the years to the National Institute of Standards and Technology (NIST) "clock" operating at a transmitting frequency of 10 MHz. The cesium standard NIST-7 has an accuracy of 5 × 10-15 seconds. Now that's accurate! In fact, the definition of a "second" is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom.

We set our clocks, watches, and chronometers to the all-important "beep" of the radio signal that denotes the correct time to the second. In addition; avid listeners of the NIST clock are also treated to the following (from the NIST web site).

The OMEGA Navigation System status reports are voice announcements broadcast on WWV at 16 minutes after the hour. The OMEGA Navigation System consists of eight radio stations transmitting in the 10- to 14-kHz frequency band. These stations serve as international aids to navigation. The status reports are updated as necessary by the U.S. Coast Guard. Current geophysical alerts (Geoalerts) are broadcast in voice from WWV at 18 minutes after the hour. The messages are less than 45 s in length and are updated every 3 hours (typically at 0000, 0300, 0600, 0900, 1200, 1500, 1800, and 2100 UTC). Hourly updates are made when necessary.

Marine storm warnings are broadcast for the marine areas that the United States has warning responsibility for under international agreement. The storm warning information is provided by the National Weather Service. Storm warnings for the Atlantic and eastern North Pacific are broadcast by voice on WWV at 8, 9, and 10 minutes after the hour. An additional segment (at 11 minutes after the hour on WWV) is used occasionally if there are unusually widespread storm conditions. The brief voice messages warn mariners of storm threats present in their areas. The storm warnings are based on the most recent forecasts. Updated forecasts are issued by the National Weather Service at 0500, 1100, 1700, and 2300 UTC for WWV. Since March 1990 the U.S. Coast Guard has sponsored two voice announcements per hour on WWV giving current status information about the GPS satellites and related operations. The 45-s announcements begin at 14 and 15 minutes after each hour.

WWV radiates 10,000 watts on 5, 10, and 15 MHz. The WWV antennas are half-wave dipoles that radiate omnidirectional patterns. The station uses double sideband amplitude modulation. The modulation level is 50 percent for the steady tones, 25 percent for the BCD time code, 100 percent for the seconds pulses and the minute and hour markers, and 75 percent for the voice announcements. That's a lot of information being broadcast, and you can easily pickup these signals with the high frequency 10 MHz Time Receiver shown in this project. The WWV Time receiver has excellent sensitivity, selectivity, and dynamic range. (from the NIST web site http://www.nist.gov/)

Circuit description

The 10 MHz WWV Receiver is shown in the block diagram of Figure 10-3 and in the main schematic diagram in Figure 10-4. The WWV Time Code receiver is an AM TRF or Tuned Radio Frequency or TRF type receiver. This receiver project is designed specifically for 10 MHz time signal operation. The block diagram of the WWV receiver illustrates the four major sections of the receiver. The receiver's front-end, as shown in the schematic diagram, features two sensitive dual-gate MOSFETs in the front-end circuit with a single-pole filter. An RF gain control is shown at VR1 which adjusts the input sensitivity, via a 10k ohm potentiometer. Note inductor L1 is 4.1 µH coil, which consists of 27 turns of 22 ga. AWG wire wound on a

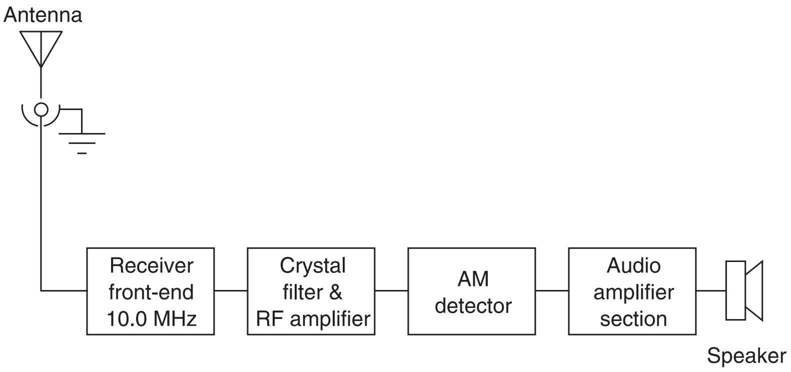

Figure 10-3 *10 MHz WWV receiver block diagram*

T-68 ferrite core. Inductors L2 and L4 consist of 12 turns of 22 ga. AWG wire on an FT37-43 ferrite core, and finally L3 consists of 25 turns of #26 ga. AWG wire on a T50-2 ferrite core. For even greater selectivity (but greater insertion loss), you can consider moving the L1 tap to 1 turn from ground. Fine tuning the WWV receiver is accomplished by adjusting CV1 and CV2 trimmer capacitors. The front-end MOSFETs are extremely sensitive to static electricity, so be very careful in handling them. Note the two ferrite beads, one is placed in series with the Drain lead of Q1, while the second ferrite bead is in series with the Drain of Q2. These ferrite beads are important, so be sure to use them. The receiver front-end, at J1, should be connected to a dipole antenna "cut" for 10 MHz. TRF receivers are especially sensitive and are subject to overloading a BCB or Broadcast Band Interference, so internal lead lengths should be kept short between components and the front-end should be shielded and the receiver placed in a metal enclosure for best results.

The output impedance of Q2 is 2000 ohms, which nicely matches the input impedance of the Cohn crystal filter, in the crystal filter section of the receiver. This filter utilizes three 10 MHz crystals. Choose 10 MHz crystals that are marked for a 20 pF or 32 pF load capacitance if possible. Using a 10 MHz crystal oscillator, find three that are closest to one another in frequency. You may substitute 2.2k ohm resistors instead of the specified 2k with a slight penalty in pass band shape. The crystal filter section utilizes a single dual-gate MOSFET transistor at Q3. Coil L5 is 12 turns on an FT37-43 ferrite core. The output of the Cohn crystal filter is next fed to the input of the AM detector stage.

The AM detector has three distinct advantages; it has high bandwidth, low distortion and incredible (and variable) sensitivity. The variable bias control allows the listener to adjust the bias to maintain detected audio fidelity even when the RF signal is weak. The detector uses a Schottky UHF mixer diode at D1. Increasing the diode bias from zero volts to maximum causes three things to happen: increased sensitivity, increased audio high frequency response, and a slight increase in receiver noise.

The AM detector section matches the 2000 ohm impedance of the crystal filter stage quite nicely. A sensitivity control at VR2 is a 1 megohm potentiometer, which feeds directly to L6, a 1000 µH coil. Coil L6 is connected directly to a Schottky diode at D1. The resultant signal is next sent through a 5.6k ohm resistor and on to a 1 µF capacitor which feeds the nJFET at Q4. The Source lead of Q1 is connected to the Drain lead of Q5, and the Source lead of Q5 is connected to ground via a 5.6k ohm resistor. Note the two 22 µF electrolytic capacitors on each of the Drain leads of the nJFETs.

When the WWV RF signal is weak, turning the bias off may result in the detected WWV signal disappearing. Increasing the bias will bring the WWV signal back in. You run the bias control pot about half way and, of course, higher as WWV fades out. The fidelity that the bias adds even when the WWV signal is strong is quite pleasing to the ear. For the 1 µF and 2.2 µF capacitors, I used polyester film types which sounded better than electrolytic capacitors.

The audio amplifier section features low noise audio amplifier. Distortion is very low as long as the input is

not over driven. The audio amplifier section consists of a dual NE5532 op-amp and three transistors. Transistors Q6 and Q7 are NPN types, while transistor Q7 is a PNP type. The input signal from the detector is fed directly to the volume control at VR3, a 10k ohm potentiometer. The input signal is first sent to the non-inverting stage of the first op-amp at pin 3. The output of the first op-amp section at pin 1 is next sent to the second stage of the op-amp through a .1 µF capacitor in series with a 4.7k ohm resistor to pin of U1:b. The output of U1, at pin 7 is then fed to the output transistor stage. The output of the transistor pair is two 1000 µF capacitors which coupled to a 330 µF capacitor which feeds the 8 ohm speaker.

The entire WWV receiver is powered from a 12 volt "wall-wart" power or can be powered from a 12 volt battery for portable operation.

Receiver assembly

You are probably quite anxious to begin the assembly of the receiver project; it is best to follow the assembly steps in order. Try to avoid the urge to "jump ahead" installing components. Locate your layout and schematic diagram. Place all the components in front of you and locate a 27-30 watt pencil tip soldering iron. Make sure you have a large work table in order to spread out all the parts and diagrams. A printed circuit board is highly recommended for this project, so you should have your circuit board in front of you oriented correctly, in order to begin populating the PC board. Remember that the components will be mounted on the "component" side of the circuit board and soldered on the "solder" side of the circuit board, the side with the printed circuit traces. Locate a spool of 60/40 tin/lead rosin core solder for this project.

First we will begin by locating all of the resistors for the project. Most all of the resistors are ¼ watt carbon composition type resistors except for the potentiometer. Before we begin building the Time receiver, take a moment to refer to the resistor color chart shown in Table 10-1. Note that each resistor will have three or four color bands beginning at one end of the resistor body. The first color code represents the resistor's first digit value, while the second color band denotes the resistor's second digit value. The third color band represents the multiplier value of the resistor and the fourth band denotes the tolerance value of the resistor. If the fourth color band is silver then the resistor has a tolerance of 10%, while a gold band denotes a 5% tolerance. If there is no fourth color band then the resistor has a tolerance of 20%. The first color band of a 10,000 ohm resistor, for example,

Table 10-1
Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000	
Blue	6	6	1,000,000 (M)	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No color				20%

would be brown with a value of (1). The second color band would be black with a value of (0). The third color band would be orange with a value of (000). Read the color codes on the resistors and compare them to the parts list and layout diagram so that you place the correct resistor in the correct hole on the printed circuit board. You can install the resistors in groups of four or five. Solder the first group of resistors onto the circuit board, then cut the excess component leads flush to the edge of the PC board using a pair of small end-cutters. Then move on to the next group of resistors until all of the resistors have been installed.

Next we will move on to installing the capacitors. Most all of the capacitors will have some sort of marking on them, so compare the value or marking on the component with the parts list before installing the components on the PC board. Note that capacitors C24, C25, C26, C27 are all electrolytic capacitors; these capacitors will have additional polarity markings on them and they must be installed with respect to these polarity markings in order for the circuit to work properly. Each of these capacitors will have a white or black band with either a plus or minus marking on one side or edge of the component. You must orient the capacitor correctly, so you should refer to the layout diagram and schematic diagram when installing these parts. Also note that capacitors C32 through C38 are also all electrolytic types. All the other capacitors have no polarity marking so they can be installed in either direction. Now, you will want to refer to the capacitor code chart shown in Table 10-2, which illustrates the codes used for small size capacitors. Often very small capacitors will not have their actual value printed on them, because there may not be enough room, so a three-digit code was developed. Look at the chart and compare the numbers on the chart with the actual capacitors to help identify them. You can go ahead and install all of the capacitors at this time. It is best to install the capacitors in groups of four or five at a time, then solder them on to the circuit board before moving on to the next group of capacitors; this helps keep some order to the building process. It is also advisable to check off each of the components against the parts list, so you can keep tabs on your progress and make sure that all of the parts are accounted for. Solder a group of four or five components, cut the excess leads and then move on to the next group of components. This will keep things in an orderly fashion.

Next, go ahead and locate and install the Schottky diode at D1. Note that the diode has a polarity marking on the glass enclosure. At one end of the diode body you should see a black or white band; this denotes the cathode side of the diode. Look at your schematic diagram to observe the direction of the cathode band in the circuit before you install the diodes.

The WWV receiver incorporates six inductors; five of the inductors are wound on ferrite cores, while L6 is a ready-made 1000 µH choke coil. Refer to the chart in Table 10-3 for details on winding each of the coils. When winding the coil you will have to scrape the insulation off each of the wire ends in order to solder the coil to the circuit board. You will need to secure the coil to the circuit board using a couple of "dabs" of rubber cement. Once the coils have been secured to the PC board, you can solder the coil leads to the circuit board, and then remove the excess lead lengths.

Locate the three crystals, Y1, Y2 and Y3 and place them on the PC board. Now solder the crystals to the PC board and then trim the excess leads flush to the edge of the circuit board.

Before we attempt to install the semiconductors, take a quick look at the semiconductor pin-out diagram shown in Figure 10-5. Now locate the MOSFETs Q1, Q2 and Q3. These devices are very static sensitive and must be handled very carefully using an anti-static wrist-band to avoid damage before they are soldered into the circuit. Transistor sockets are highly recommended for all of the transistors, see the pin-out diagram for the MOSFETs and make sure you can identify each of the leads before placing the MOSFETs on to the circuit board. The MOSFETs have two Gate leads, G1 and G2, as well as a Source lead (S) and a Drain lead (D). Once you are sure of each of the leads, you can go ahead and install the MOSFETS onto the circuit board. The AM detector portion of the receiver utilizes two nJFETS at Q4 and Q5, these semiconductors are also static sensitive and must be handled with extreme care to avoid damage. The nJFETS have three leads, like most conventional transistors, but they have a Gate, Source and Drain lead,

Table 10-2
Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

unlike conventional transistors, with a Base, Emitter and Collector. Once the nJFETS have been identified, they can be installed on the circuit board. Finally, the audio amplifier section utilizes three conventional transistors. Transistors Q6 and Q7 are NPN types, while Q8 is a PNP transistor. Transistors have three "legs" and must be oriented correctly. Notice that the part contains a "flat" side with the writing imprinted on it. Be sure to follow the parts diagram for correct placement. To install, slide the center legs through the circuit board and push the component as close to the board as possible without "straining" the leads. Identify the transistor pin-outs and then go ahead and install the transistors onto the circuit board. Remember to trim the

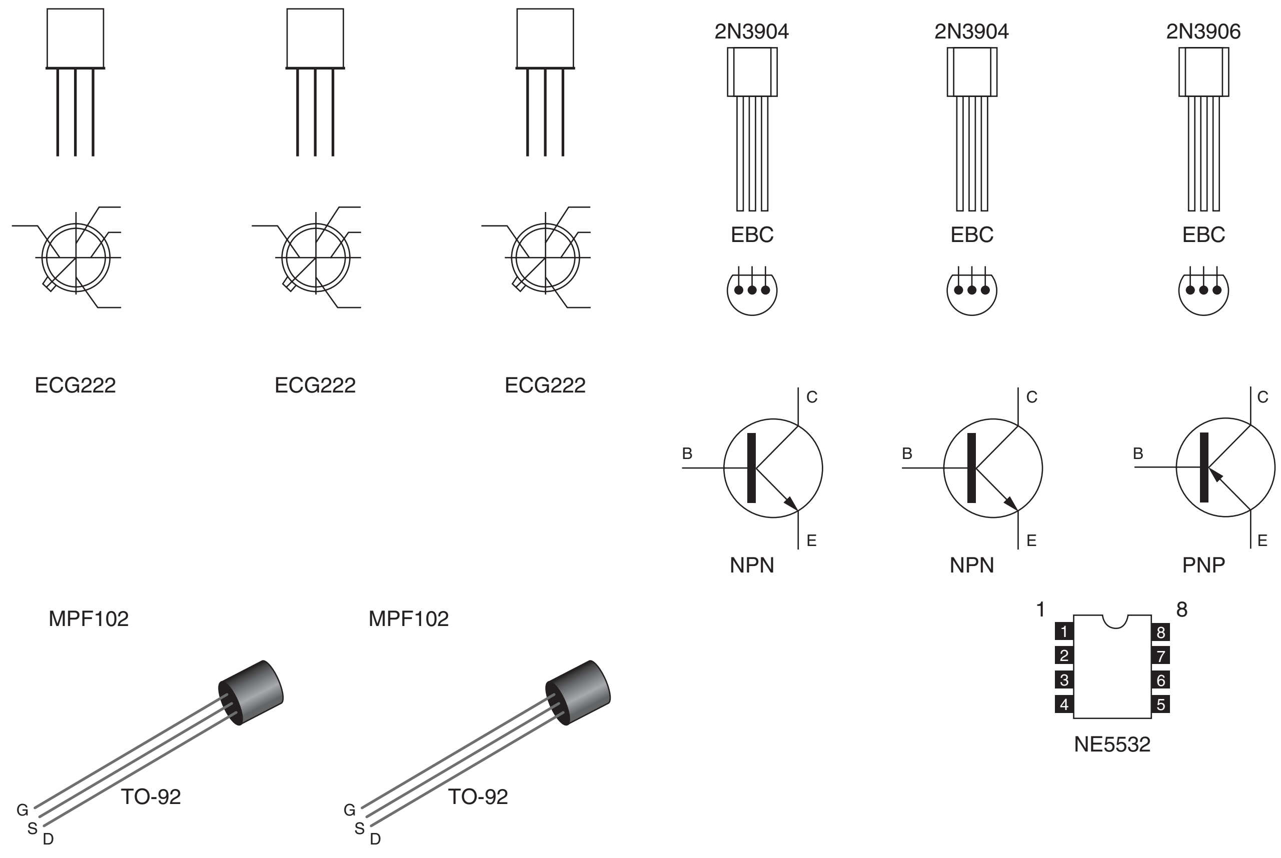

Figure 10-5 *Semiconductor pin-outs*

excess transistor leads after all of the transistors have been installed on the PC board.

It is a good idea to use an IC socket for each of the integrated circuits in the event of a component failure at a possible later date.

Leads length from the board

Now that your soldering skills are at their peak, we'll install the integrated circuit. An integrated circuit socket is highly recommended in the event of a possible circuit failure. It is much easier to simply unplug a "burnt" IC, rather than trying to un-solder a defective IC from the circuit board. Most hobbyists have considerable trouble trying to un-solder multi-pin integrated circuits from a PC board successfully, so it is easier to install a socket from the beginning. Most IC sockets will have a notch or cut-out and one end of the plastic package. Pin 1 will be just to the left of the notch or cut-out. Make sure you orient the socket, so that pin 1 will be close to C29, C31 and R22. When installing the IC into the socket make sure you align pin of the IC with pin 1 of the IC socket.

That's a lot of parts! Take a short break and rest your weary eyes. Before we start up again, we will check your solder joints for "short" circuits and "cold" solder joints. First, pick up the circuit board with the foil side of the board facing upwards toward you. Take a close look at the solder joints in front of you. The solder joints should all look clean, bright and shiny. If any of the solder joints look dark, dull or "blobby," then you need to remove the solder from that particular joint, re-apply solder and re-solder the joint all over again. Next, we will inspect the circuit board for possible "short" circuits. Look closely for small solder "blobs" that often bridge circuit traces. Also look carefully for any "stray" components leads which may have stuck to the foil side of the PC board. Sometimes sticky rosin from solder can leave a residue that will "hold" pieces of wire on the board, often causing "short" circuits between circuit traces.

Identify and install the three potentiometer; they can now be mounted on the metal enclosure that you chose to use for the receiver. Make up three or four inches leads for each of the potentiometer leads, so you can connect the potentiometer to the circuit board. All three potentiometers can be mounted on the front panel of the receiver enclosure. Using a length of speaker wire, connect the speaker to the circuit board. The speaker can be mounted on the top or front of the enclosure.

If you desire you can customize your new receiver with an LED power indicator. Install a red LED on the front panel. Being a diode, this component is polarized and must be oriented correctly. Examine the LED and notice how one lead is longer than the other. The longer of the two leads is the anode, or (+) connection. Most diodes also have a flat side molded in the component body. This corresponds to the cathode or (–) side of the part. This flat should face in the direction of the band marking of the diode. Leave the diode's leads as long as possible as this component will also mount to the front panel as a power indicator. You can connect up the LED across the power input of the circuit's +12 volt lead and ground.

You can also customize the receiver by installing a closed circuit earphone jack if desired, so that the jack will bypass the speaker when the headphones are plugged into the jack.

Moving to the rear of the enclosure, install antenna connector J1, you can use an RCA jack or a BNC connector as desired. Next, go ahead and mount a coaxial power plug on the rear panel of the chassis and then solder the connectors to the circuit board using a length of insulated wire. Now you will need to decide how you will power your new WWV receiver. You elect to power the receiver from a 12 volt battery or re-chargeable power pack or from a 12 volt DC "wall-wart" power supply.

Congratulations, you have successfully completed your WWV receiver; now let's move on to final testing of the receiver!

Initial receiver testing

This project was designed to be pretty much "plug and play," with minimal testing upon completion. Turn all three potentiometers to their mid-point position. Connect up you power supply or battery and depress the power switch. The power on LED should illuminate. Connect up your outdoor antenna via connector J1.

Now increase the RF gain control, more clockwise. You can also adjust the volume control for more gain as well. You should begin to hear the "beep" signal from the WWV Colorado transmitting station. You may have to adjust VR2 until the signal is sound best in the speaker. If the signal is too strong, you may have to adjust the RF gain and volume control as needed.

In the event that you do not hear any sounds from your new receiver, you will have to turn off the receiver and remove the battery and do a close inspection of the circuit. The most common reasons for circuit problems is due to placing the wrong component in a particular circuit board location or possible reverse placement of a component. Take a look at the Time-Code Receiver circuit board very carefully. Sometimes it is better to get a pair of "fresh eyes" or have a friend take a look at your circuit to find a possible error. Look at each of the resistors and make sure you have placed the correct resistor in each resistor location; read the color code carefully. Check the placement of the diodes and electrolytic capacitors to make sure you have installed them with respect to their polarity marking. Next, take a close look to make sure that you have installed the transistors correctly, looking closely at the pin-outs with respect to the manufacturer's pin-out diagram. Finally, examine the circuit to make sure that the integrated circuit has been oriented properly in its IC socket, since this is a common cause for error. Once you have fully inspected the circuit board and located your error, you can re-connect the battery and switch on the receiver to test it once again.

Antenna considerations

In order to obtain the best reception on your new WWV Time-Code receiver you will want to construct an optimum antenna. Using a random length of wire will give poor results. A very efficient method to use with the WWV Time-Code receiver is a dipole antenna "cut" for the proper frequency of 10 MHz. Half-wave dipoles are very effective antennas and are simple to construct. For low-power work or receiver use, you can use low-cost RG-58 52 ohm coax from the dipole antenna to your new receiver. The formula for dipole antennas: 234/(frequency in MHz) = ¼-wavelength in feet will give the length of wire needed for each leg of the dipole. For example, if you wanted to build a 10 MHz dipole for your Time-Code receiver, you would divide 234 by 10 MHz and the result would be 23.4 feet per leg on either side of the center insulator. The diagram in Figure 10-6 illustrates a dipole antenna which can be used with the Time-Code receiver. Depending upon your location, you will want to orient the antenna for best reception. The antenna should be placed broad-side or parallel towards Colorado for best reception.

Using your new WWV receiver

You will have fun learning about other interesting things on WWV besides the time function feature, such as accurate tone frequencies, geophysical alerts (solar activity reports), marine storm warnings, the global positioning system (GPS) and Omega navigation system status reports.

Table 10-4 shows the broadcast schedule for WWV in Fort Collins, CO. A similar schedule is available for WWVH in Hawaii. This diagram is extracted from a National Institute of Standards and Technology (NIST) publication. If you want to order a copy, it is available for a modest charge from the Government Printing Office, Washington DC 20402. Write and ask for a current list of available publications. The two features of most interest are precise frequency of the carrier signal, to calibrate radio and test equipment, and precise time information given each minute as a voice transmission. But there are many other interesting parts of their transmissions.

☐ Beginning of each hour is identified by 0.8-second-long, 1500-Hz tone.

☐ Beginning of each minute is identified by 0.8-second-long, 1000-Hz tone.

☐ The 29th and 59th second pulses of each minute are omitted.

☐ 440 Hz tone is omitted during first hour of each day.

There are various tones which can be used to check audio equipment or musical instruments and they can be captured to detect the start of each hour or each minute. At certain intervals, voice announcements are made for the benefit of other government agencies.
The predominant ones are as follows:

Marine storm warnings are prepared by the National Weather Service and broadcast for areas of the Atlantic and Pacific Oceans which are of interest to the US Government.

Global Positioning System status announcements are prepared by the Coast Guard to give current status information about the GPS satellites.

Omega Navigation System reports are prepared by the Coast Guard to give the status of the 8 Omega transmitting stations in the 10–l4 kHz frequency range. These serve as navigation aids.

Geophysical alerts are prepared by the Space Environment Service Center of NOAA. They are broadcast on the 18th minute of the hour and give information of interest to amateur radio operators, as well to as various scientific organizations regarding solar activity, geomagnetic fields, solar flares, and other geophysical statistics. This propagation information can help you decide when the DX will be good.

- Beginning of each hour is identified by 0.8 second-long, 1500 Hz tone.
- Beginning of each minute is identified by 0.8 second-long, 1000 Hz tone.
- The 29th and 59th second pulses of each minute are omitted.
- 440 Hz tone is omitted during the first hour of each day.

You will have fun learning about other interesting things on WWV at certain times besides just the time function feature. Features such as accurate tone frequencies, geophysical alerts (solar activity reports), marine storm warnings, and global positioning system (GPS) and Omega navigation system status reports.

Chapter 11

VHF Public Service Monitor (Action-Band) Receiver

Parts list

VHF Public Service Monitor Receiver:

R1,R2,R3 10k ohm potentiometer

J1 PC mount RCA jack

J2 PC mount subminiature speaker jack

B1 9 volt transistor radio battery

ANT telescoping antenna

Misc PC board, battery holder, battery clip, speaker, etc.

Keep an ear on the local action from your easy chair with the VHF Public Service Receiver project, shown in Figure 11-1. The VHF Public Service Radio will allow you to tune the VHF high-band Police and Fire band, marine band, weather band, as well as railroad frequencies. The receiver tunes any 5 MHz portion of the 136 to 175 MHz band. Excellent performance, less than 1 uV sensitivity. The receiver features: tuned input, low noise pre-amp stage with true dual-conversion superhet design with 2 pole Ceramic High Intermediate Filter or I-F and 6 pole ceramic low I-F filters! The receiver also features front panel volume, squelch, and tuning controls. This is a great inexpensive receiver to put on your desk at home or to “watch” local radio activity while you are away from home on vacation or business trip.

Circuit description

The heart of the VHF Public Service Receiver shown in the block diagram of Figure 11-2 is the MC3359

integrated circuit. The integrated circuit is a complete high gain low power FM IF sub-system which includes an oscillator, a mixer, a limiting amplifier, AFC, quadrature discriminator, op-amp, squelch, scan control and mute switch all combined in a single IC. The MC3359 was designed to detect narrow-band FM signals using a 455 KHz ceramic filter.

Let's get into more details of the VHF Public Service Receiver by examining the schematic diagram shown in Figure 11-3. VHF signals from the antenna are amplified through the tuned input circuit (L1, C3 and L2, C4) by Q1, a microwave bipolar transistor. Q1's output is fed to the input of the SA602 IC, an efficient single-package (8-pin DIP) mixer-product detector-oscillator. The tuneable oscillator section of the SA602 is aligned to operate at 10.7 MHz higher than the signal fed and amplified by Q1. For example, to receive 144-148 MHz signals, the oscillator must tune 154.7 to 158.7 MHz in order for the SA602's mixing capability to produce a steady 10.7 MHz output signal to the rest of the circuit. The oscillator frequency is determined by L3 and its associated capacitors, and varied by the varactor tuning network using D1 and varied by R1.

The output from pin 4 of the SA602 passes through a ceramic 10.7 MHz filter, amplified by transistor Q2 and applied to input pin 18 of U2. Q3 provides AFC (Automatic Frequency Control) by keeping the local oscillator of U1 from drifting away from an incoming signal. This is accomplished by tuning the varactor circuit in the direction opposite the drift.

Figure 11-3 *VHF public service block diagram*

The MC3359 IC has an internal oscillator controlled by the 10.24 MHz crystal. The 10.24 MHz signal is mixed with the 10.7 MHz input from U1 to convert down to the low IF of 450 kHz. The 450 kHz IF is filtered by FL2 and then amplified by a limiting amplifier in U2. Audio demodulation takes place in the quadrature detector, with L4 adjusting the detector. The audio modulation is detected in U2, and the background noise is used to control the squelch. U3 amplifies the audio output from pin 10 of U2 to a practical level for speaker or headphone operation. Pin 16 of U2 will ground the input of U3 when the squelch is closed. L4, a 450 kHz IF coil, permits adjustment of the 90 ° voltage-current phasing ("quadrature") of FL2's output to the FM detector demodulator (pin 8 of the MC3359).

Circuit assembly

Look for a clean well lit area in which to assembly your shortwave receiver. You will need a 27 to 30 watt pencil tip soldering iron, some 60/40 tin/lead rosin core solder, a few hand tools, including a pair of end-cutters, a needle nose pliers, a few screwdrivers and a pair of tweezers to pick up small parts. Locate your schematic and layout diagrams and we will begin to construct your new shortwave receiver. Let your soldering iron tip heat both the component lead wire and PC board trace enough so that the wire itself AND the foil trace BOTH become hot enough TOGETHER to melt a bit of solder so that it flows smoothly from the pin to the PC board trace. Locate the printed circuit board and all the components and we will start.

Locate all of the resistors for the project and place them in front of you. Each resistor has a color code which describes its value. The first color band at one edge of the resistor body represents the resistor's first digit value, while the second color band denotes the second digit of the resistor value. The third color band represents the multiplier value of the resistor. A fourth color band is the tolerance value. A silver band denotes a 10% tolerance, while a gold band denotes a 5% tolerance. The absence of a fourth color band denotes a 20% tolerance value. Check the color code against the parts list and schematic before installing them onto the circuit board. Refer to the resistor color chart in Table 11-1. Place about four or five resistors on the PC board and place these resistors in their respective locations carefully making sure each one is in the correct location. Next, solder each of the resistors onto the circuit board. Trim off the excess component leads with a small pair of end-cutters. Pick up and identify the next grouping of resistors and install them on the circuit board, follow up by soldering this next batch of resistors

Table 11-1
Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%

Silver			0.01	10%
No color				20%

to the circuit board; remember to trim the extra lead lengths form the PC board.

Once all the resistors have been installed onto the circuit board, we can move on to identifying all of the capacitors for the project. Note that there will be different looking capacitors for this project, some will be small disks, while others will be larger body devices with minus and plus marking on them. These larger capacitors with polarity marking are electrolytic capacitors and they have polarity which must be observed for the circuit to work correctly. Look through the parts pile and locate the capacitors and place them in front of you. You will notice a number of small disk capacitors, we will install these first. Look closely at each of the disk capacitors at their markings. Sometimes the capacitors are very small and they may not have their actual value printed on them but will instead have some sort of code marked on them. Refer to the parts list for these codes or the capacitor code chart in Table 11-2. Locate four or five of these small disk capacitors, identify them and install them on the circuit board, while referring to the schematic and layout diagrams. After inserting the disk capacitors onto the circuit board, you can go ahead and solder them to the circuit board. Remember to cut the excess component leads. Next, move on and install another grouping of small disk capacitors, then solder them in place on the printed circuit board. Cut the extra component leads after soldering in the capacitors. When you are finished installing the small capacitors we will move on to the larger electrolytic types.

Capacitors C14, C32, C33 and C35 are all 100 uF to 200 µF electrolytic types. These capacitors will have either a plus or minus marking and/or black band denoting polarity. You must orient these capacitors with respect to their polarity markings. Check both the layout diagram and the schematic diagram for polarity references. Note also that capacitors C15, C30 and C36 are also electrolytic capacitors with a 4.7 µF value. These too must be oriented correctly for the circuit to operate correctly when power is applied. It is possible to actually damage the circuit upon power-up if these capacitors have been installed incorrectly, so pay careful attention when mounting these capacitors. Install the electrolytic capacitors in groups of two or three. Once they have been placed on the circuit board, you can move on to soldering them in place. Remember to trim the excess component leads from the PC board after soldering.

Next we will move to installing the two diodes. Diode D1 is the varactor "tuning" diode while D2 is a 1N4148 silicon diode. When mounting the diodes be careful to observe polarity markings on the diodes. Usually each diode will have a black or white band at one end of the diode body. This color band denotes the cathode end of the diode. Refer to the schematic diagram and layout diagrams in order to see how the diodes should be mounted with respect to polarity considerations.

Before we go ahead and install the semiconductors, take a look at the semiconductor pin-out diagram in Figure 11-4 which will help you orient the components. Now locate the transistors from the components. Transistor Q1 is a 2SC2498 or 2SC2507A, while transistors Q2, Q3 and Q4 are 2N3904 NPN types. Transistors have three leads, a Base lead, a Collector lead and an Emitter lead. The symbol for the Base is a vertical line, while the Collector and Emitter are slanted lines pointing to the Base lead. The Emitter lead is shown with a small arrow pointing towards or away from the Base lead. Refer to the schematic and layout diagrams to determine the orientation of the transistors. Clearly identify Q1, the 2SC2498 or 2SC2570A transistor. Do not confuse it with the other transistors supplied. Position Q1 as shown on the PC board layout, with the flat side facing to the right, toward the middle of the board. Press the transistor snugly into the PC board so that only a minimum amount of wire lead is exposed above the board. In soldering, don't be afraid to use enough heat to make good clean connections.

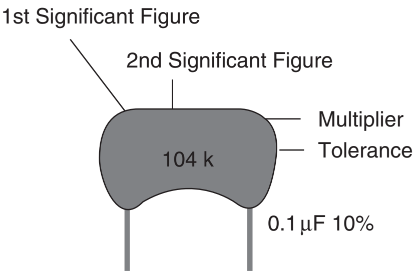
Once the transistors are in place on the PC board, you can go ahead and solder them to the foil side of the PC board. Don't forget to trim the extra component leads.

Now we are going to install FL1, the ceramic filter. This component looks like a capacitor with three leads and may be installed either way. Next go ahead and locate FL2, the 450 kHz filter. Its three leads are delicate and fit in only one way. At this time you can locate Y1, the 10.24 MHz crystal. No special procedure is required. Simply press the crystal firmly into its holes as far as it will go. Now go ahead and solder in the crystal and ceramic filters, remove the excess leads if any.

Table 11-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.



CSGNetwork.Com 6/4/92

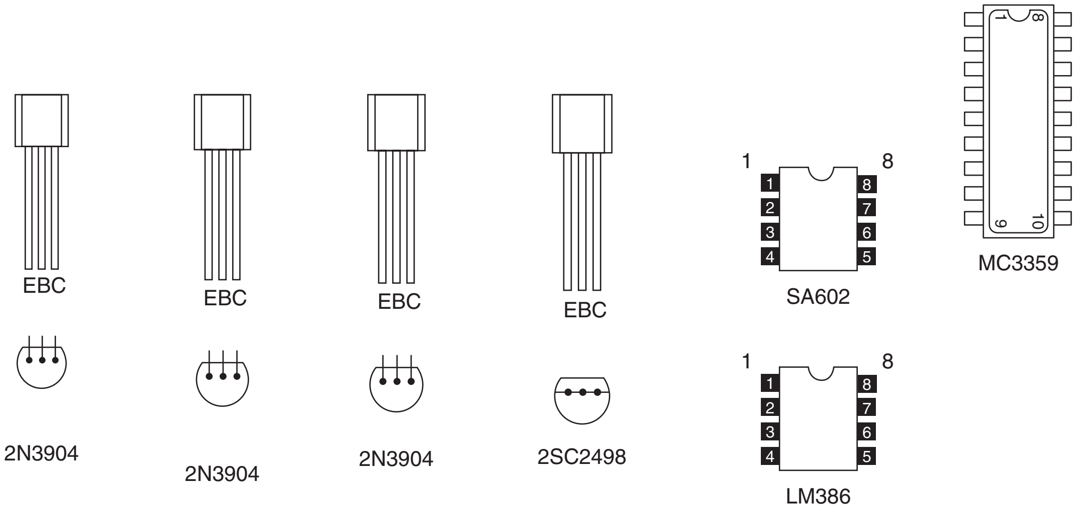

Figure 11-4 *Semiconductor pin-outs*

Look through the remaining components and locate the inductors L1 through L4. Coils L1 and L2 are small 1 and ½ turn coils. Go ahead and install coils L1 and L2, they are both the same. Now, locate and install L3, the slug tuned coil. It is important that the body of this coil be snug against the PC board for mechanical stability, which directly affects the frequency stability of the receiver. Make good, solid solder connections, when installing the above coils. Finally locate coil L4, the 455 kHz quadrature coil, soldering the two pins and the two mounting tabs. Remove any excess lead lengths if any; see Table 11-3 for coil winding information.

Let's move on to installing the SA602 IC, you may wish to use an 8-pin DIP socket rather than soldering the IC directly to the board. Reasons for doing this might include the peace of mind of beginners afraid of damaging the IC, or experienced builders testing the merits of the SA602's cousin, the SE602. However, please be aware that we have seen more service problems with improper socket insertion than from soldering heat damage to ICs. Even if this is your first IC, don't be afraid to use enough heat to make eight clean connections, but DO be sure to correctly orient the end marked by a band, dot, or notch. Before soldering, make sure that the IC or socket is perfectly flat against the top of the PC board. Install U1, the SA602, in accord with the preceding directions.

Now, install MC3359 IC, U2. As in the case of the SA602 IC, you could choose to install an 18-pin IC socket rather than soldering the IC directly. Re-read the discussion of IC sockets offered for the installation of U1. Larger ICs such as the MC3359 require considerably more care in socket insertion. Notice that the end of the IC marked by a band, dot, or notch must be oriented correctly as shown on the parts layout diagram. Solder each of the 18 connections carefully.

Table 11-3

Coil winding information

L1,L2	2-turn coil - #24 ga. Insulated magnet wire - 5/32″ OD dia. Air-core coil.
L3	3 ½ turn coil ferrite slug-tuned coil, unwind original coil from form and rewind 3½ turns of #24 ga. insulated magnet wire on form - use series 49A coil Circuit Specialists (49A127MPC).
L4	450 kHz shielded quadrature coil TOKO America Coils (7MC-81282).

Make sure you have good lighting as well as good technique to make sure that no solder "bridges" flow between the connections.

Finally locate and install U3, the LM386 IC audio amplifier integrated circuit. Once again use of an IC socket is highly recommended. Solder the IC socket to the PC board and insert the LM386 paying particular attention to the small notch or indented circle on the top of the IC body. Pin 1 is to the left of the notch, cut-out or indented circle.

Take a short well-deserved break and when we return, we will install the remaining components on the PC board and finish up building the receiver. Now locate power switch S1. Press S1 firmly into its six holes and solder all six pins. The switch fits the board only one way. Next, install J1, the RCA-style antenna jack and solder all four points. Now, install J2, the subminiature headphone jack. Solder all three points. Be gentle and patient in inserting, so as not to damage the solder tabs.

Locate all three potentiometers and we will install them now. Potentiometer controls R1, R2 and R3 are all mounted in a row next to switch S1. Insert the three PC mount potentiometers into their positions. Check that the controls are pressed in firmly and straight against the top of the board. Solder the three center pins and then the two larger mechanical mounting tabs. Use enough solder for a solid connection.

The circuit board may require a few jumpers; "cut" component leads make good jumpers. Insert the jumpers and solder into place, remember to trim the excess leads. We are now down to the home-stretch. Install the battery snap terminal in the two holes below S1, making sure that the positive (red) lead is inserted into the (+) hole on the PC board.

Finally, go ahead and mount the battery bracket, it may be attached in a variety of ways. A wire jumper can be passed through the two holes on the PC board, then both ends soldered on the underside of the board. You may prefer to use very small screws or even a double-sided mounting adhesive strip or glue. In using such methods, make sure that the battery will not block the PC board's mounting hole in its vicinity.

Wiring of the PC board is now complete. If you have the patience, we suggest a short break. Then take a magnifying lens and a bright light and examine all your solder joints, touching up any connection which appears less than perfect. Make sure all excess leads have been trimmed, and that one is not bent back flat against the board, possibly causing a short. Brush the solder side of the board with a stiff brush to make sure that no loose wire trimmings or solder drippings are lodged between connections. Connect up a suitable antenna and connect up the 9 volt battery to the receiver and you are ready to try out the receiver for the first time.

After power is first applied and you have connected up your antenna, you will need to adjust the gain control to midrange. Next, you should adjust the squelch control just below the threshold point, so that you can hear the normal background hiss. Now begin turning the tuning control and you should soon come across a public service transmission from a local police or fire broadcast.

In the event that you do not hear any hiss coming from the speaker or headphones, or you do not hear any stations after about 20 to 30 minutes, then you may have to troubleshoot the receiver for any errors that may have occurred during the building process. First, disconnect the battery and antenna and un-mount the receiver circuit board from the enclosure. Have a friend assist you in inspecting the circuit board; a different set of eyeballs can often help to find errors quickly.

The most common causes for circuit failure are resistors placed in the wrong locations, the second possible cause for errors are improper installation of diodes and electrolytic capacitors. Make sure that you re-check the orientation of these components one more time and refer to the schematic, and parts layout diagrams. Another possible cause for mistake is the improper installation of transistors and integrated circuits. Be sure to recheck the orientation of transistors. Each transistor has three leads, an Emitter, a Collector and a Base lead. Closely inspect and compare the schematic diagram along with the parts layout diagram and manufacturer's specifications sheets to ensure that you have oriented the transistors correctly. Lastly, integrated circuits are often placed backwards in their sockets. After you have checked all the above tips, make sure that the battery is connected correctly with the black battery or minus lead (–) connected to the circuit ground and the plus (+) or red battery lead connected to the power input regulator of the circuit. Reconnect the battery and the antenna and then switch the receiver to the "On" position and retest the receiver once again to make sure that it is now working.

Testing, alignment and adjustment

In order to prepare the VHF FM Receiver for reliable monitoring operation, you will need a few basic tools, such as useful VHF signal source, a hexagonal, non-metallic coil slug alignment tool for L3, and a small screwdriver to adjust L4. To align your new receiver, you will need to locate some sort of a signal source. This signal can be from your test bench equipment or from a "live" source such as a local repeater. The "live" signals are best for fine-tuning, but they also have that VHF communications character of being fast and to the point. Good test bench signal sources include your own 2-meter transceiver, if you are licensed to use it, a signal generator or grid-dip oscillator. If you do not have a steady test signal source for the band within 135–175 MHz of primary interest to you, and still wish to verify immediately the proper operation of your receiver, a good and steady VHF signal source will be your local NOAA Weather Service station, broadcasting around 160 MHz. Once you have verified reliable reception of your regional NOAA station, adjustment to your desired listening range will become easier.

If you do not already have a set of plastic or nylon coil alignment tools and do expect to try further ham radio or electronic hobby projects, such tools are worth having and can be found inexpensively at any electronics store including Radio Shack. While a metal hex key wrench can fit the coil slug, the metal itself would damage the coil inductance drastically and therefore should not be used. With patience and sandpaper, a useable tool might be formed from a wood or plastic rod.

The alignment procedure should begin as follows: first make sure the power switch is off. Next, connect the antenna, earphone or speaker and battery, then turn the slug of L3 until it is even with the top of the coil form. Then turn the slug of L3 clockwise seven turns back into the form.

Now, turn the slug of L4 until it is flush with the top of the coil and then turn it two turns back into the coil. Next turn all three controls to the left, fully counterclockwise. Now, you can turn the power switch to "On." Now turn R2 (volume control) until you hear some noise. Finally, adjust L4 for maximum noise from the speaker.

Further alignment now consists of adjusting the oscillator coil L3 to permit the tuning control (R1) to cover the 5 MHz segment between 135 and 175 MHz of primary interest to you. Assuming you wish to adjust for the 2-meter 144–148 MHz Amateur Band, adjust L3 until you hear your intended test signal. If you are a beginner with no license or other equipment, any ham operator with a 2-meter transceiver should be willing to give you the test signal and extra help that you need. Your new VHF receiver is very sensitive, so operate the transceiver on low power on a simplex frequency from a distance of at least across the room. An 8″ piece of wire will be a sufficient receiving antenna for such tests. If you don't know any hams, visit a friendly two-way radio service center to get close to the test signal you need!

Receiver sensitivity

Your FM receiver features sensitivity under 1 uv. Radio hams constantly marvel at how an FR146 displayed at hamfests tunes in dozens of hand-held QSOs on the premises without an antenna connected! You can expect to monitor local repeater and simplex transmissions easily, using a simple ground-plane style antenna.

Customization

For many people, a pilot lamp to indicate "power on" is more than a nice touch. They expect it and depend on it. Adding a simple LED power-on indicator to your VHF receiver is easy. All you need is the LED itself and a small 1k to 2.2k resistor. Study the PC traces between the positive battery supply wire and the on-off switch. The unused connectors on top of your switch are an ideal point to get the + DC voltage needed for the anode (longer lead) of the LED. Plan where and how you wish to install the LED in your enclosure.

Locating the LED immediately above the on-off switch is logical and ideal. The simplest way to make a good installation is to drill a neat hole just slightly smaller than the diameter of the LED. Then, enlarge the hole a little bit at a time just enough to let the LED be pressed in and held firmly. The resistor may be connected to either the anode or cathode of the LED, but the anode MUST go to + DC, with the cathode connected to the nearest common ground point.

Antenna considerations

For local VHF reception, the VHF receiver will operate fine just using a whip antenna. If you wish to receive stations which are further away than just the local stations, you may want to install some sort of an outdoor antenna such a ground plane or Discone antenna for VHF operation. Since most of the transmissions in this band are of vertical polarization, vertical antennas, ground plane and Discone antennas will work best in this band. Various VHF scanner type antennas from your local Radio Shack store will work fine. The chart illustrated in Table 11-4 shows the utilization of the VHF Public Service band. Have fun and enjoy you new VHF "action" band receiver.

Table 11-4

VHF high-band frequency band utilization

150.995 MHz to 151.130 MHz	Highway maintenance
151.145 MHz to 151.475 MHz	Forestry conservation
152.030 MHz to 152.240 MHz	Mobile telephone
152.270 MHz to 152.450 MHz	Taxi services
152.510 MHz to 152.810 MHz	Mobile telephone
153.410 MHz to 154.115 MHz	Utilities/light/power/water and local gov't
153.830/153.890/154.010/154.070 MHz	Fire
154.130 MHz to 154.445 MHz	Fire
154.650 MHz to 155.700 MHz	State & Local police
155.715 MHz to 156.255 MHz	Local Gov't / police/ highway maintenance
156.275 MHz to 157.425 MHz	Marine Frequencies
157.530 MHz to 158.265 MHz	Taxi & Mobile telephones
158.280 MHz to 158.460 MHz	Utilities water/power/industrial
158.730 MHz to 159.210 MHz	Highway Maintenance & police
159.225 MHz to 159.465 MHz	Forestry
159.495 MHz to 160.200 MHz	Motor carrier trucks
160.215 MHz to 161.565 MHz	Railroad
161.640 MHz to 161.760 MHz	Broadcast pickups & Studio to Xmiter Links
161.800 MHz to 162.00 MHz	Maritime Shore Stations
162.400 MHz to 162.550 MHz	NOAA weather broadcasts
162.250 MHz to 173.500 MHz	Gov't sonobuoys
169.00 MHz to 172.000 MHz	Low power wireless mikes
173.2037 MHz to 173.396 MHz	Fixed/mobile industrial & remote control
173.400 MHz to 173.5000 MHz	Remote control & telemetry

Chapter 12

6 & 2-Meter Dual-Band Amateur Radio Receiver

Parts list

6N2 Meter Amateur Radio Receiver

R1 68 k, ¼w, 5% resistor

R2 47 k, ¼w, 5% resistor

R3, R7 3.3k, ¼w, 5% resistor

R5 20 k 5% ¼W

R8 8.2k, 5% ¼W

R9 Jumper wire (use a discarded resistor lead)

R10, R12 1k, ¼w, 5% resistor

R11 10 k, ¼w, 5% resistor

R15 10 ohm, ¼w, 5% resistor

VR1, VR3 100 k potentiometer (chassis mount)

VR2 5k, 20% linear potentiometer (chassis mount)

C1 120 pF, 25v capacitor (121)

C2 .005 µF, 35v 20% capacitor (502)

C3,C4,C9 .1 µF +80, −20% 50v capacitor (104)

C5 3.9 pF, 50v disk capacitor

C6 33 pF, 50v, 10% disk capacitor

C7 470 pF, 50v, 10% 50 v disk

C8 7 pF, 25v, 20% disk capacitor

C10 1000 pF, 50v, 10% disk capacitor (102)

C11,C13,C16 .01 µF, 50 v, +80, −20% capacitor (103)

C17 51 pF, 25v, 10% capacitor (51K)

C12 68 pF, 25v, 10% capacitor (68K)

C14, C21 4.7 µF, 50v Radial capacitor

C15 220 µF, 16v Radial capacitor

C18,C19,C20 .1 µF, 50v, +80, −20% capacitor (104)

C22 .047 µF, 50v, +80, −20% capacitor (473)

D1, D2 Diode 1N914 silicon diode

The 6N2 receiver is a dual conversion, dual band amateur radio receiver; it combines the excitement of two very active amateur radio bands in one small receiver, see Figure 12-1. The 6N2 receiver will allow radio enthusiasts, both the young and old, to get a glimpse of the active world of VHF amateur radio. This receiver combines both the 2-meter and the 6-meter bands which are popular with radio enthusiasts around the country. The 2-meter band is probably the most active ham radio band especially for newcomers with a technician class license. Two-meter band coverage is usually quite good in most parts of the country. The 2-meter band features many ham radio repeaters, and in some have wide-area long-range repeaters in most US states and in many Canadian provinces. These ham radio repeaters allow amateur radio operators to communicate over long distances. The 6-meter band has often been called the “magic band.” This amateur band is usually only used for fairly local coverage but when the band is “open” you can often hear hams on the opposite side of the US or in Cuba or the Caribbean, which is really exciting!

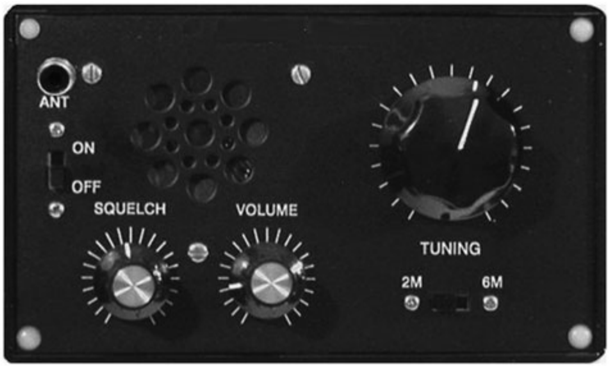

Figure 12-1 *6N2 meter amateur radio receiver*

You can listen-in to these exciting two ham radio bands and hear all the action, day or night with the 6N2 portable receiver. You may just decide the action sounds like something you would like to be part of, and you can easily get your own ham radio “ticket” or license. Contact the Amateur Radio Relay League (ARRL) at http://www.arrl.org; they have many books, publications as well as introductory videos. They are a great resource in locating local ham radio clubs, where you can make friends and learn a lot about ham radio and communication.

The 6N2 radio is known as a narrow band FM VHF receiver. FM of course is a type of modulation and is denoted as Frequency Modulation. Frequency modulation means the data or voice changes the frequency of the radio wave. The other popular forms of modulation are AM (Amplitude Modulation) and PM (Phase Modulation). We also mentioned narrow band, which notes that the selectivity of the entire system is limited to only enough frequencies to pass voice or low frequency data. A commercial broadcast FM receiver would have a bandwidth large enough to pass music and high frequency data transmissions.

The 6N2 receiver is a dual conversion, two-band radio receiver. In a dual conversion receiver, the original radio frequency is converted first to a 10.7 MHz intermediate frequency (I-F) and amplified in (Block 4). The 10.7 MHz signal is then converted to 455 kHz and amplified in (Block 3). Noise is removed and the

Figure 12-2 *6⁄2 meter amateur radio receiver block diagram*

modulated signal is recovered from the 455 kHz I-F signal in (Block 2). The audio signal is amplified to drive a speaker in (Block 1), see Figure 12-2. The 6N2 receiver specifications are illustrated in Table 12-1.

So you ask, why dual conversion? To answer this question, take a look at the diagram shown in Figure 12-3, and it may become more clear. In order to obtain the desired intermediate frequency (I-F) signal by mixing the local oscillator with the desired radio frequency, an unwanted output may result due to a transmission spaced one intermediate frequency or (I-F) on the opposite side of the oscillator (image). By using a large I-F frequency, this image is moved further out of the band of desired frequencies. The second conversion provides the selectivity to filter out the desired narrow band transmission.

The 6N2 receiver operates on two of the most popular VHF amateur radio bands. The 6N2 VHF amateur radio receiver receives both the 6-meter ham band and the 2-meter ham bands, and you can select the band with a band-switch.

To help you visualize the relationship between frequency and wavelength, take a look at the diagram shown in Figure 12-4. If the speed of a wave (meters per second) is divided by the number of waves that pass a given point (cycles per second), the seconds cancel and you obtain the wavelength λ = meters per cycle. The speed of radio waves is approximately 300,000,000 meters per second. If the frequency is 50 to 54 MHz, the wavelength becomes 300,000,000/50,000,000 or 6 meters. So for the 2-meter band, which is approximately 150 MHz, the wavelength becomes 300,000,000/150,000,000 or 2 meters. The actual bands are: 2-meter band which covers 144 MHz to 148 MHz, and the 6-meter band which covers 50 MHz to 54 MHz.

The 6N2 dual band VHF receiver is composed of four major blocks, i.e. blocks 1 through 4. It is a bit easier to follow how the receiver works if we break it down into smaller defined blocks, see Figure 12-5. The heart of the receiver is the integrated circuit at U1, an almost complete FM receiver on-a-chip. The FM receiver chip only requires timing components, a crystal and RF tuning components, a filter. The output of the FM radio chip is sent to the audio amplifier chip at U2. Power for the receiver is regulated via the regulator chip at U3.

Table 12-1
The 6N2 amateur radio specifications

2-meter band covers 144 MHz to 148 MHz
6-meter band covers 50 MHz to 54 MHz

- Single supply voltage (4-12 v)
- Idle current - 4 milliamps
- Inputs referenced to ground
- Input resistance - 50 k
- Self-centering output voltage
- Total harmonic distortion less than 0.2%
- Output power with 9 volt supply voltage
- Voltage gain with 10 µF from pin 1 to 8 - 200 or 46 dB
- Voltage gain with pins 1 and 8 open - 20 or 26 dB
- Bandwidth with pins 1 and 8 open - 300 kHz

The receiver is relatively straightforward and can therefore be constructed in stages, one through four. We will begin with Stage 1, which can be built and tested separately. You can progress step by step and build and test each stage before moving on to the next stage. Let's begin with Block 1, the audio amplifier stage.

The audio amplifier – block 1

impedance of the amplifier is low enough to drive an 8 ohm speaker directly. The coupling capacitor value is picked to pass audio signals down to 100 cycles by matching the reactance of the capacitor with the speaker impedance.

Due to the high input resistance of the amplifier (50 k), the audio coupling capacitor C3 can be as small as 0.1 µF. The equivalent resistance at the junction of R8 and VR3 is approximately 6.6 k (the parallel combination of R8, VR3 and the 50 k input impedance of the LM-386). The capacitor C2 and this equivalent resistance sets the 3 dB corner used to attenuate any IF voltage at pin 13. A simple RC filter attenuates at a rate of 6 dB per octave (an octave is the same as doubling the frequency). By using 6.6 k as the equivalent resistance and 0.005 µF as the capacitance, we get a 3 dB corner at approximately 4.8 kHz. To get to 455 kHz, you must double 4.8 kHz approximately 6.6 times. This equates to a reduction of the IF voltage at the R8 - VR3 junction of 39.6 dB (6 dB per octave times 6.6 octaves), or 95 times.

Recovering the data – block 2

In working with FM receivers, there are some terms that need to be defined. First, let's determine the term **deviation** as the frequency swing of the incoming FM signal. When no modulation is present, the incoming signal is a fixed frequency **carrier wave (Fc)**. **Positive deviation (Fp)** is the increase in Fc due to modulation, and **negative deviation (Fn)** is the decrease in Fc due to the modulation. The detector must be linear over the maximum total deviation (Fp max. - Fn max.) produced by the transmitter or distortion will occur. Before the second I-F signal reaches the detector, it is applied to a **limiting amplifier** inside the integrated circuit. A limiting amplifier is designed to remove any amplitude variations in the signal by amplifying the signal well beyond the limit of the amplifier. The frequency variations (FM) are not affected by the limiter. The limiter removes the affects of fading (driving through a tunnel) and impulse noise (lightning and ignition). These affects produce significant unwanted amplitude variations in the received signal, but minor frequency variations. Noise immunity is one of the great advantages of frequency modulation over amplitude modulation. The remaining signal contains only the frequency modulation.

The 6N2 receiver uses a quadrature detector to demodulate the FM signal. After the noise is removed by the limiter, the signal is internally connected to the quadrature detector. A parallel tuned circuit must be connected from pin 12 to the power supply. This circuit produces the 90° phase needed by the quadrature detector. A resistor shunting this coil sets the peak separation of the detector. If the value of the resistor is lowered, it will increase the linearity, but decrease the amplitude of the recovered audio.

The quadrature detector combines two phases of the I-F signal that are 90° apart, or in quadrature, to recover the modulation. The shifted signal is used to gate the non-shifted signal in a synchronous detector. When the frequency increases above the carrier frequency (positive deviation), the phase shift increases causing a decrease in the width of the gated impulse output. In a similar manner, when negative deviation occurs, the gated impulse output will widen. The gated output is then filtered to remove the pulses and recover the modulating signal.

455 kHz conversion – blocks 3 & 4

The first local oscillator should be set at 133.3 MHz to 137.3 MHz for the 2-meter band and 39.3 MHz to 43.3 MHz for the 6-meter band. This oscillator is free-running varactor-tuned. The first mixer converts the RF input to an I-F frequency of 10.7 MHz. This I-F signal is then filtered through a ceramic filter and fed into the second mixer. If the oscillator of the second mixer is precisely set at 10.245 MHz, it will produce an output containing the sum (20.945 MHz) and the difference (0.455 MHz or 455 kHz) frequencies. This 455 kHz signal is then sent to the limiter, detector, and audio circuits. The mixers are doubly balanced to reduce spurious (unwanted) responses. The first and second mixers have conversion gains of 18 to 22 dB respectively.

Conversion gain is the increase in a signal after the signal has been converted to a new frequency and amplified. For both converters, the mixers are designed to allow the use of pre-tuned ceramic filters. After the first mixer, a 10.7 MHz ceramic bypass filter is used. This eliminates the need for special test equipment for aligning I-F circuits. The ceramic filter also has a better aging and temperature characteristic than conventional LC tuned circuits.

Assembling the 6N2 receiver

Before constructing your new 6N2 receiver, you will need to locate a clean well lit, well ventilated work space. Locate a small pencil tipped 27 to 33 watt soldering iron. You should also locate a spool of 22 ga. rosin core solder, a small container of “Tip Tinner” from your local Radio Shack store. “Tip Tinner” helps to clean and dress the soldering iron tip. Place the schematics and parts layout diagram in front of you along with all of the project components. A few small tools would be helpful to constructing your project, so find a small pair of end-cutters, a pair of tweezers, a magnifying glass, a small Phillips and flat-blade screwdrivers, and we can begin. When building a project with integrated circuits it is wise to consider installing integrated circuit sockets on the PC board, as a form of insurance in the event of a possible circuit failure somewhere down the road. It is much more easy to simply unplug a damaged IC and simply replace it by plugging in a new one.

Before we get some momentum on the project, you may also want to refer to the chart in Table 12-2. This table lists the color codes for the resistors, and will greatly aide you in constructing the receiver. Go ahead and locate resistor R1, a 68 k resistor, its color code is (blue-gray-orange). Now locate resistor R2, a 47 k ohm resistor with (yellow-violet-orange) color code. Place these resistors on the circuit board in their respective locations and solder them in place. Now you can identify the remaining resistors and place them on the circuit board and solder them in their proper locations. Use your end-cutters to trim the excess component leads. Cut the extra component leads flush to the edge of the circuit board.

Now locate and install capacitors; first locate and identify capacitors C1 and C2. Capacitor C1 is a small disk capacitor marked (121) or120 pF. Small capacitors often do not have their actual values printed on them but use a three-digit code to represent their value. Refer to the chart in Table 12-3 to help you identify the small capacitors. Now look for capacitor C2, its value

Table 12-2

Table 12-3

Capacitance code information

This table is designed to provide the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, some are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

is .005 µF, but may be marked (502). Go ahead and install these capacitors in their respective locations on the circuit board. Remember to trim the excess component lead lengths with your end-cutters. Next, locate the remaining small capacitors and install them on the circuit board.

Next, we are going to locate and install the electrolytic capacitors. Electrolytic capacitors are generally larger in size and higher in value than the small value capacitors and usually they are vertical or horizontally mounted. Remember, electrolytic capacitors have polarity and must be installed with respect to this polarity if the circuit is going to work properly. The capacitor's value will be printed on the body of the capacitor along with a white or black polarity marking, either a plus or minus marking. Pay attention to this plus or minus marking and align it with the proper holes on the PC board, you will have to refer to the schematic and or parts layout diagram when placing the electrolytic capacitors. Locate and install the remaining electrolytic capacitors onto the circuit board. Remember to trim the excess electrolytic capacitor leads after they are soldered in place.

In this project there are two silicon diodes. Diodes are generally rectangular in shape like a resistor but they are often clear glass or painted black. You will see a black or white band at one edge of the diode body, this marking denotes the diode's polarity. The colored band is the diode's cathode lead. When installing the diode make sure that you observe the polarity marking by referring to the parts layout and the schematic diagram. Polarity is important and must be observed in order for the circuit to work properly.

The 6N2 receiver has two crystal filters, a 455 kHz one and a 10.7 MHz one. These devices are small three-lead devices and look much like a small capacitor with three leads. Make sure that you can identify them properly before installing them on the circuit board. The 455 kHz unit connects to U1 at pins 5, 6 and 7, while the 10.7 MHz crystal filter is connected to pins 17, 18 and 19. The receiver also employs a single 10.24 MHz crystal which is connected between pins 4 and 6. This is a two-lead device and is usually a small metal can.

Now locate the air-wound coils L1 and L4. Coil L1 is 4½ turns of wire, it will be placed on the right edge of the PC board, and coil L4, a 1½ turn air-wound coil, will be mounted at the bottom center of the board. Coils L2 and L3 are 9 turn coils wound on a coil form with a ferrite tunable slug in the center of the form. Coil L5 is a 0.64 mH coil in a small metal can with five leads. Coil L5 is a tunable slug tuned coil with a yellow ferrite core, see Table 12-4 for coil winding details.

The 6N2 receiver utilizes three integrated circuits. Before we go ahead and install the integrated circuits, let's take a brief look at the semiconductor pin-out diagram shown in Figure 12-6. The main receiver chip U1 is the Motorola MC3362, a 24 pin dual conversion FM receiver on-a-chip which contains oscillators, mixers, quadrature discriminator, and meter drive/carrier detect circuitry all in one chip. The audio amplifier at U2 is an LM386 chip, while U3 is 5 volt regulator, an LM78L05. When installing the integrated circuits, you will need to identify the pin-outs of each of the integrated circuits. It is advisable to install IC sockets prior to installing the ICs on the circuit board, to avoid the rare event of circuit failure at a late date. It is much easier to simply unplug an IC and insert another without un-soldering a 24 pin chip from the circuit board. Integrated circuits will generally have a small cut-out at one end of the IC package or a small indented circle at one end of the chip. Pin one (1) of the integrated circuit will be to the left of these markings. Be sure to orient the IC before placing into its proper socket. Note that pin 1 of U1 will connect to the junction of capacitors C7 and C16.

Table 12-4

Coil Winding Information

L1	4.5 turns insulated magnet wire - #22 ga. Air-core coil wound on ¼″ form then remove coil.
L2, L3	8½ turns #24 ga. insulated magnet wire coil-wound on 49A Series form - ferrite slug adjustable (49A127MPC) Circuit Specialists. Remove original coil from form and rewind 8½ turns.
L4	1.5 turns insulated magnet wire - #22 ga. Air-core wound on ¼″ form then remove coil.
L5	.64 mH Coil (yellow) 455 kHz I-F Transformer Circuit Specialists - (42IF301).

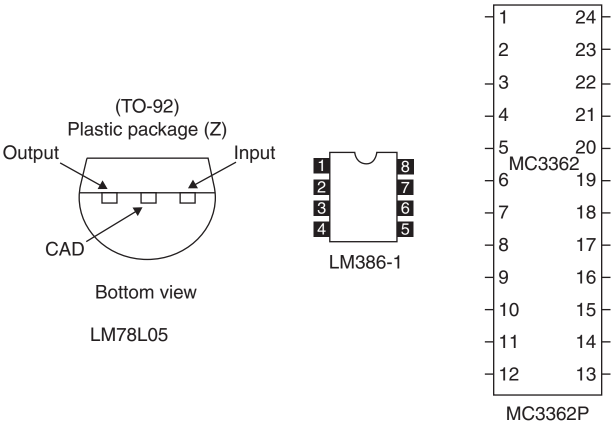

Figure 12-6 *Semiconductor pin-outs*

Finishing the PC board assembly

Now cut three 3″ pieces of wire from the roll of 22 gauge solid wire and strip ¼″ of insulation off each end. Using these wires, solder the 5k potentiometer (VR2) to the PC board. Be sure to mechanically attach each wire. Note that VR3 is the tuning control potentiometer, the center lead is connected to the PC board hole marked (D), while the left-most pot terminal gets connected to the hole marked (N). The final potentiometer wire on the right side of the potentiometer goes to the hole marked (P).

Finally, connect up a short piece of coax to the terminals on the PC board marked ANT and GND. The center wire of the coax goes to the terminal marked antenna (ANT) and shield wire from the coax goes to the terminal marked ground or (GND). The other free end of the coax goes to RCA antenna jack which gets mounted on the front panel of the chassis box.

After completing the circuit board, take a short break and when we return, we will examine the circuit board for possible "cold" solder joints and "short" circuits. Pick up the circuit board with the foil side of the circuit board facing upwards toward you. First, we will look at the circuit board for possible "cold" solder joints. Take a close look at the solder joints, they should all look clean, shiny and bright. If any of the solder joints look dark, dull or "blobby," then you should un-solder that particular joint and clean it and then re-solder the joint so that it looks clean, shiny and bright. Next we will examine the circuit board for possible "short" circuits.

The front panel assembly

The speaker was mounted on the receiver's front panel. Using the three black 4-40 screws, 4-40 nuts and #4 internal tooth washers, mount the three small right-angle brackets to the speaker mounting holes. The short side of the brackets should be against the panel. Use a blunt tool to bend the brackets over the speaker. Using the hardware shown, mount the phono jack. Using the hardware shown, mount the On-Off switch, 2M/6M switch, squelch pot, volume pot, and tuning pot to the front panel.

Orient the speaker terminals, so they don't interfere with the nearby battery mounting. Solder the loose end of the shielded cable to the phono jack, center conductor to the phono jack terminal and shield to the GND terminal. Peel the backing off one side of the ½″ wide, double-sided tape and stick it to the battery clamp. Peel the backing off the other side of the double-sided tape and stick it to the inside bottom of the plastic case. With the power switch OFF, connect a 9V alkaline battery to the battery snap and put the battery into the battery clamp. When the final test and alignment (next section of manual) is completed, place the front plate on the plastic case and insert the four nylon plugs into the holes in each corner of the plate.

Connecting the front panel parts to the PC board

To wire the speaker, pot and switch, cut the indicated length of wire from the roll of 22 gauge solid wire and strip ¼″ of insulation off each end. Next, go ahead and mount the phono jack at J1. Finally mount the On/Off switch, the 2 meter/6 meter band switch, the squelch potentiometer, the volume potentiometer, and tuning potentiometer to the front panel as shown in Figure 12–7. For the jumper wire, cut 2″ of 22 gauge solid wire, strip ¼″ of insulation off each end and solder to the points indicated. Attach two 4″ long pieces of insulated wire to the speaker terminals and solder them. Now solder two 4″ pieces of insulated wire to the On-Off switch, use the center terminal and one of the outside terminals on the switch. Next attach three 3″ long insulated wires to the volume control on VR3.

Next locate the Squelch control (VR1) and solder two 3″ long insulated wires to the potentiometer. Take the two free wires and connect them to the PC board. The center terminal from the potentiometer goes to the PC board hole marked (Q), while the other potentiometer lead goes to the hole marked (R).

Take the free ends of the two speaker wires and solder them to the circuit board at their respective terminal strip on the bottom left side of the PC board. Now take the two free ends of the On-Off switch leads and solder them to the terminals on the left side of the PC board. Next take the three potentiometer leads and solder them to the PC board. The center terminal of VR3 goes to the terminal marked (D) on the circuit board. The left-most potentiometer terminal goes to the hole marked (C) on the PC board, while the right-most potentiometer terminal goes to the hole marked (E) on the circuit board. Finally locate the 9 volt snap battery terminal stip and connect it to the battery terminals on the far left marked BATT.

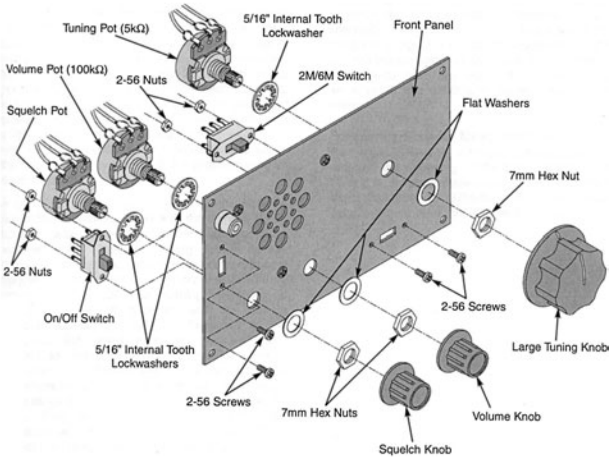

Figure 12-7 *6N2 meters*

Now that your 6N2 receiver has been completed, it is time to test out your receiver to see if it is going to work. Connect up the 9 volt battery clip to the 9 volt battery. Connect an antenna to the antenna terminal. For testing purposes you can simply connect a 19″ piece of wire to the antenna terminals, or if you have an outdoor antenna you can connect it up to the receiver. Position the band switch to the 2-meter band position. Now adjust the volume control to the mid-way position, and adjust the squelch control counterclockwise so that you just break the squelch and you should hear the receiver noise coming from the speaker. If all is well, you should hear a hissing sound or receiver noise. Adjust the tuning control around the band, back and forth, and you should eventually hear a ham radio operator calling another friend.

In the event that you hear no receiver noise and the receiver appears “dead,” you will have to disconnect the antenna and battery clip and examine the receiver’s circuit board for any errors which might have occurred during construction. Some of the most common causes for construction errors include installing diodes and electrolytic capacitors backwards in the circuit; remember that these components have polarity and it must be observed in order for the circuit to work properly. Another common problem is having resistors installed in the wrong place on the circuit board. Finally, when installing semiconductors such as transistors and FETs, you must refer to the manufacturer’s pin-out diagram and the parts layout diagram along with the schematic when constructing the circuit. Often times transistors are installed incorrectly; also check the orientation of all integrated circuits to make sure that you have oriented them correctly with respect to their marking and pin numbers. Hopefully you have found your error by now and are ready to reassemble the circuit in order to test once again.

Reconnect the antenna and battery leads and turn the On-Off switch to the “On” position. Turn up the volume control to the midway position, and set the BAND switch to the 2-meter position. The 2-meter band will generally be much more active than the 6-meter band unless there is a 6-meter band "opening." Now, you will need to adjust the squelch control. The correct adjustment of the squelch control is to advance the control until the receiver noise is silenced. When the receiver is tuned across the band and a signal is found, the squelch will release and the transmission will be heard. As you continue tuning away from this signal, the squelch should again come into effect and "squelch" the receiver noise. Remember that the function of the squelch control is to eliminate static when there is no signal present. This control sets the level of passable signals. The squelch control works by raising the voltage to the (–) input to the audio amplifier and thus disabling the amplifier output. Turn the squelch control fully counterclockwise. The audio should produce a hissing sound. Turning the squelch control clockwise should quiet the audio. Check the leads going to the control.

Now that the receiver seems to be functioning, you will need to calibrate the receiver using an RF frequency generator. You will need to borrow an RF signal generator from a friend or local radio enthusiast in order to calibrate your receiver for best operation.

Frequency measurements

Attach a two foot or longer length of wire to the male RCA plug and connect it to the radio antenna jack. Install a fresh battery and turn the power ON. Make sure that the squelch control is fully counterclockwise and the volume control is set at mid-position. A "rushing" noise should be heard from the speaker when no signal is present, which is normal. Slowly tune the radio on each band and listen for activity. Reception will only be possible if someone is transmitting. If you know someone with a 2M or 6M transmitter, you should test your receiver with known frequencies of transmission and adjust the high frequency oscillator for proper tuning of desired bands.

A calibrated RF generator may also be used to adjust the oscillators. Start with the 2-meter band. Loosely couple the output of the RF generator to the receiver input. Turn the tuning control on the receiver to the full counterclockwise position (lowest frequency). With the squelch control tuned fully counterclockwise (OFF), a "rushing" noise will be heard. Tune the RF generator until the receiver noise disappears and note the frequency on the generator dial. Next, rotate the receiver tuning control to the full clockwise position (higher frequencies). Repeat the above procedure to determine the upper frequency of your tuning range. If the range is too low, decrease L4 by spreading the turns. If the range is too high, substitute the 39 pF capacitor with the 33 pF capacitor in C6. Then, repeat both procedures to determine the upper and lower frequency limits. With a little perseverance, you should arrive at a range covering the 2-meter band (144 to 148 MHz). Set the generator at different points (144, 145, 146, etc.) and tune the radio for quieting at each setting. Mark the dial with the appropriate values. Using the plastic alignment tool to adjust L3, follow the same procedure for the 6-meter band (50 to 54 MHz). **Note:** Before the receiver is properly adjusted, you may receive a broadcast from an FM station or TV station. These signals will be distorted because they are wide band FM transmissions and the 6N2 is a narrow band amateur receiver.

If a frequency counter is available, it can be used to measure the frequency of the local oscillator at pin 20 of U1. On the 2-meter band, the counter should read 133.3 MHz to 137 MHz, and on the 6-meter band, it should read 39.3 MHz to 43.3 MHz.

Antenna considerations

For local VHF reception, the VHF receiver will operate fine just using a whip antenna. If you wish to receive stations which are further away than just the local stations, you may want to install some sort of outdoor antenna such as a ground plane or discone antenna for VHF operation. Since most of the transmissions in this band are of vertical polarization, vertical antennas, ground plane and discone antennas will work very well in this band. Various VHF scanner type antennas from your local Radio Shack store will work fine as well.

Connect up a whip antenna or an outdoor Discone antenna and you can now begin to listen-in to the exciting world of VHF ham radio communication. The charts in Table 12-5 illustrate the band plan for the two popular ham radio VHF bands. Note the SSB satellite and long-range portion of the 2-meter band from 144.1 MHz to 144.3 MHz and the 6-meter DX windows around 51.1 and 52.05 MHz.

Chapter 13

Active and Passive Aircraft Band Receivers

Parts list

Active Aircraft Receiver

R1,R2,R3	10k potentiometers
R5,7,11,18,25,27	1k ohm [brown-black-red]
R6,R28	270 ohm [red-violet-brown]
R8,12,17,23	10k ohm [brown-black-orange]
R26	22k ohm [red-red-orange]
R13,R22	33k ohm [orange-orange-orange]
R4,9,15,16,20,21,24	47k ohm [yellow-violet-orange]
R19	100k ohm [brown-black-yellow]
R10,R14	1 megohm [brown-black-green]
C3,C5	3.9 pF ceramic capacitor
C11	10 pF ceramic capacitor
C12,C14	27 pF ceramic capacitor
C2,C4,C6	82 pF ceramic capacitor
C1,7,8,13,16	.001 µF disk capacitor (marked.001 or 102)
C9,17,19,20,28,30	.01 µF disk capacitor (marked .01 or 103 or 10 nf)
C23,C24	.1 µF disk capacitor (marked .1 or 104)
C22	.47 µF electrolytic capacitor
C10,15,21,25,26,31	4.7 to 10 µF electrolytic capacitor
C18,27,29	100 to 220 µF electrolytic capacitor
Q1	2SC2498 or 2SC2570A NPN UHF transistor
Q2	2N3904 NPN transistor
U1	SA602 8 pin IC
U2	MC1350 8 pin IC
U3	LM324 14 pin IC
U4	LM386 8 pin IC
D1	BB505 varactor diode (marked BB505)
D2	1N270 germanium diode
D3	1N4148 silicon diode
L1,L3,L5	See Table 13-3
L2,L4	See Table 13-3
L6	See Table 13-3
L7	See Table 13-3
FL1	10.7 MHz ceramic filter - (Murata/ Digi-Key)

S1 PC mount DPDT switch

J1 PC mount RCA jack

J2 subminiature phone jack

B1 9 volt battery

Misc PC board, battery clip, battery holder

*** Ramsey Electronics Inc.

Passive Aircraft Monitor

R1,R2 10 megohm, $^1/_4$ watt, 5% resistor

R3 100k ohm potentiometer - volume (chassis mount)

R4,R5 3.3k ohm, $^1/_4$ watt, 5% resistor

R6 100 k ohm, $^1/_4$ watt, 5% resistor

R7 100 ohm $^1/_4$ watt, 5% resistor

C1 1.5 pF, 35 volt mica/poly capacitor

C2 5-18 pF trimmer capacitor (tuning)

C3 .01 µF, 35 volt ceramic disk capacitor

C4 330 pF, 35 volt polyester capacitor

C5,C8 100 µF, 35 volt electrolytic capacitor

C6,C7 1 µF, 35 volt electrolytic capacitor

D1 1N34 germanium diode

L1 .15 µH choke coil - (Digi-Key)

U1 LM358 dual op-amp

S1 SPST toggle switch

B1 9 volt transistor radio battery

PH high-impedance (2 k ohm) headphone

Misc battery clip, battery holder, wire, enclosure, etc.

Eavesdroping in on the pilots as they trace their way across the sky can be very fascinating and exciting listening for aircraft enthusiasts of all ages. An aircraft receiver will allow you to listen-in to high flying commercial aircraft from jumbos to pipers, as well as control towers passing instructions to the airplanes overhead. It will provide many hours of interesting listening.

In this chapter, we will present two different types of aircraft receivers: a passive aircraft receiver and an active aircraft receiver. A passive aircraft receiver is a more simple receiver with no local oscillator to interfere with the on-board aircraft electronics. A passive aircraft receiver is defined as a tuned detector with an amplifier which can be carried aboard an airplane in order to listen-in to the pilot while you are on a flight. You will be able to listen-in to the pilot in flight as well as the control tower when in fairly close range. This type of receiver does not interfere with the airplane's electronics and in most instances you will be permitted to use this type of receiver on-board your aircraft. The active receiver is a more sensitive active receiver which can be used at home to listen-in to high-flying aircraft as well as control towers over longer distances. Listening to aircraft communications can be very interesting but very cryptic, with lots of bursts of information passing in a short period of time.

Active aircraft band receiver

Ideal for arm-chair pilots, student pilots and the seasoned pilots, this sensitive receiver will pick up planes up to 100 miles away. The active aircraft band receiver tunes the aircraft band between 118 and 136 MHz and will allow you to listen to control towers, centers, and planes en-route to their destination. The active aircraft band receiver, shown in Figure 13-1 has good sensitivity, image rejection, signal-to-noise ratio and stability. It is designed for casual "listening in" both

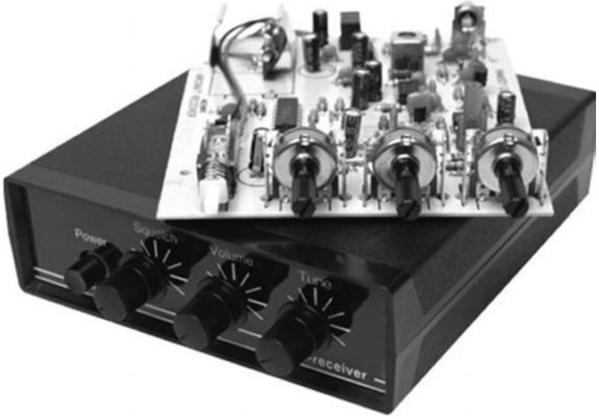

Figure 13-1 *Active aircraft band receiver*

ground and air communication, for both commercial airlines and general aviation, and it will provide you with many years of easy sky-monitoring enjoyment.

This project is especially good for people with an interest in learning more about aviation and electronics and radio. The active aircraft receiver can be built by folks of all ages and skill levels.

What you can hear

A basic fact about the VHF Aviation Band which even licensed pilots can overlook or forget is that communications are in the AM mode, not FM, as in the case of the FM broadcast band immediately below it, and the VHF public service and ham bands immediately above it. No matter where you live, you will be able to receive at least the airborne side of many air traffic communications. If you know where to tune, you'll hear any aircraft you can see, PLUS planes a hundred miles away and more, since VHF signals travel "line of sight". An airliner at 35,000 feet altitude in the next state is still line of sight to your antenna. Similarly, whatever ground stations you may hear are also determined by this "line of sight" character of VHF communication. If there are no major obstacles between your antenna and an airport (tall buildings, hills, etc.), you'll be able to hear both sides of many kinds of aviation communication. Be prepared for them to be fast and to the point, and for the same airplane to move to several different frequencies in the span of a few minutes! The most common types of ground services with which pilots communicate is the control tower, ground control, clearance delivery and ATIS or "Automatic Terminal Information System."

At most metropolitan airports, a pilot communicates with the FAA on a frequency called "Clearance Delivery" to obtain approval or clearance of the intended flight plan. This communication is done before contacting ground control for taxi instructions. From the control tower, ground movements on ramps and taxiways are handled on the "Ground Control" frequency, while runway and in-flight maneuvers near the airport (takeoffs, local traffic patterns, final approaches and landings) are on the "Control Tower" frequency. ATIS, or "Automatic Terminal Information System" is a repeated broadcast about basic weather information, runways in use, and any special information such as closed taxiways or runways. Such a broadcast offers an excellent steady signal source for initial adjustment of your receiver. If you are close enough to the airport to receive ATIS, you will hear the Approach Control and the Departure Control transmissions. These air traffic radar controllers coordinate all flight operations in the vicinity of busy metropolitan airport areas, and are called the ATC Center.

When you hear a pilot talking with "Jacksonville Center" or "Indianapolis Center," you know the aircraft is really enroute on a flight rather than just leaving or just approaching a destination. A pilot will be in touch with several different "Regional Centers" during a cross-country flight. These smaller centers are called "Unicom" centers.

Airports without control towers rely on the local "Unicom" frequency dedicated only to advisory communications between pilots and ground personnel such as fuel service operators. The people on the ground can advise the pilot on the status of incoming or outgoing aircraft, but the pilot remains responsible for landing and takeoff decisions. Typical Unicom frequencies are 122.8 and 123.0 MHz.

The FAA's network of Flight Service Stations keeps track of flight plans, provides weather briefings and other services to pilots. Some advisory radio communication takes place between pilots and a regional "FSS." If there is an FSS in your local area, but no airport control towers, the FSS radio frequency will stay interesting.

Fast talking pilot and controllers

Aviation communication is brief, but it is clear and full of meaning. Usually, pilots repeat back exactly what they hear from a controller so that both know that the message or instructions were correctly interpreted. If you are listening in, it is hard to track everything said from a cockpit, particularly in big city areas. Just to taxi, take off and fly a few miles, a pilot may talk with six or eight different air traffic control operations, all on different frequencies, all within a few minutes! Here are the meanings of a few typical communications:

"Miami center, delta 545 heavy out of three-zero for two-five."

Delta Flight 545 acknowledges Miami Center's clearance to descend from 30,000 feet to 25,000 feet altitude. The word "heavy" means that the plane is a jumbo jet such as 747, DC-10, etc.

"Seneca 432 lima cleared to outer marker. contact Tower 118.7."

The local Approach Control is saying that the Piper Seneca with the N-number (tail number) ending in "432L" is cleared to continue flying an instrument approach to the outer marker (a precision radio beacon located near the airport) and should immediately call the airport radio control tower at 118.7 MHz. This message also implies that the controller does not expect to talk again with that aircraft.

"Cessna 723, squawk 6750, climb and maintain five thousand."

A controller is telling the Cessna pilot to set the airplane's radar transponder to code 6750, climb to and fly level at an altitude of 5000 feet.

"United 330, traffic at 9 o'clock, 4 miles, altitude unknown."

The controller alerts United Airlines flight #330 of radar contact with some other aircraft off to the pilot's left at a 9 o'clock position. Since the unknown plane's altitude is also unknown, both controller and pilot realize that it is a smaller private plane not equipped with altitude-reporting equipment.

Active receiver circuit description

Now, take a look at the schematic diagram shown in Figure 13-2. The aircraft band antenna is first coupled through C1 to a three-section tuned LC filter input network. The aircraft band signals ranging from 118 to 135 MHz signals are amplified by VHF transistor Q1 and fed to the input of U1, the SA602 mixer-oscillator. Inductor L6 and its associated capacitor network establish the LO (local oscillator) frequency at 10.7 MHz higher than the incoming 118–135 MHz signals. The local oscillator frequency may be tuned across about 15 MHz by the varactor tuning network formed by diode D1 and resistor R1. The 10.7 MHz difference between the local oscillator and the received signal is fed through the 10.7 MHz ceramic filter FL1, and then amplified by Q2 and the signal is then applied to U2, the MC1350 IF amplifier IC with AGC input. The 10.7 MHz IF is peaked by inductor L7, and the AM audio signal is then demodulated by diode D2 and fed through the four op-amps of U3, the LM324, where volume control, AGC output, audio filtering and squelch functions are managed. The LM386 (U4) is the audio amplifier, and is capable of driving simple communications speakers to excellent volume levels.

Circuit construction

The aircraft band receiver is best constructed on a printed circuit board for best results. Place your schematic diagram in front of you, heat up your 27 to 30 watt pencil tipped soldering iron and prepare to insert

the components into the circuit board. You can fabricate your own circuit board from scratch if you are an experienced builder or you could elect to build the receiver from the kit supplier, Ramsey Electronics, listed in the Appendix. We will build the receiver in sections and will begin first with the antenna and input pre-amplifier section.

Before we go ahead and build the aircraft receiver, let's take a few moments to look at Table 13-1, which illustrates the resistor color chart. Resistors have three or four color bands, which begin at one edge of the resistor body. The first color band represents the resistor's first digit value, while the second color band denotes the second digit of the resistor value. The third color band represents the multiplier value of the resistor. The fourth color band denotes the tolerance value of the resistor. A silver band represents a 10% tolerance, while a gold band notes a 5% tolerance value. The absence of a fourth color band states that the resistor has a 20% tolerance value. Therefore, a 10,000 ohm or 10 k ohm resistor would have a brown band (1) a black band (0) and a multiplier of (000), and an orange band.

Go ahead and install resistors R4, R5 and R6, then solder them in place on the PC board. Then cut the excess leads from the PC board with a pair of end-cutters. Cut the excess leads flush to the PC board.

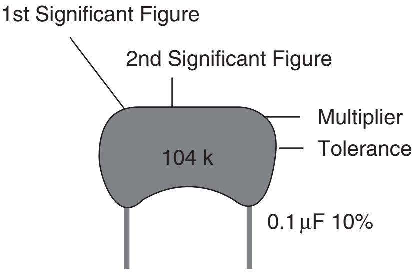
Next we are going to install the capacitors for the project. Capacitors are described as electrolytic and non-electrolytic types. Electrolytic types are large sized and larger in value than non-electrolytic types. Electrolytic type capacitors have polarity, i.e. both a positive and negative terminal, often with color band and/or (+) or minus (−) marking on them. These electrolytic capacitors must be installed with respect to these polarity markings if you expect the circuit to work correctly. Take your time installing them and refer regularly to both the schematic and parts layout diagrams. Non-electrolytic capacitors can sometimes be very small in size, and often their actual value will NOT be printed on them. A three-digit code is used to help identify these capacitors; refer to Table 13-2. For example, a .001 µF capacitor would be marked with (102), while a .01 µF capacitor would be marked with (103).

Go ahead and install capacitors C1 through C8 into their respective PC holes on the PC board, being sure to observe polarity on the capacitors before installing them on the PC board. Most electrolytics will have a black band or a plus or minus marking next to a pin. Solder the capacitors to the PC board, then remove the excess leads. Next install inductors L1, L2, L3 and L4 into

Table 13-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.



CSGNetwork.Com 6/4/92

Value	*Type*	*Code*	*Value*	*Type*	*Code*

Table 13-3
Coil winding information

L1,L3,L5	1.5 turns #28 ga. magnet wire, 5 mm inner diameter air core - about 1 mm spacing (2-turns works fine)
L2,L4	.33 µH, molded inductor (Digi-Key M9R33-ND)
L6	.1 µH, 3.5 turns, slug tuned coil (Digi-Key TK2816-ND)
L7	10.7 MHz shielded I-F transformer (Mouser 42FIF122) or Circuit Specialists

their respective holes, followed by L5; see Table 13-3 for winding instructions. When you have inserted the inductors, you can solder them in place and then cut the excess component leads flush to the edge of the circuit board.

Before you go ahead and install the transistors and integrated circuits, refer to the semiconductor pin-out diagram shown in Figure 13-3, which will help you orient the components. Now locate and install transistor Q1, being sure you have the correct component before installing it on the PC board. Be sure you can identify all three leads as to their correct pin-outs before inserting it into the circuit board to avoid damage to the circuit once power is later applied. Solder Q1 to the board and then remove the excess leads.

Next we are going to move on to installing the Local Oscillator components. First install resistors R1, R7, R8, and R9 followed by resistors R10, R11, R12 and then resistors R25, R26 and R28. Solder the resistors into their respective locations and be sure to remove the excess lead lengths. Next we will install capacitors C9, C10, C11 and C12 followed by capacitors C13, C16, C17, C19 and C20 followed by C30 and C31. Be sure to observe the polarity of the capacitors when installing them on the board to prevent circuit damage when power is first applied. Install the capacitors into their respective location on the PC board. Once inserted, solder the capacitors to the circuit board and then remove the excess leads.

Now locate diode D1 and D2, and note that the cathode or black band side of the diode points to the battery. Diode D1 is the varactor "tuning" diode. Go ahead and install these diodes, then solder them to the board. Remove the excess leads. Locate transistor Q2 and install it on the PC, once you have identified all the leads. Solder Q2 to the board, and then remove the excess leads with your end-cutter. Now locate and install inductor L6, the 3.5-turn slug tuned coil and L7, the 10.7 I-F transformer. Remember to trim the extra lead lengths as needed. Locate the FL1, the 10.7 MHz ceramic filter, it will have three leads and is usually a small square component. Solder it in place and remove the excess leads. Finally install the 8-pin SA602 local oscillator-mixer at U1. It is advisable to install an IC socket into place in the proper location and then insert the IC into the socket. This is good insurance in the event of a possible component failure at some later point. When inserting the IC into the socket be sure to first identify which pin is #1. Usually each IC will have a small circle or cut-out on the top or top left side of the IC. Usually the pin is just to the right of this indented circle.

Next we will install the LM324 IC circuit components. First locate resistors R13, R14, R15, R16, R17, R18 and R19 followed by resistors R20, R21, R22, R23 and R24. Install these resistors in their respective locations and then solder them in place on the

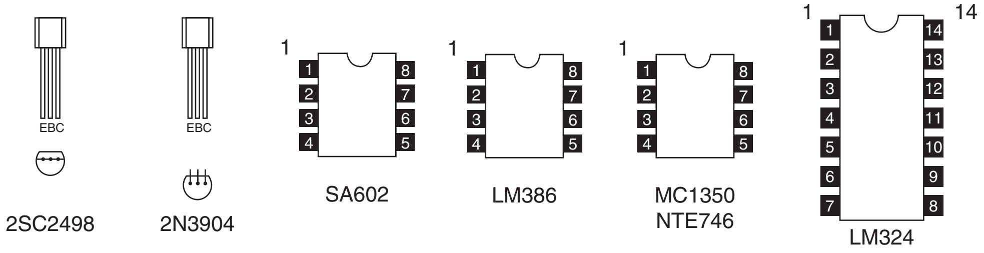

Figure 13-3 *Semiconductor pin-outs*

PC board. Remember to cut the extra leads. Now locate diode D3, remember to observe the polarity when installing D3. Solder the diode in place, then remove the excess lead lengths. Now locate and install capacitors C18, C21, C22 followed by capacitors C23, C24 and C25. Remember electrolytic capacitors have polarity markings and they must be observed for the circuit to operate correctly. You will see either a plus or minus marking at one end of the capacitor. Once installed, solder the capacitors in place and then remove the extra leads by cutting them flush to the circuit board. Finally install an integrated circuit socket for U3 and then place U3 into the socket, but be sure to install it correctly, observing the indented circle as near pin 1 on the IC.

Finally we are going to install the audio amplifier components. First locate resistor R27 and install it on the PC board. Next solder it in place and cut the extra leads. Now, locate and install capacitors C26, C27, C28, and C29. Remember C26 and C27 are electrolytic types, so polarity must be observed before installing them. Finally install an IC socket for U4 the LM386 amplifier IC. When installing U4 be sure to observe the correct orientation before inserting it into the socket to prevent damage when power is applied.

Now you finish up the circuit by installing the 9 volt battery holder, the 9 volt battery clip, followed by switch S1. Once these components have been installed you can locate and install jacks J1 and J2 onto the circuit board.

If you haven't already installed the potentiometers, R1, R2 and R3, go ahead and install them and solder the controls firmly in place. Be sure the mounting tabs are completely soldered for a good mechanical connection.

Let's take a short break and when we return we will inspect the PC board for poor solder joints and "short" circuits before applying power to the circuit board. Pick up the circuit board and bring the foil side of the board up towards you to inspect the board. First, we will look for "cold" or poor solder joints on the PC board. Take a look at each of the solder joints. You want to make sure each of the solder joints appears to look clean, smooth and shiny. If you see any solder joints that look dull or "blobby" then you will need to remove the solder from the joint with a solder-sucker or wick and then re-solder the joint, so that it appears to be clean, shiny and smooth.

Next we will inspect the PC board for "short" circuits. Often "stray" or "cut" component leads will "bridge" across or between circuit traces on the PC board. These possible "shorts" can cause damage to the circuit when power is first applied, so it is best to remove any "bridging" leads or solder blobs or "shorts" before power is sent to the circuit board. Look over the board carefully for any signs of "bridging" wires or blobs of solder. Once you are comfortable with your inspection, you can lay the circuit board back down on the table.

Enclosure recommendations

If your first goal is economy and rugged portability, you will find that the circuit board can be nicely mounted in a standard VHS videotape storage box, which also gives room for a speaker or earphone storage, and even a roll of antenna wire. The controls are easily mounted at one end of such a box. It may be necessary to cut away the molded posts which secure the tape cassette itself. These storage boxes come in several styles, so pick one which truly looks practical as a project enclosure.

The most economical metal enclosure nicely suited for Ramsey PC board kits is the Radio Shack 270-253A. This metal utility cabinet can accommodate one or two different receiver boards plus a speaker, with room for various refinements you might want to add, such as a bigger battery pack, fine tuning control, and so forth. When you have selected your enclosure, you can place the circuit board into the case and mount it. Be sure to allow the extension of the squelch control, the volume control and the tuning control on the front panel of the chassis. The speaker can be mounted on the top of the case, and the earphone and antenna jack can be mounted on the rear of the receiver.

Congratulations, you have successfully completed your active aircraft band receiver. Now you are ready to test and adjust the receiver before setting down and enjoying it. Now, you can attach a speaker or pair of headphones to jack J2. Next, attach a whip antenna to jack J1, and then connect a 9 volt battery to the battery clip leads and we can go ahead and test the active aircraft receiver. Now, turn the On-Off switch to the "ON" position. Be sure to turn down the squelch control to below the threshold point, so you can hear a hissing sound coming from the speaker or headphone. Now, turn up the volume control to about midway. Take a few minutes to tune up and down the band with the main tuning control. If after about 15 minutes, you do not hear any transmissions on your radio or if you do not hear any hissing sounds from the speaker, then you know there could be a problem with your receiver.

In the event of a problem with your new aircraft band receiver, you will have to disconnect the speaker, antenna and battery and visually inspect the circuit board for any errors. Often a second or new pair of eyes is very helpful in locating problems on circuit boards. The most likely causes of circuit failure are misplaced components or components such as diodes and electrolytic capacitors installed backwards. The second most likely cause for problems are semiconductors, such as transistors installed backwards. Be sure to re-check the manufacturer data sheets for proper pin-out information when installing the transistors. Finally, check the orientation of the integrated circuits in their respective sockets; sometimes the ICs can be put in backwards in their sockets causing the circuit to malfunction. Once you have fully inspected and hopefully located your problem, you can reconnect the battery, headphones and antenna and then retest the receiver once again.

Antenna considerations

An antenna for your new aircraft receiver can be as simple as a 21″ piece of wire, an extendable whip antenna or a roof-mounted ground-plane aviation antenna. Most folks near an airport will get plenty of in-the-air action from a wire or whip antenna, but if you're more than a few miles away, a decent roof-mount antenna is the way to go. Radio Shack sells an ideal antenna designed for scanners which covers the aircraft band nicely and it costs around $30. A low cost TV antenna works well, even better if rotated 90 degrees (remember aircraft antennas are vertically polarized).

Adjustment and alignment

Alignment of the air-band receiver consists of simply adjusting L6 for the desired tuning range and peaking the IF transformer (L7). If you are using a signal generator, frequency counter or other VHF receiver for calibration, remember that you want to set the local oscillator frequency 10.7 MHz higher than the desired signal or range to be received. Adjustment of the L6 oscillator coil MUST be made with a non-metallic alignment tool. The use of a metal tool of any kind will detune the coil drastically, making alignment almost impossible. Also, if you're receiving FM broadcast stations, you have the slug tuned too far down in the coil form. Turn it until it is higher in the form and try again. One other thing that you can do to improve the operation of your kit is to spread out the three 2-turn coils at the antenna input, L1, L3, and L5. Stretching these out will give you greater sensitivity.

Once you know you are receiving aircraft or airport transmissions, adjust the IF transformer (L7) for best reception. Typically, L7 is adjusted 2–3 turns from the top of the shield can. If you don't have any signal reference equipment at home, and are not yet hearing airplanes, your best bet is to pack up your AR1C and needed tools and head for the nearest airport! If there is no control tower, don't hesitate to visit a general aviation service center on the airport grounds. If you've never done this before, you will probably find it to be a fun and interesting experience. Ask which are the most active frequencies and adjust L6 and your front panel tuning control until you hear the action. A ground service operator or private pilot may be willing to give you a brief test transmission on the 122.8 Unicom frequency. Remember, also, that if your airport has ATIS transmissions, you can get a steady test signal as soon as you are line-of-sight with its antenna.

The aircraft receiver does not produce a loud hiss when no signal is being received (unlike an FM receiver or expensive AM receiver); this is due to the somewhat limited amount of IF or Intermediate Frequency gain. Increasing the IF gain would produce a hiss and marginally better sensitivity (about a microvolt) but also require much more alignment, AGC circuitry, and builder ability—far beyond the intention of this kit.

Tuning the aircraft receiver

With the varactor tuning control capable of going across 10–15 MHz, and with pilots and controllers talking so briefly, you will need to get used to tuning your receiver! You'll find that ANY knob gives smoother tuning than the bare control shaft, and that a "vernier" dial will make the procedure even easier—but at the expense of being able to check up and down the band quickly, which you might like to do if you're tracking the same airplane. The air-band receiver is designed to let you explore the entire communications section of the aviation band. If you become really interested only in being able to check a certain frequency such as a nearby FAA control tower, or Unicom, it will be helpful to mark that spot on a dial template such as is reproduced for your convenience below.

"VOR" or "OMNI" transmissions

While driving around the countryside you may have come across a tall white "cone" structure near your airport or in the middle of a big farming field; it is useful for you to know that these are VHF navigational aids operating in the 118–135 MHz frequency range, just below the air-ground communications range, sending a steady signal which may be helpful in initial alignment. If you tune in such a signal on your receiver, remember that you will have to increase the local oscillator frequency later in order to listen to air traffic communications.

Passive aircraft receiver

The passive air-band receiver is a type of "crystal" radio which contains no local oscillator which might interferes with the on-board aircraft's sensitive electronics. The passive aircraft receiver broadly tunes from 118 MHz to 136 MHz, and was designed to listen-in to in-flight communications between your pilot and the control tower. The passive aircraft receiver is shown in Figure 13-4. The passive aircraft receiver can be built small enough to place inside your vest pocket and it operates from an ordinary 9 volt battery.

The passive aircraft receiver is basically an amplified type of "crystal radio" designed to receive AM aircraft transmissions. The "passive" design uses no oscillators or other RF circuitry capable of interfering with aircraft communications. This receiver utilizes a coil/capacitor tuned "front-end," which feeds an RF signal to a detector diode. The tuning capacitor may be any small variable with a range from about 5 pF to about 15 or 20 pF. The 0.15 µH inductor may be a molded choke or a few turns wound with a small diameter. Experiment with the coil to get the desired tuning range. The aircraft frequencies are directly above the FM band so a proper inductor will tune FM stations with the capacitor set near maximum capacity. (The FM stations will sound distorted since they are being slope detected.) A 1N34 germanium detector diode or a Schottky diode like the 1N5711 or HP2835 should be used as the detector diode in this receiver circuit. The 10 megohm resistors provide a small diode bias current for better detector efficiency.

The LM358 dual op-amp amplifier draws under 1 ma so the battery life should be quite long. Potentiometer R3 is used to adjust the gain to the second stage of the dual op-amp. The second op-amp stage drives a 100 ohm resistor in series with a 100 µF capacitor. You must use a high impedance "crystal" headphone, since the op-amp output will not drive a speaker directly. A speaker amplifier may be added to drive a speaker or low-z earphone, if desired, but the power consumption will increase sharply, as will the size of the receiver.

The passive aircraft receiver is powered from an ordinary 9 volt transistor radio battery. The entire aircraft band receiver can be built inside a small plastic box. Simply mount an SPST slide switch on the side of the case to apply power to the circuit. If you elect, you can install a ⅛″ phone jack for the "crystal" headphone.

Construction

The passive air-band receiver can be constructed on a regular circuit board or it could be built on a

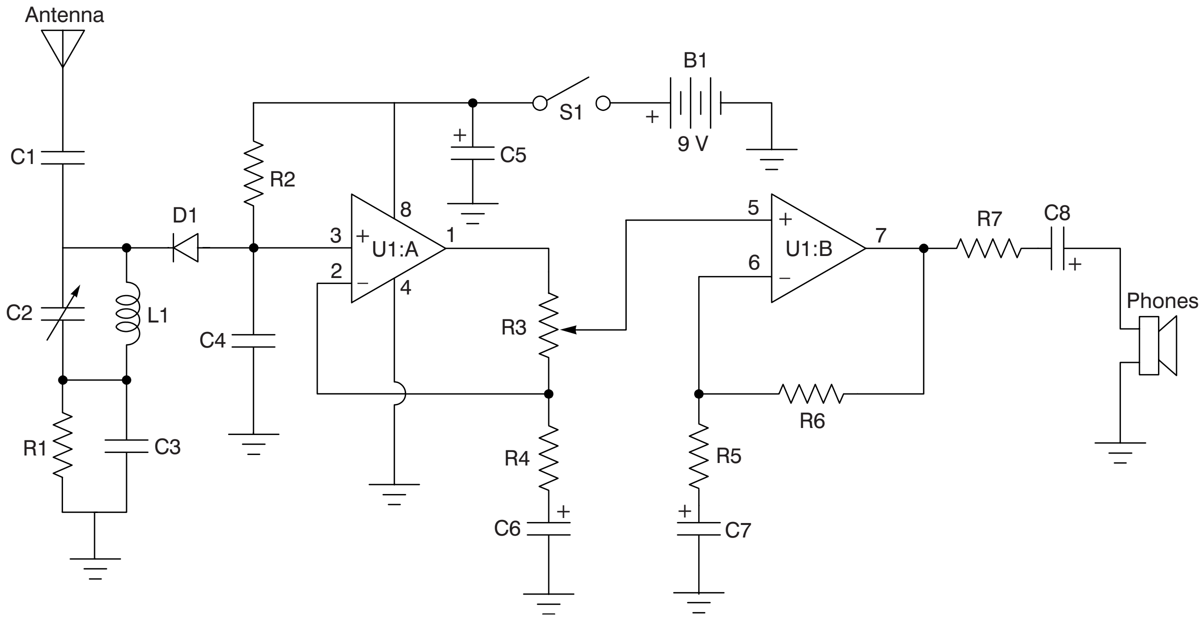

Figure 13-4 *Passive aircraft receiver schematic*

"quick-board" which contains ready-made circuit traces, these are available at Radio Shack stores.

You may want to lay out the circuit so that the tuning control is at one edge of the board, which will make things a little easier when installing the circuit in an enclosure. Building the circuit is pretty straightforward and should only take a few hours to build. Refer to Table 13-1 for identifying the resistors and Table 13-2 for identifying the small capacitors in the circuit. Remember it is very important to install the diode correctly with respect to its polarity in order for the circuit to work properly. The passive air-band receiver also contains a few electrolytic capacitors, and you will remember that these devices have polarity and it must be observed for the circuit to work. The aircraft receiver uses a dual op-amp to amplify the signals and you will have to ensure that it is installed correctly. An integrated circuit is highly recommended for the op-amp. In the event of a circuit failure at some later date, it is much easier to simply unplug an IC rather than trying to unsolder one from a PC board to replace it with a new one. When installing the IC into its socket, you will have to make sure that you orient it correctly. An IC will typically have a notch or small cut-out at one end of the IC case. Pin one (1) will be to the left of the cut-out of notch when viewed from the top of the IC. In this project pin 1 of the IC connects to potentiometer R3, while pin 8 of the IC is connected to the power source. Note that pin 4 of the IC is connected to the circuit ground.

You can elect to use a small speaker in this circuit, but in order to make a miniature receiver you may want to simply use a small ⅛″ mini jack and just plug into a pair of small earphones. The circuit is powered from a standard 9 volt battery; remember the black or minus (−) battery clip is connected to ground, while the plus (+) or red battery clip lead is connected to capacitor C5 at the plus (+) end.

You will want to have the tuning capacitor C2 near the edge of the circuit board, so that you can allow the tuning knob to protrude through the case so you can easily tune the receiver. Once the receiver has been completed, you should take a few minutes rest.

After the break, you should inspect the foil side of the circuit board for any "cold" solder joints. Cold solder joints often look dark, dull or "blobby." If you see any solder joints that look this way, you should re-solder the connections. You should also take a moment to examine the circuit board for any "short-circuits" which may be the result of a "stray" component lead shorting between circuit traces.

You can make yourself an antenna from a piece of stiff 20 ga. wire as a whip antenna to capacitor C1, or install a miniature jack in order to plug in a whip antenna. The antenna can be a 6″ piece of #20 ga. stiff solid copper wire or a small telescoping aluminum antenna connected to capacitor C1. Radio Shack has a good selection of whip antennas. You could elect to solder the wire antenna directly to C1 and just bring the antenna out the top of the enclosure, or you could install a small ½″ mini jack for the antenna on the rear of the enclosure. The selectivity is reduce as the antenna length is increased so best performance is achieved with the shortest acceptable antenna. Try increasing the 1.8 pF capacitor value when using very short antennas and decreasing it for long antennas. In order to "tune" the passive aircraft receiver you can either leave a small hole on the side of the plastic enclosure to adjust the frequency using a plastic tuning tool, or you need to find a way to attach a plastic knob onto the tuning screw; you will have to drill a larger hole in the case to bring the knob outside the case for easy tuning.

To test the passive aircraft receiver, park near your local airport. Turn on the passive air-band receiver, attach your wire antenna or pull up your telescoping antenna and tune the receiver. You should try to listen when you see an aircraft take-off or land or when you see an aircraft taxiing along the runway. If you can get close to the tower in a small airport, that should ensure that you will be able to test your receiver adequately. As you see a plane arrive or leave, "tune" around the band and you should hear either the pilot or the control tower. If you plan on taking the passive aircraft receiver on-board an aircraft to listen-in to the pilot during your flight, you should ask the pilot or stewardess if it is permitted aboard your aircraft. Generally you are given permission without a problem. Enjoy building and using your new aircraft receivers!

Chapter 14

VLF or Very Low Frequency Radio Receiver

Parts list

VLF Whistler Receiver

R1,R4 10k ohm ¼w, 5% resistor

R2,R3 22k ohm ¼w, 5% resistor

R5 6.2 megohm, ¼w 5% resistor

R6 1 meg ohm potentiometer (trimpot) - single turn

R7 10 megohm, ¼w 5% resistor

R8 1k ohm, ¼w 5% resistor

R9 1k ohm, ¼w 5% resistor

R10 3.3k ohm, ¼w 5% resistor

R11,R12 820 ohm, ¼w 5% resistor

R13 10k ohm potentiometer (panel)

R14,R17 10 ohm, ¼w, 5% resistor

R15,R16 2.2k ohm, ¼w, 5% resistor

C1,C3 47 pF, 35 volt mica capacitor

C2 100 pF, 35 volt mica capacitor

C4,C5,C6 3.3 nF, 35 volt mylar capacitor

C7,C15 .01 μF, 35 volt ceramic disk capacitor

C8 27 pF, 35 volt mica capacitor

C9 1 μF, 35 volt electrolytic capacitor

C10 .18 μF, 35 volt tantalum capacitor

C11 .12 μF, 35 volt tantalum capacitor

C12 1.8 μF, 35 volt tantalum capacitor

C13 .68 μF, 35 volt tantalum capacitor

C14 .22 μF, 35 volt tantalum capacitor

C16 .068 μF, 35 volt tantalum capacitor

C17,C18 .22 μF, 35 volt tantalum capacitor

C19 .05 μF, 35 volt ceramic disk capacitor

C20,C22,C24 100 μF, 35 volt electrolytic capacitor

"Natural Radio" is a name sometimes used for describing radio noise with natural origins, mainly due to but not confined to lightning. At first suggestion, you may think that listening to lightning crackles would be dull or uninteresting, but electromagnetic radiation from lightning can travel great distances and undergo strange modifications along the way. The frequencies of the original pulse can be spread out in time (a process called "dispersion") since the higher frequencies travel a little faster than the lower. The result is that the short impulse from a lightning strike in South America can sound like a chirp in Texas. Slower sweeping tones are called "whistlers" and they are a bit of a mystery. The energy from a lightning bolt streams out into space into a region called the "magnetosphere," magnetized plasma created by the interaction of solar wind with the Earth's magnetic field. The lightning pulse is reflected or "ducted" back down to Earth after a very long trip during which time the frequencies are spread out by a dispersion-like process. Short whistlers might be due to dispersion, but some whistlers last five seconds so ordinary dispersion is probably inadequate an explanation. A radio wave can travel a million miles in five seconds, so to accumulate that much difference in arrival times, the signal would have to travel hundreds of millions of miles, assuming a pretty steep dispersion curve. More likely, the whistler is an emission from the magnetosphere triggered by the lightning pulse. When conditions are just right, numerous lightning strikes combine with numerous reflections to give an eerie chorus that sounds a bit like a flock of geese.

Most people have never heard of Natural Radio produced by several of natures's processes, including lightning storms and aurora, aided by events occurring on the Sun. The majority of Earth's natural radio emissions occur in the extremely-low-frequency and very-low-frequency (ELF/VLF) radio spectrum. Whistlers, one of the more frequent natural radio emissions to be heard, are just one of many natural radio "sounds" the Earth produces at all times in one form or another, and these signals have caught the interest and fascination of a small but growing number of hobby listeners and professional researchers for the past four decades.

Whistlers are amazing sounding bursts of ELF/VLF radio energy initiated by lightning strikes which "fall" in pitch. A whistler, as heard in the audio output from a VLF or "whistler" receiver, generally falls lower in pitch, from as high as the middle-to-upper frequency range of our hearing downward to a low pitch of a couple hundred cycles-per-second (Hz). Measured in frequency terms, a whistler can begin at over 10,000 Hz and fall to less than 200 Hz, though the majority are heard from 6000 down to 500 Hz. Whistlers can tell scientists a great deal of the space environment between the Sun and the Earth and also about Earth's magnetosphere.

The causes of whistlers are generally well known today though not yet completely understood. What is clear is that whistlers owe their existence to lightning storms. Lightning stroke energy happens at all electromagnetic frequencies simultaneously. The Earth is literally bathed in lightning-stroke radio energy from an estimated 1500 to 2000 lightning storms in progress at any given time, triggering over a million lightning strikes daily. The total energy output of lightning storms far exceeds the combined power output of all man-made radio signals and electric power generated from power plants.

Whistlers also owe their existence to Earth's magnetic field (magnetosphere), which surrounds the planet like an enormous glove, and also to the Sun. Streaming from the Sun is the Solar Wind, which consists of energy and charged particles, called ions. And so, the combination of the Sun's Solar Wind, the Earth's magnetosphere surrounding the entire planet, and lightning storms all interact to create the intriguing sounds and great varieties of whistlers.

How do whistlers occur from this combination of natural solar-terrestrial forces? Some of the radio energy bursts from lightning strokes travel into space beyond Earth's ionosphere layers and into the magnetosphere, where they follow approximately the lines-of-force of the Earth's magnetic field to the opposite polar hemisphere along "ducts" formed by ions streaming toward Earth from the Sun's Solar Wind. Solar-Wind ions get trapped in and aligned with Earth's magnetic field. As the lightning energy travels along a field-aligned duct, its radio frequencies become spread out (dispersed) in a similar fashion to light shining into a glass prism. The higher radio frequencies arrive before the lower frequencies, resulting in a downward falling tone of varying purity.

A whistler will often be heard many thousands of miles from its initiating lightning stroke—and in the opposite polar hemisphere! Lightning storms in British Columbia and Alaska may produce whistlers that are heard in New Zealand. Likewise, lightning storms in eastern North America may produce whistlers that are heard in southern Argentina or even Antarctica.
Even more remarkably, whistler energy can also be "bounced back" through the magnetosphere near (or not-so-near) the lightning storm from which it was born!

Whistlers are descending tones. Their duration can range from a fraction of a second to several seconds, with the rate of frequency shift steadily decreasing as the frequency decreases. A whistler's note may be pure, sounding almost as if it was produced using a laboratory audio signal generator; other whistlers are more diffuse, sounding like a breathy "swoosh" or composed of multiple tones. On occasion, some whistlers produce echoes or long progressions of echoes, known as "echo trains," that can continue for many minutes.

Whistlers can occur in any season. Some types are more likely to be heard in summer than winter and vice-versa. Statistically, the odds are especially high for good whistler activity between mid-March and mid-April.

Whistlers and the sounds of the dawn chorus are not heard equally well everywhere in the world. Reception of these are poor in equatorial regions, with best reception at geomagnetic latitudes above 50°. Fortunately the continental United States and Canada are well positioned for reception of whistlers and other signals of natural radio.

Considered by many listeners to be the "Music of Earth", whistlers are among the accidental discoveries of science. In the late 19th century, European long-distance telegraph and telephone operators were the first people to hear whistlers. The long telegraph wires often picked up the snapping and crackling of lightning storms, which was mixed with the Morse code "buzzes" or voice audio from the sending station. Sometimes, the telephone operators also heard strange whistling tones in the background. They were attributed to problems in the wires and connections of the telegraph system and disregarded.

The first written report of this phenomenon dates back to 1886 in Austria, when whistlers were heard on a 22-km (14 mile) telephone wire without amplification. The German scientist, H. Barkhausen, was eavesdropping on Allied telephone conversations during World War I. In order to pick up the telephone conversations, he inserted two metal probes in the ground some distance apart and connected these to the input of a sensitive audio amplifier. He was surprised to hear whistling tones which lasted for one or two seconds and which glided from a high frequency in the audio range to a lower frequency where they disappeared into the amplifier or background noise level. On occasion, the whistlers were so numerous and loud that he could not detect any type of telephone.

Later, three researchers from the Marconi Company in England reported in 1928 on the work they had done in whistler research. Eckersley, Smith, and Tremellen established a positive correlation between whistler occurrence and solar activity, and they found that whistlers frequently occur in groups preceded by a loud click. The time between the click and the whistlers was about three seconds. They concluded that there must have been two paths of propagation involved; one for the click which preceded the whistler, and a second, much longer path, over which the whistler and its echoes propagated.

Eckersley was able to show in 1931 that Earth's magnetic field permits a suitably polarized wave to pass completely through the ionosphere. This was in accordance with the magneto-ionic theory. Tremellen had on one occasion observed that during a summer thunderstorm at night every visible flash was followed by a whistler. This served as the first definite evidence of the relationship between lightning discharges and whistlers—the click being the lightning discharged which caused the whistler. As the Marconi workers continued their research, they also discover a new type of atmospheric which sounded somewhat like the warbling of birds. Since the sound tended to occur most frequently at dawn, they gave it the name *dawn chorus*.

L.R.O. Storey of Cambridge University began an intensive study of whistlers in 1951. He confirmed Eckersley's law which showed that most whistlers originate in ordinary lightning discharges, and found the path of propagation of the whistler to be along the lines of the Earth's magnetic field.

Other interesting sounds include "tweeks," which have been described by one listener as a cross between chirping birds and a hundred little men hitting iron bars with hammers. The ephemeral "dawn chorus," is a cacophony of sounds that resembles nothing else on Earth.

Tweeks are abrupt descending notes that resemble "pings." They are usually heard at night during the winter and early spring.

The dawn chorus has been variously described as sounding like birds at sunrise, a swamp full of frogs, or seals barking. In fact, it varies constantly. "Hooks," "risers," and "hiss" are all part of the dawn chorus, but sometimes these sounds are also heard as solitary events. A hook starts out like a whistler but then abruptly turns into a rising tone. Risers increase in frequency from beginning to end. And hiss sounds just like its name. Appropriately enough, dawn chorus is best heard around dawn, but it may occur at any time of the day or night. The dawn chorus is most likely to be heard during and shortly after geomagnetic storms.

A whistler receiver

You cannot easily buy a radio capable of tuning 1 to 10 kHz, but it is possible to build a sensitive receiver to permit you to hear the sounds of natural radio. We will explore what causes these sounds and see how you can study them yourself.

A whistler receiver, even though whistlers and related emissions occur at acoustical frequencies, is a receiver of radio signals. To hear whistlers, you must intercept their electromagnetic energy with an antenna and transform it to the mechanical vibrations to which our ears respond.

The "classic" whistler receiving system consists of an antenna for signal collection, an amplifier to boost the signal level, and headphones or a speaker to transform the signal to sound waves. (A magnetic tape recorder can be substituted for the headphones or speaker.) A whistler receiver can simply be an audio amplifier connected to an antenna system. However, powerful man-made interference immediately above and below the frequencies of interest tend to seriously overload receivers of this sort and make reception of whistlers and related phenomena difficult.

To overcome these problems, a good whistler receiver circuit includes a circuit called a low-pass filter that attenuates all signals above 7 kHz. This greatly reduces interference from such sources. To escape interference from AC power lines and other forms of non-natural radio noise, the receiver is designed for portable operation "in the field" away from such interference sources.

A sensitive dual FET whistler receiver is shown in the photo in Figure 14-1, and in the schematic diagram in Figure 14-2. The antenna is first fed to an RF filter

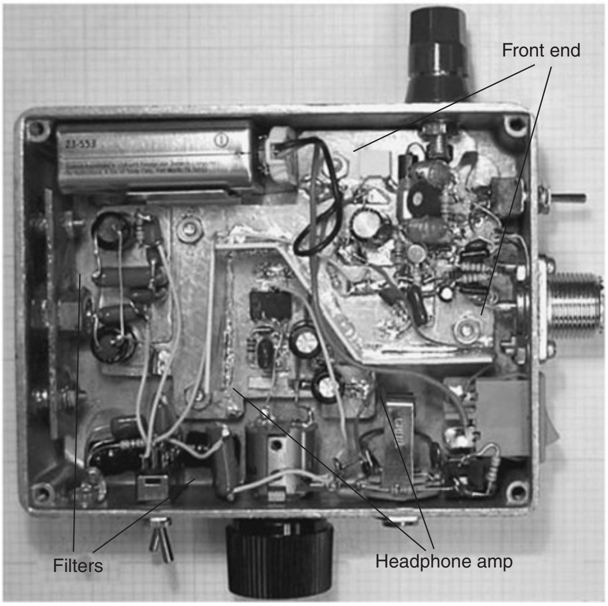

Figure 14-1 *VLF whistler receiver*

which is composed of resistors R1 through R4 and capacitors C1 through C3. This filter only allows the desired frequencies to be sent to the next section of the receiver. The RF filter is next fed to the 60 Hz filter or "trap" which filters out 60 Hz power line frequencies before the RF signals are amplified. The 60 Hz filter can be switched in and out of the circuit with switch S1:a. The dual matched FET transistor Q1 along with transistor Q2 are used to amplify the RF signals of the desired band of frequencies. The amplified signals are then fed to the input of a set of selectable filters which can be switched in and out of the circuit. Toggle switch S2 is used to switch in the high-pass filter circuit, while switch S3 is used to switch-in the low-pass filter. You can select either or both filters if desired.

The output of the low-pass filter circuit is coupled to the final audio amplifier stage via capacitor C17. Potentiometer R12 controls the audio level entering the LM386 audio amplifier at U1; also note that R12 also contains a switch S5, which is used to supply power to the LM386 audio amplifier. The output of the LM386 is coupled to an audio output jack via capacitor C20. Note that capacitor C18 is coupled to a recorder output jack to allow a chart recorder or analog to digital converter to be used to monitor and record the output from the whistler receiver. The whistler receiver is powered from a 9 volt battery for both stationary and field receiving applications.

Building a whistler receiver

Before we start building the Whistler receiver, you will need to locate a clean, well lit and well ventilated area. A workbench or large table top to spread out all you diagrams, components and tools for the project. First, you will need a small pencil tipped 27 to 33 watt soldering iron, a spool of 22 ga. 60/40 tin/lead solder, and a small jar of "Tip Tinner." "Tip Tinner" is a soldering iron tip cleaner/dresser and is available at your local Radio Shack store. You will also want to locate a few small tools such as a pair of end-cutters, a pair of needle-nose pliers, a pair of tweezers and a magnifying glass. Look for a small flat-blade screwdriver as well as a small Phillips screwdriver to round out your tools for the project. Next locate all the components for the Whistler project as well as all of the diagrams including the schematic, parts layout diagram and the necessary charts and tables and we will begin.

In order to construct a stable well performing radio receiver, it is recommended practice to build the Whistler receiver on a printed circuit board, with large ground plane areas. You will need to use good RF building practices, such as keeping leads as short as possible, clean solder joints, etc. With your circuit board in hand we will begin building the circuit.

Take a look at the schematic diagram and you will notice that there are dotted or dashed lines. These dashed lines represent shielded compartments on the circuit board. These shielded areas are used to separate different portions of the circuit from one another. You can create a shielded area by soldering a vertical piece of scrap circuit board material onto the circuit board ground plane areas on the circuit board. You could also modularize the circuit building three small circuit boards, one for the RF filter and "trap" circuit, one for the high-pass and low-pass filter, and a third board for the audio amplifier and power circuit. Small metal shield covers could be built using scrap circuit board material.

First, you will need to locate the resistors for the project, and you will also want to refer to the resistor color code chart in Table 14-1, which will help you to identify each of the resistors. Resistors generally have three or four color bands which are used to denote the

Gold			0.1	5%
Silver			0.01	10%
No color				20%

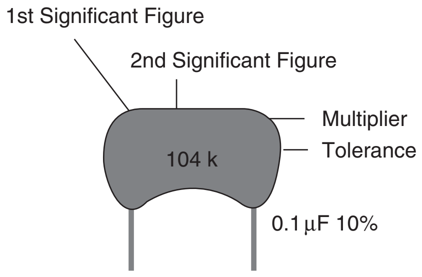
resistor's value. The first color band will be closest to one edge of the resistor. The first color band represents the first digit of the value. Resistor R1, for example, is a 10k ohm resistor. Its first color band would be brown (1), the second color band would be black (0) and the third color band which denotes the resistor's multiplier value would be orange or (000), so 10,000 or ten thousand ohms. A fourth color band represents the resistor's tolerance value. The absence of a fourth color band denotes a 20% tolerance, while a silver band represents a 10% tolerance and a gold denotes a 5% tolerance resistor. Use the color code chart to identify resistors R1, R2 and R3. When you are confident that you know the color codes and can identify these resistors, you can go ahead and solder these resistors onto the circuit board. Use your end-cutters to cut the excess component leads flush to the edge of the circuit board. Now locate another grouping of resistors and install them to the circuit board, then solder them in place on the PC board. Remember to trim the extra component lead lengths from the PC board. Install the remaining resistors onto the circuit board, until all have been mounted to the board, solder them in place and trim the leads as necessary.

Next, we are going to install the capacitors for the Whistler receiver. Capacitors come in two major types, i.e. electrolytic and non-electrolytic. Generally the non-electrolytic capacitors are the small types such as ceramic disks, mylar or polyester types. These small capacitors may have their actual value printed on them, or if the capacitors are very small may instead have a three-digit code printed on them. Refer to the chart in Table 14-2, which will help you identify these capacitors. A .001 µF capacitor, for example, would have (102) marked on the body of the device to denote its value of .001 µF. Electrolytic capacitors are generally the larger capacitors with polarity marking on them. You will find either a black or white color band on them or a plus (+) or minus (–) marking on them. Electrolytic capacitors have polarity, so this means that you have to orient them correctly while installing them in order for the circuit to work properly. Reversing electrolytic capacitors can often cause the circuit to malfunction, and it can destroy the component and/or the circuit itself, so be careful when installing them. Refer to the schematic and the parts layout diagram when installing electrolytic capacitors.

Let's begin installing the capacitors now. Try and separate the electrolytic capacitors from the other types of capacitors. Locate a few of the non-electrolytic capacitors, identify them and install a few of the capacitors on the circuit board. Go ahead and solder these capacitors onto the PC board, once you are sure you have correctly identified them. Trim the excess

Table 14-2
Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.



CSGNetwork.Com 6/4/92

Value	*Type*	*Code*	*Value*	*Type*	*Code*
1.5 pF	Ceramic		1,000 pF /.001 µF	Ceramic / Mylar	102

component leads from the PC board. Install a few more non-electrolytic capacitors and solder them to the board, remember to cut the extra leads from the board. Install the remaining non-electrolytic capacitors to the circuit board and solder them in place.

Next, locate the electrolytic capacitors and we will install them on the PC board. Refer to the schematic and parts layout diagrams to make sure you can orient the capacitors correctly before soldering them. Place a few electrolytic capacitors on the board and solder them in, trim the excess leads as necessary. Add the remaining electrolytic capacitors on to the PC board and solder them in place.

The Whistler receiver also has a number of coils in the circuit, most of them are low cost and readily available from Mouser Electronics, see Appendix. Identify the coils for the project and place them in their respective locations on the PC board. Now, solder them in place and remember to trim the excess component leads flush to the edge of the circuit board.

Looking at the circuit you will notice three transistors, more correctly one dual FETs and one conventional transistor. Before we go ahead and install the semiconductors, take a quick look at the semiconductor pin-out diagram shown in Figure 14-3. The FETs are very sensitive to static electricity damage, so be extremely careful when handling them, use a grounded anti-static wrist-band. The FETs have three leads much like a regular transistor but their pin-outs are a bit different. An FET will usually have a Drain, Source and Gate lead; see pin-out diagram for each particular FET, when installing them on the PC board. The conventional transistor at Q2 is a PNP type which has a Base, Collector and Emitter lead, once again refer to the transistor pin-out diagram, the schematic and parts layout diagrams when installing the transistor and FET. Installing the FET and transistor incorrectly will prevent the circuit from working correctly and may damage the component as well, so be careful when installing the FET and transistor.

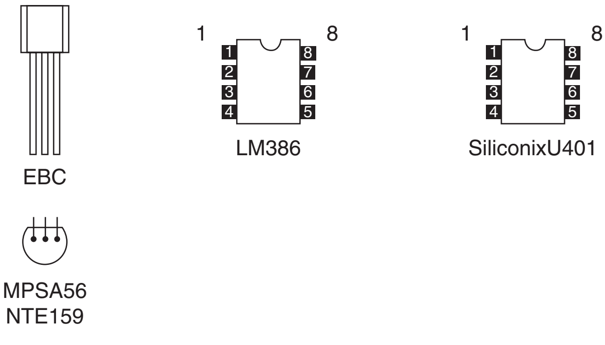

Figure 14-3 *Semiconductor pin-outs*

The receiver has a single integrated circuit at U1, an LM386 audio amplifier IC. As an insurance policy against a possible circuit failure in the present or possible future date, it is recommended that you use an integrated circuit socket. Integrated circuit sockets will usually have a notch or cut-out at one end of the socket; this is supposed to represent pin 1 of the IC socket. You will have to align the socket correctly so that pin 2 of the IC socket connects to the ground bus. Note that pin 1 is not used in this application. When installing the IC into the socket, you will note that the IC itself will have either a small indented circle, a cut-out or a notch at one end of the plastic IC body. Pin 1 of the IC is just to the left of the notch. Insert the IC into the socket making sure pin of the IC is aligned with pin of the socket.

Take a short break and when we return we will check over the printed circuit board for “cold” solder joints and possible “short” circuits. Pick up the PC board with the foil side facing upwards toward you. First we will inspect the PC board for possible “cold” solder joints. Take a look at all of the solder joints. All the solder joints should appear to look clean, shiny and bright, with well formed solder connections. If any of the solder joints appear dull, dark or “blobby,” then you should un-solder and remove the solder from the joint and re-solder the joint all over again, so that it looks good. Next, we will inspect the PC board for possible “short” circuits. “Short” circuits can be caused by small solder balls or blobs which stick to the underside of the board. Many times rosin core solder leaves a sticky residue on the PC board. Sometimes “stray” component leads will adhere to the underside of the board and often they can form a bridge across the PC traces on the PC board causing a “short” circuit, which can damage the circuit upon power-up, so be careful to remove any component leads or solder blobs from the underside of the board.

The VLF Whistler receiver was housed in a metal chassis box to prevent “stray” RF from affecting the circuit operation. The main circuit board can be mounted to the bottom of the enclosure with 1/8″

plastic standoffs. The 60 Hz "trap" filter switch, the high-pass filter and low-pass filter switches, along with the power on-off switch, were mounted on the front panel of the chassis box. The headphone power amplifier power switch, the headphone jack and volume control at R13 were also mounted on the front panel of the chassis box. The SO-238 antenna jack, the 1/8″ record jack and the ground binding post were all mounted on the rear panel of the chassis box. A 9 volt battery holder was used to secure the battery to the left rear corner of the chassis box. Once the circuit has been mounted in the selected chassis, you can move on to applying power and testing the VLF receiver. Connect a fresh 9 volt battery to the VLF receiver, connect a pair of headphones and a whip antenna to the antenna terminals. Turn the power switch to the "ON" position and you should hear a hissing sound from the headphones. If the receiver is totally quiet and you hear nothing, you have a problem! First, you will need to disconnect the battery, the headphones and the antenna, and you will need to carefully examine the circuit board. The most common cause for circuit failure is improper installation of electrolytic capacitors and diodes. Remember that these components have polarity and it must be observed for the circuit to work correctly. Look over the circuit very carefully. It is often advisable to have a second pair of eyes. Have a knowledgeable electronics friend help you examine the circuit board for mistakes. Another cause for possible errors are the incorrect placement of resistors. Often colors are mistaken and resistors are installed in the wrong location. Another possible problem can be the installation of the semiconductors, namely in this circuit the transistors or FETs. Check the manufacturer's pin-out diagrams for the particular device and carefully re-examine the installation. Hopefully at this point you have found your error and corrected it and you can then re-connect the battery, antenna and headphones and re-test the VLF receiver to make sure it is now working.

Using your VLF receiver

The whistler receiver works best out doors in open areas, with a vertical antenna of roughly 3 to 12 feet in height. It can also be used in wooded or obstructed areas with wire antennas between roughly 50 to 200 feet in length connected instead of the vertical antenna. Wire antennas should be insulated and supported off the ground as high as you can place them. The performance of a wire antenna improves the more you can get it in the clear and the more vertically it can be positioned. If you do use a wire antenna, you may have to reduce the value of the input resistor R1 for best results.

The whistler receiver also needs a ground connection, also called a counterpoise. A simple but often effective ground can be provided by your body in contact with the ground terminal (BP2). I have used an improvised finger ring attached to a wire connected to the ground terminal. Other places to make a ground connection include car bodies, wire fences, or other large metal objects not connected in any way to an AC power circuit. Another approach is to use short sections of copper tubing as ground stakes which can be driven into the ground and connected to your receiver. Try several different grounding schemes to see which one provides the quietest reception. Don't be too surprised, however, to discover that you wind up having to still make body contact with the ground terminal for quietest reception!

The prototype receiver, with a whip antenna, was mounted on a piece of wood approximately 2″ × 60″. You can install the antenna at one end of the long rectangular piece of wood (it can be mounted on a bracket or just taped on) and the receiver can be mounted at the other end of the piece of wood, about one foot down from the antenna using duct tape, two-sided foam tape or a mounting bracket. A length of wire was run from the receiver's ground terminal down the wood and taped in place at several places. Now I had a handy walking stick that was easy to carry and use! The base can be stuck into any convenient hole, jammed into a rock pile, clamped onto a fence or vehicle, or even held by hand.

For the best chance of hearing whistlers and related phenomena, you will have to put some distance between the whistler receiver and the AC power grid. The bare minimum distance is about one quarter mile from any AC power line; the more distance you can put between the receiver and AC power lines, the better. You'll need to do some exploration to discover quiet sites near you. Once you arrive at a potential listening site, set up your receiver, put in a ground connection, and see what happens. What you will hear depends to some extent on the time of day, but you can always expect some sharp, crackling static. The intensity and volume of this static will depend on propagation conditions and where thunderstorms are in relation to your location. Chances are that you'll also hear some power line hum, but hopefully it won't be very loud. If your listening site is too noisy, you need to try another listening site.

If your ears have good high frequency response, you will probably hear a continuing sequence of one-second tones. These are from the OMEGA radio-navigation system. OMEGA is transmitted from 10 to 14 kHz, and OMEGA transmitters are very powerful. You may also hear anything that can produce an electrostatic discharge, particularly if the humidity is low. These miscellaneous noise sources can include wind noise, the buzz of insects flying near the antenna, dry leaves or grass moving, and even the electrostatic charges that build up on your clothing. Passing vehicles will often produce noise from their electrical and ignition systems. And if you have a digital watch, keep it away from the antenna or you'll be listening to it instead of whistlers!

Anything you hear other than whistlers and related phenomena or OMEGA signals are likely to be the result of extraneous signals "overloading" your receiver. Burbling sounds (possibly mixed with OMEGA tones) are caused by military signals in the 15 to 30 kHz range, perhaps overloading the receiver. A "ticking" sound at a 10 Hz rate is from Loran-C radio-navigation signals at 100 kHz. In general, don't be surprised if you experience "overloading" from transmitters operating on any frequency if they are within sight of the location where you're using your whistler receiver! Table 14-3 illustrates some very low frequency stations around the world that broadcast low frequency signals, these signals are located at the upper edge of the VLF receiver's range.

Table 14-3

Very low frequency radio stations

Time of listening

Most of the VLF signals, such as clicks, pops, and tweeks, can be heard almost at any time of the day or night. Whistler occurrence is a function of both thunderstorm occurrence and propagation conditions through the ionosphere. The rate is higher at night than during the day because of the diurnal variation in the D-region absorption, which is highest when the Sun is above the horizon. At night, the D-layer does not exist since it is ionized by solar ultraviolet rays. The whistler rate, or the number of whistlers heard per minute, has a marked dependence on sunspot activity, the rate increasing with the sunspot number. Whistlers are heard only when sufficient ionization exists along the path to guide the waves along the Earth's magnetic field. This ionization is assumed to be supplied from the Sun during a solar. To hear a whistler or other signals such as *dawn chorus*, you will no doubt have to get away from the power line and industrial noise. The listening time for these signals will be from near local midnight to early morning hours.

Observing and recording hints

Remember the best location to observe VLF signals is out in the countryside, in an area where few cars or trucks are likely to pass. You will want to get as far away from power lines as possible for optimum results. The lower the power line noise is, the stronger the VLF emission signals will be.

Some whistlers are related phenomena and so short-lived and impossible to predict that you might want to consider using a tape recorder to record the signals in the field unattended. Take a portable, battery-operated, cassette tape recorder with you and use a long audio cable to run to the tape recorder from the audio output of the VLF receiver. Any tape recorder with an external microphone input can be used. Best results are obtained with a recorder which has no ALC or automatic level control. The VLF receiver shown has an output jack which can be coupled to a recorder input for field recording. You may have to place the tape recorder away from the receiver to avoid picking up motor noise.

After returning home with your recording, if your receiver was out in the field, you can "play" your recording back into the sound card of your personal computer using an FFT or DSP sound recording program to analyze the recording. For those who are going to use their whistler receiver as a stationary receiver at home, you could use your PC to record on a continuous basis. Audio recording and FFT programs are available on the Internet for free. Good luck and happy exploring!

Additional notes

You can view spectrograms of whistlers as well as hear excellent recordings of many more whistlers than we used in generating the audio clip for this article, courtesy of NASA: http://image.gsfc.nasa.gov/poetry/inspire/advanced.html

A free Fast Fourier Transform (FFT) Waveform Analyzer program and an Audio Waveform Generator program can be downloaded for use on your own computer at:

Chapter 15

Induction Loop Receiving System

Parts list

Induction Loop Transmitter I

TX Mono amplifier or receiver - 5-10 watts output

R1 10 ohm 10 watt 10% resistor

L1 loop coil around room (see text)

Induction Loop Transmitter II

R1 10k ohm potentiometer chassis mount

R2 220 ohm ¼ watt resistor, 5% (red-red-brown)

R3 2.2k ohm ¼ watt, 5% resistor (red-red-gold)

R4 1 ohm ½ watt, 5% resistor (brown-black-gold)

R5 10 ohm 10 watt, 10% resistor

C1 10 µf, 25 volt electrolytic capacitor

C2,C5 100 nF, 35 volt poly capacitor

C3 100 µF, 35 volt electrolytic capacitor

C4 470 µF, 35 volt electrolytic capacitor

C6 2200 µF, 35 volt electrolytic capacitor

U1 TDA2002/3 6 to 10 watt audio amplifier module

HS heatsink for U1

L1 loop coil (see text)

Misc PC board, wire, hardware, chassis, etc.

Induction Loop Receiver

R1 1 megohm ¼ watt, 5% resistor

R2 10k ohm ¼ watt, 5% resistor

R3 1000 ohm potentiometer (tone)

R4 470 ohm ¼ watt, 5% resistor

R5 10k ohm potentiometer (volume)

R6 10 ohm, ¼ watt, 5% resistor

C1 39 nF, 35 volt mylar capacitor

C2 1 µF, 35 volt electrolytic capacitor

C3,C7 .1 µF, 35 volt disk capacitor

C4 4.7 nF, 35 volt poly capacitor

C5 10 µF, 35 volt electrolytic capacitor

C6 220 µF, 35 volt electrolytic capacitor

Q1	BC548 transistor
U1	LM386 audio amplifier IC
L1	800 turns on a 9 × 70 mm ferrite rod (see text)
S1	SPST on-off switch
B1	9volt transistor radio battery
PH	8 ohm headphones
Misc	PC board, wire, ⅛″ phone jacks, battery clip, case

Induction loop technology has been around for many years, for use with the hearing impaired. Induction loop communication systems were originally designed to provide assistance in the school classrooms for the deaf, but today induction loop communications technology is now used for many other applications, such as museum displays, theater communications, mine and cave communication systems, and signal tracing. Induction loop systems have been installed in churches, public halls and auditoriums, schools, lecture halls, cinemas, service counter windows, drive-thru order and pick up windows, information kiosks, offices, airports, train stations, parks, tour and guide buses, automobiles, boats, riding academies, and homes.

Induction loop amplification operates on the basic principle of electronics called magnetic induction. When an electrical current is amplified and passes through a loop of wire, a magnetic field is generated around the wire. The field varies in direct proportion to the strength and frequency of the signal being transmitted. When another wire is placed close to the field of the first wire, an identical electrical current is induced within it. The second current can be amplified and converted into an exact duplicate of the original sound signal.

In technical language, a current is said to be “induced” in the second wire. Hence the term “induction.” In an induction loop system, the induction loop coil in the transmitter sends an electromagnetic signal, which is “induced” to the receiver’s induction loop coil in the receiving unit. An Induction Loop System consists of an amplifier and a loop, the amplifier is connected to a sound source such as a TV, a radio, a public address system or a dedicated microphone. It then amplifies this sound signal and sends it out, in the form of an alternating current, through the loop. The loop itself consists of insulated wire, one turn of which is placed around the perimeter of the room in a simple loop system. When the alternating current from the amplifier flows through the loop, a magnetic field is created within the room. The magnetic field “induces” the signal into the Induction loop coil in the induction receiver unit.

In the portable induction receiver, the induction coil picks up the induced signal from the transmitting loop coil. The fluctuations in the magnetic field are converted into alternating currents once more. These are in turn amplified and converted by the induction loop receiver into sound. The magnetic field within the loop area is strong enough to allow the person with the hearing aid or Induction Loop Receiver to move around freely in the room and still receive the sound at a comfortable listening level.

Many modern day hearing aids incorporate a telecoil into the hearing device. So if a hearing aid user switches to the T or MT position on their hearing aid, the telecoil in the hearing aid picks up the induced signal from an induction loop transmitter and amplifies the signal for the hearing aid user to hear. This is a convenient feature for hearing aid users, in classrooms, churches, and museums with induction coil transmitters.

The listener can receive an audio signal without being physically or electrically connected to the loop, so in effect induction loop transmission is a form of wireless telephony. The listener receives the sound in one of two ways; either through the use of the T-coil or telephone switch on a hearing aid instrument or through an induction receiver that can work with earphone, which we will discuss in our project.

The basic induction loop system consists of a “transmitter” section and a “receiver” section, as shown in Figure 15-1. The “transmitter” section consists of a microphone or signal source, an audio amplifier to boost the signal, and a large loop or wire around the room or listening area. The “receiver” section consists of a smaller loop coil, an audio amplifier which boost the incoming audio and a pair of headphones.

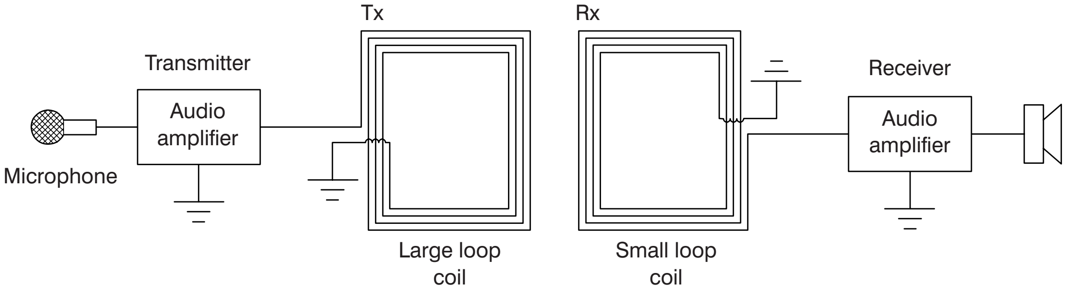

Figure 15-1 *Induction loop communications system block diagram*

"Transmitter" loop unit

You can easily build your own induction loop communication system. First we will begin by describing the "transmitter" section of the system, as shown in Figure 15-2. In its simplest form an induction loop "transmitter" can consist of a mono or stereo Hi-Fi receiver, a resistor and a large loop coil placed around the perimeter of a house, room, or your easy chair. If you have a stereo receiver with a speaker output A-B switch, you can select the (B) output for your induction loop system. You would place an 8 ohm, 10 watt resistor across the output of the left channel's output and then place an 8 ohm, 10 watt resistor in series with a large loop coil as shown. When you wanted to use the induction loop system, you would switch to the (B) speaker output; it's that simple.

If you wanted to construct your own amplifier specifically for an induction loop audio system, you could utilize the 6 to 10 watt audio amplifier shown in Figure 15-3. In order to drive an induction loop, you would need an amplifier with at least about 5 watts of power or more to have a workable system. The amplifier shown in this diagram would work just fine for driving a large loop coil. An audio input signal is fed into the audio input section at the point marked (A) on the schematic. Your audio source could be adjusted via the potentiometer at R1. Note, that you may need an additional pre-amp ahead of the amplifier if you use a low output microphone. You can feed a radio or TV signal directly into the potentiometer at R1 to drive the induction loop "transmitter." The audio amplifier module shown is an 8 watt National Semiconductor LM2002 module, but you could also use a higher power module such as their LM2005. The output of the audio amplifier is wired in series with an 8 to 10 ohm, 10 watt

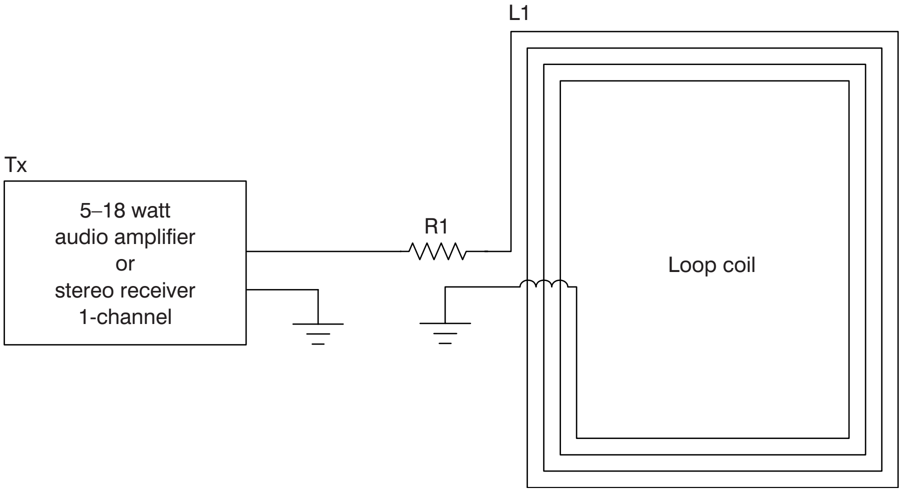

Figure 15-2 *Induction loop transmitter I*

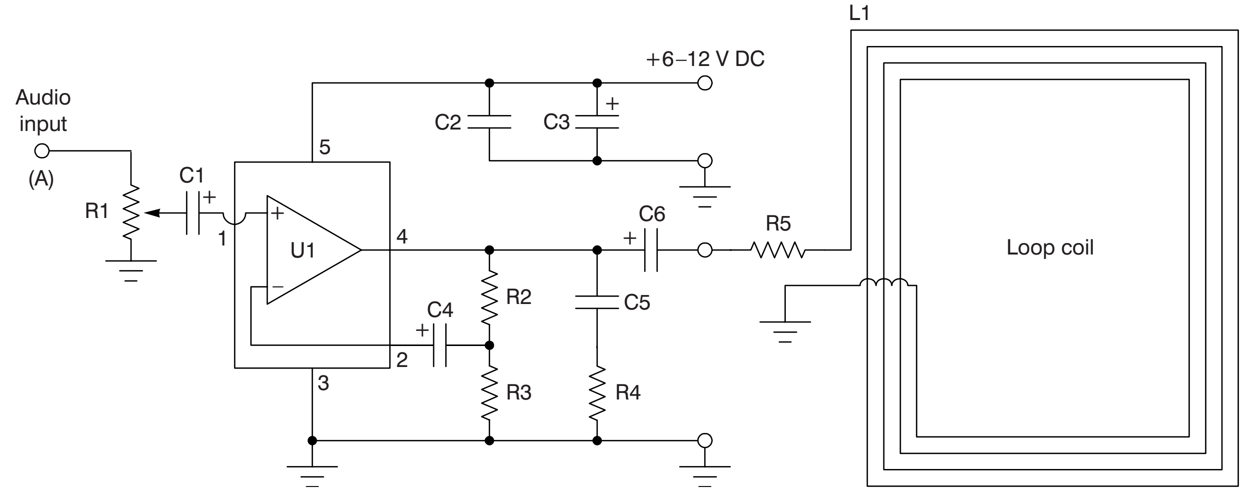

Figure 15-3 *Induction loop transmitter II*

resistor in order to drive the coil. This resistor also protects the output of the audio amplifier.

The inductive loop is a winding of wire through which an audio signal passes, which creates a field within which the audio signal can be detected by appropriate equipment, either a telecoil in a hearing aid or an induction loop receiver. The loop coil is basically a simple 4 or 5 turn loop placed around the room fed from an audio amplifier. The loop then converts the sound to a magnetic field that can be received by a second loop coil and amplified. Note that more turns in the transmission coil result in a stronger transmitted signal. The loop should have a DC impedance of at least 8 ohms, or you can add a resistor in series with the coil to reach 8 ohms.

Pick a path around the room on the ceiling, or under the carpet. A room measuring 15′ × 20′ will have a perimeter of 70′, which will require a minimum of four complete turns of 22 gauge wire, six turns of 20 gauge wire, or nine turns of 18 gauge wire. Pick a path around the room near the ceiling, and wind (or hang) your "coil," or loop, starting and ending at the amplifier. If the back of your amplifier says something like "8 ohms minimum," double the required wire length (load). Buy 120% of the wire you'll need to ensure that you can complete the loop. You should add a power resistor to ensure an appropriate load and reduce wire length, but the amplifier output will be divided between the loop and the resistor, proportionately, which means less radiated energy. This solution requires a lot of energy so try not to compromise. If required, get 4 ohms at 10 watt minimum. There's another and simpler approach: I have a coil built into my favorite chair. It's only 18″ in diameter, but includes 120′ of 28 gauge wire (0.071 ohms per foot). That's about 25 turns of that relatively thin wire.

Another approach to constructing a large loop is to take a long length of 25 pair telephone cable 'Inside Wire' that's long enough to go around the perimeter of a room. Then get a 66 block (or some other kind of punch down block) and punch down the wires so they connect in a multiple turn loop. In this way you can add or subtract turns as you wish if you need that later. You could tack this "telephone" cable to the ceiling of the basement underneath the room you choose.

Connect either end of the loop coil wire to the plus (+) or red terminal and the other end to the minus (−) black terminal, on the audio amplifier's speaker terminals. Most amplifiers or stereo receivers have SPEAKER A and B switches; put your coil circuit on the unused output (B). Remember to place an 8 to 10 ohm, 10 watt resistor in series with the speaker output and the coil loop windings.

"Receiver" loop unit

The induction loop receiver, shown in the photo Figure 15-4 and the schematic diagram in Figure 15-5, is very sensitive and can be the basis for a monaural induction loop wireless headphone system. The induction coil receiver is used inside the area of transmission loop. The receiver coil at L1 consists of 800 turns of #26 ga. enamel wire wound on a 9 × 70 mm ferrite core.

Another approach to constructing a small loop coil for your inductive loop receiving coil is to obtain a "telephone pickup coil" if available or a suitable coil from some other device. The coil in the prototype was salvaged from a surplus 24 volt relay. Actually, two relays were needed since the first was destroyed in the attempt to remove the surrounding metal so that a single solenoid remained. Epoxy putty was used to secure the thin wires and the whole operation was a bit of a challenge. A reed relay coil will give reduced sensitivity but would be much easier to use. The experimentally inclined might try increasing the inductance of a reed relay by replacing the reed switch with soft iron. Avoid shielded inductors or inductors with iron pole pieces designed to concentrate the magnetic field in a small area or confine it completely (as in a relay or transformer) unless you can remove the iron. The resulting coil should be a simple solenoid like wire wrapped around a nail. Don't try to wind your own—it takes too many turns. Evaluate several coils simply by listening. Coils with too little inductance will sound "tinny" with poor low frequency response, and other coils will sound muffled, especially larger iron core coils. This prototype was tested with a large 100 mH air core coil with superb results but the 2″ diameter was just too big for this application. The induction receiver develops a 1–2 mV signal across its internal coil from the fluctuating magnetic field. Transistor Q1 provides pre-amplification to drive a headphone amplifier. The tone at R3 control varies the amount of gain in the high frequencies. Capacitors C1 and C2 block AC hum (C2 also blocks DC to the amplifier input). C3 functions as a low-pass filter to prevent oscillation. The output of the volume control at R5 is fed to the input of an LM 386 audio amplifier IC. In this configuration the amplifier has a gain of 200. Capacitor C7 and R6 form the output "boost" circuit which drives the output to the speaker through C6. The output of the LM385 at pin is used to drive an 8 ohm headphone. The induction loop receiver circuit can be powered from a 9 volt DC power supplies or batteries.

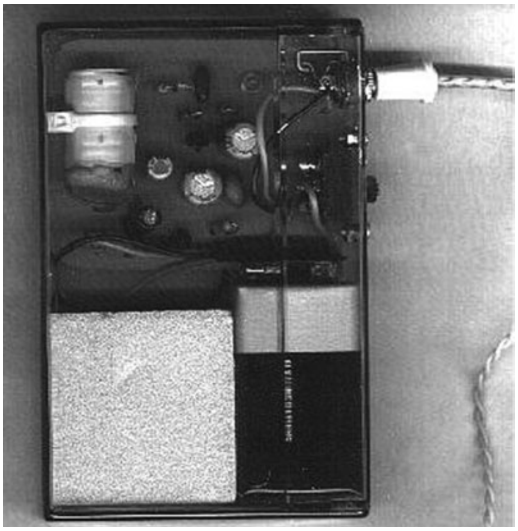

Figure 15-4 *Induction receiver*

Are you ready to begin constructing the induction receiver circuit? First you will need to locate a clean, well lit work table or work bench. You will want a large table so you can spread out all the components, the diagrams and tools that you will need to build the project. Next you will need to locate a small pencil tipped 27 to 33 watt soldering iron and some 60/40 tin/lead rosin core solder for the project. Try and locate a small container of "Tip Tinner," a soldering iron tip cleaner/dresser which conditions the soldering iron tip; this is available from your local Radio Shack store. You should also locate a few small hand tools such as a pair of end-cutters, a pair of needle-nose pliers, a pair of tweezers, a small flat-blade and a Phillips screwdriver and a magnifying glass.

The induction loop receiver prototype was constructed on a small glass-epoxy circuit board which measured 2¼″ × 3″. A circuit board makes for a more reliable and professional circuit. Place all the diagrams in front of you on the work table along with all of the components for the induction loop receiver and we will begin building the project.

The induction loop receiver project contains about four resistors and two potentiometers. Locate the resistors using the color chart in Table 15-1, this will help you identify each of the resistors. Place the resistors into their respective locations on the circuit board, then solder them in place on the PC board. Locate your end-cutters and trim the excess component

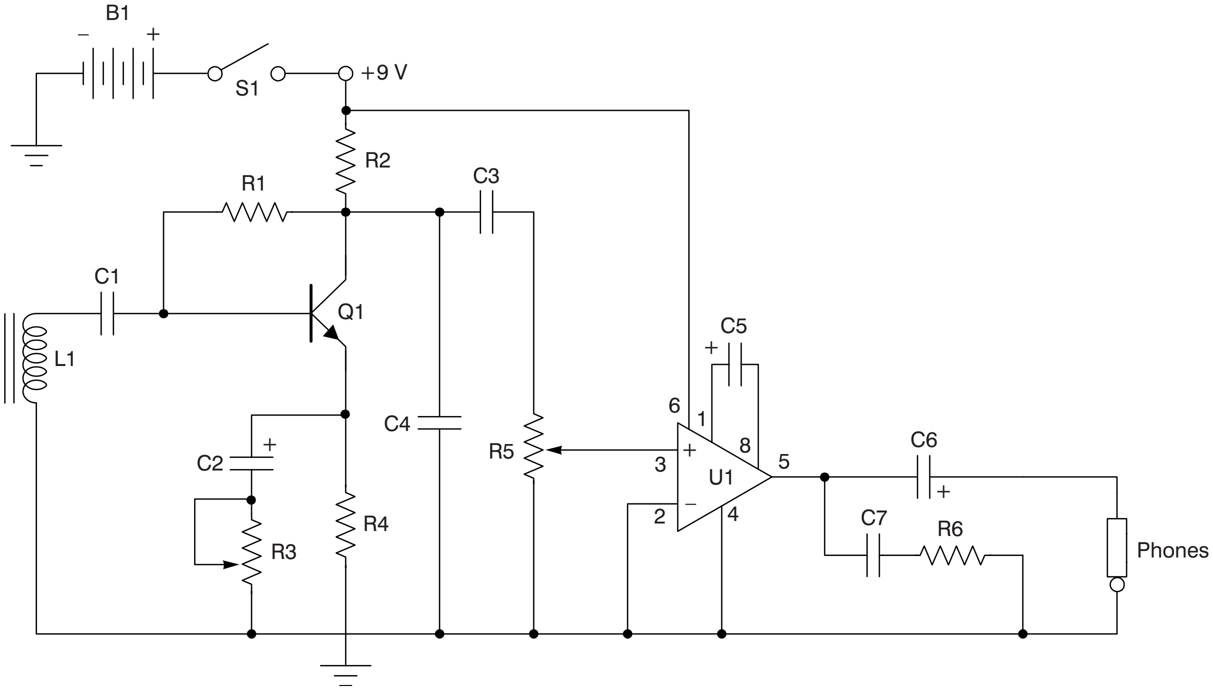

Figure 15-5 *Induction loop receiver schematic*

leads, by cutting them flush to the edge of the circuit board. Potentiometer R3 is a CP board mounted type, you can go ahead and install it on the board and then solder it in place; you can remove any excess leads if necessary.

Next we are going to move to installing the capacitors for the project. There a two distinct types of capacitors—small ceramic, mylar or polyester capacitors and larger electrolytic types. The small capacitors will most likely have a three-digit code stamped on them and not their actual value, since often the capacitor body is very small. Refer to the chart shown in Table 15-2, which illustrates the capacitor codes. You can search through the parts pile and try and identify the capacitors against the code chart and place the correct value into its respective location on the circuit board. After all of the small capacitors have been placed on the PC board, you can solder them in place. Remember to cut the excess leads from the components. Now, locate the larger electrolytic capacitors and place them in front of you and determine where they will go on the circuit board. Once you are certain where the capacitors should be placed on the board, you should take another look to make sure that you have installed the capacitors correctly with respect to its polarity. If an electrolytic capacitor is not installed correctly the circuit will not work properly and may be damaged upon power-up. So you will want to install them correctly the first time through.

Note, there are a number of capacitors in this project, and in looking over the schematic, you will notice that a few of the capacitors will have polarity marking on them. These capacitors are electrolytic types and you must observe the polarity when installing them on the circuit board in order for the circuit to work properly. Electrolytic capacitors will have either a white or black band at one side of the capacitor body or they may be marked with a plus (+) or minus (–) marking on the capacitor body and this denotes the polarity. Refer to the schematic and parts layout diagrams when installing electrolytic capacitors in order to install them correctly with respect to their polarity markings.

Before we go ahead and install the semiconductors, take a brief look at the diagram depicted in Figure 15-6. The semiconductor pin-out diagrams will help you orient the semiconductors when building the induction receiver. The induction loop receiver also incorporates one transistor at Q1 which is connected to R1/R2 and R4 and C2. Transistors generally have three leads protruding from the bottom of the body. A Base lead,

Table 15-1

Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000	
Blue	6	6	1,000,000 (M)	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No color				20%

a Collector lead and and an Emitter lead. Referring to the schematic you will note that the vertical line on the transistor symbol is the Base lead, while the Collector lead is connected to the junction of R1 and R2. The Emitter lead has the small arrow pointing downwards which connects to the junction of C2 and R4. Refer to the actual transistor pin-out diagram to see where each lead exits the transistor case. Generally small plastic TO-92 transistor case bodies will have all three leads in-a-row with the Emitter at one end, the Base lead in the center, and the Collector lead at the opposite end of the device.

The induction loop receiver has one integrated circuit at U1, this is an LM386 audio amplifier chip, which has eight leads in a dual in-line package. Prior to installing the IC, you should install a good quality IC socket. An IC socket is good insurance in the event of a possible circuit failure at some point in time. Since most people cannot successfully un-solder an integrated circuit without damaging the PC board, an IC socket makes good sense. Place the IC socket on the circuit board and solder it in place on the PC board. Locate the LM386 and take a look at the chip. You will note that the IC package will have either a cut-out, a notch or small indented circle at one end of the IC package. Pin 1 of the IC will be just to the left of the notch or cut-out. Orient the IC correctly into the socket, while referring to the schematic and layout diagrams. Place the IC into the socket.

The receiver loop coil at L1 can be either the 800 turn coil wound on a plastic form, an old "high" impedance relay, or one of the black plastic suction cup-telephone pickup devices. Solder the coil in place between the circuit ground and the capacitor at C1. You could also elect to use a second 1/8″ phone jack to allow the coil to be plugged into the circuit using a 6″ to 8″ length of coax cable.

The volume control used for the prototype was a chassis mounted miniature 10k ohm potentiometer. We used a mini 1/8″ PC style phone jack on the circuit board at the output of the audio amplifier at C6; this will allow you to plug in a headphone for listening.

Take a short well deserved rest and when we return we will check the circuit board for possible "short" circuits and "cold" solder joints. Pickup the circuit board with the foil side of the circuit board facing upwards toward you. Look the circuit board over carefully to see if there are any "cold" solder joints. The solder joints should look clean, smooth and shiny. If any of the solder joints look dull, or "blobby," then you

Table 15-2

Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Some capacitors actually have the numeric values stamped on them; however, many are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

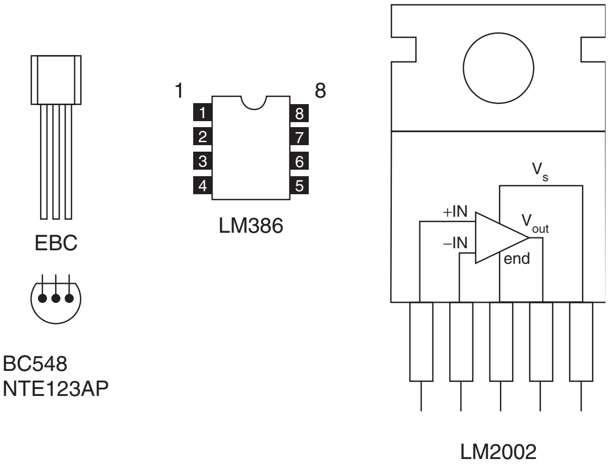

Figure 15-6 *Semiconductor pin-outs*

should remove the solder from the joint and re-solder the connection point over again until it looks good. Next we will inspect the PC board for any possible “short” circuits which may be the result of “stray” component leads which may have stuck to the foil side of the PC board. These “stray” components leads often “stick” to the board by solder residue. Solder blobs are often a cause of “short” circuits, so look the board over carefully for any solder blobs as well. Once the circuit board has been inspected, we can move on to installing the circuit board into a case or enclosure.

We mounted the induction loop receiver in a 3″ × 6″ by 1½″ metal chassis box. We placed one ⅛″ jack at the rear of the case for coil L1, then we placed the second ¼″ phone jack, power on-off switch and volume control on the front side of the chassis box. Locate a 9 volt battery clip and solder the black or minus (−) lead to the circuit ground. Next you will want to wire the red or positive (+) battery clip in series with the On-Off switch to the two power junction points on the PC board, one at R2 and the other at pin 6 of the LM386 IC. Once the circuit is inside the enclosure, you can begin testing the induction loop system. First you will want to make sure that the “transmitter” portion of the system is up and running. If you elected to use an existing stereo receiver or amplifier, make sure that the large coil is connected through a series resistor to the speaker terminals of the amplifier. Set the receiver or amplifier to MONO. If you elected to build your own audio amplifier to drive the large loop, again connect up the coil via an 8 ohm 10 watt series resistor. Once the “transmitter” is ready, with your music or audio source connected, we can move on to testing the induction loop receiver.

Switch the induction receiver to the “On” position. When you first turn on the unit you will probably hear a lot of buzzing from the wiring in the room. Rotate the receiver in a horizontal plane to find a “null” where the hum is minimal. If you can get a reasonable null, you should be able to hear the source material from the “transmitter” loop or at least some hum coming from the earphone. If your “transmitter” loop is “broadcasting” then you should hear the source music or speech on the headphone of your induction loop receiver. If all goes well, both your transmitter and receiver section will be working and you will be hearing the source material in your remote headphones.

In the event that the induction receiver does not work when first power-up, you will have to remove the battery and carefully examine the circuit board for any errors. The most common cause for failure are improper placement of resistors, electrolytic capacitors and diodes installed backwards, and semiconductors such as transistors installed incorrectly. Have a knowledgeable electronics friend provide a second pair-of-eyes to help you examine the circuit for errors. It is very easy to miss a problem since, as the builder, you will continue to see the same circuit, the same way over and over. Once the error has been found and corrected, you can re-connect the battery and test the circuit once again.

As mentioned earlier, you can use the system for hard of hearing people, for museum displays and demonstrations, for theater personnel, late night TV listening, etc. You could wind a transmitter loop around your easy chair and use the system to “broadcast” TV sound to your earphones for late night listening. This is a great Boy Scout project for helping old folks who live in nursing homes to better enjoy TV, radio and music.

You can also use the induction loop receiver by itself without the transmitter loop, to trace power wires behind a wall or ceiling by listening for a sharp increase in hum as the coil passes near the wire. Make sure that current is flowing in the wires to be traced by turning on a lamp or other appliance. Other wires can be traced if they are carrying alternating current in the audio range or a signal generator can be connected to produce the current. Connect the generator to the wire to be traced and connect the generator's "ground" to the house wiring ground. Also ground the far end of the wire you are tracing so that current flows in the wire. This ground connection can also just be a temporary wire laying on the floor running from the generator ground to the far end of the wire you wish to trace. Have fun using your new induction loop receiver!

Chapter 16

Lightning Storm Monitor

Parts list

Lightning Storm Monitor

R1 47k ohm ¼w, 5% resistor

R2,R4,R7 10k ohm ¼w, 5% resistor

R3 5.6k ohm ¼w, 5% resistor

R5 470k ohm ¼w, 5% resistor

R6,R10,R11 22k ohm ¼w, 5% resistor

R8 390 ohm ¼w, 5% resistor

R9 4000megohm or greater (see text)

R12 220k ohm ¼w, 5% resistor

R13 1 megohm ¼w, 5% resistor

R14 100k ohm ¼w, 5% resistor

R15 10 ohm

VR1 500k ohm potentiometer (chassis mount)

VR2,VR9 1 megohm potentiometer (trimmer)

VR3 3k ohm potentiometer (trimmer)

VR4,VR5,VR6 10k ohm potentiometer (chassis mount)

VR7 25k ohm potentiometer(trimmer)

VR8 10 megohm potentiometer (chassis mount)

VR10 10 megohm potentiometer (trimmer)

C1,C9 2.2 pF, 50 volt mica capacitor

C2,C10 180 pF, 50 volt mica capacitor

C3,C4,C6,C8,C11,C12,C22, C23 10µF, 50 volt electrolytic capacitor

C5 .01µF, 50 volt disk capacitor

C7,C21 100 pF, 50 volt mica capacitor

C13 .22µF, 50 volt disk capacitor

C14,C15,C16,C19,C24 .1µF, 50 volt disk capacitor

C17 .47µF, 50 volt disk capacitor

C18 220µF, 50 volt electrolytic capacitor

C20 470µF, 50 volt electrolytic capacitor

D1,D2 1N914 silicon diode

L1 coil optional - 3000 turns on 2′ × 6″ PVC form

Q1 J176 P-Channel JFET

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

U1 LF355 (JFET)

U2,U3,U5 LM741N op-amp

U4 LM380 audio amplifier

S1 SPDT switch (Hi/Lo)

S2 SPST switch (load) ceramic high voltage type

M1 500 ua meter (RM1200 ohm)

M2 250-0-250 FS meter (RM450 ohm)

J1 ⅛″ switches jack

J2 RCA jack - signal output jack for data collection

J3 SO-239 - Antenna-2 input jack

J4 Antenna-1 - RCA jack for whip or outdoor Ant.

CT Capacitive Hat (see text)

Misc IC and transistor sockets, wire, PC board.

Multi-voltage Power Supply

R1 5 k potentiometer - (trimmer)

R2 240 ohm, ¼watt, 5% resistor

C1,C4,C7 4700µF, 50 volt electrolytic capacitor

C2,C5,C8 .1 µF, 50 volt ceramic disk capacitor

C6,C6,C9 10 µF, 50 volt electrolytic capacitor

BR1 4-diode bridge rectifier – 3 amp, 100 volt

U1 LM317 - (+) voltage adjustable regulator

U2 LM7805 - (+) voltage regulator

U3 LM7905 - (–) voltage regulator

T1 24-VCT transformer 2-amp-center tapped

S1 SPST toggle switch - On-Off

F1 2-amp fast blow fuse

Misc PC board, wire, connectors, etc.

Intense electrical storms created by unstable weather conditions frequently occur all around the world. At any given point in time there is likely to be an electrical storm occurring somewhere in the world. Most people would really appreciate having an advance warning of an approaching electrical storm, especially hikers, boaters or backyard party goers. Why not construct your own lightning monitor to obtain an advance warning of an approaching storm before it arrives, thus giving you ample time to seek shelter from the elements. The lightning detector will give you ample warning of an approaching electrical storm before you see and hear the lightning. The sensitive lightning detector project will alert you to an oncoming storm over 50 miles away, giving you time to take cover or to go inside to safety.

During a lightning strike, is the Earth considered positive or negative, is a question often asked. In an electrical storm, the storm cloud is charged like a giant capacitor. The upper portion of the cloud is positive and the lower portion is negative. Like all capacitors, an electrical field gradient exists between the upper positive and lower negative regions. The strength or intensity of the electric field is directly related to the amount of charge build-up in the cloud. This cloud charging is created by a colliding water droplets.

As the collisions continue and the charges at the top and bottom of the cloud increase, the electric field becomes more intense—so intense, in fact, that the electrons at the Earth’s surface are repelled deeper into the Earth by the strong negative charge at the lower portion of the cloud. This repulsion of electron causes the Earth’s surface to acquire a strong, positive charge.

The strong electric field also causes the air around the cloud to break down and become ionized (a plasma).

A point is reached (usually when the gradient exceeds tens of thousands of volts per inch) where the ionized air begins to act like a conductor. At this point, the ground sends out feelers to the cloud, searching for a path of least resistance. Once that path is established, the cloud-to-earth capacitor discharges in a bright flash of lightning.

Because there is an enormous amount of current in a lightning strike, there's also an enormous amount of heat (in fact, a bolt of lightning is hotter than the surface of the sun). The air around the strike becomes super heated, hot enough in fact that the air immediately close to the strike actually explodes. The explosion creates a sound wave that we call thunder. A typical high energy lightning strike is shown in Figure 16-1.

Cloud-to-ground strikes are not the only form of lightning though. There are also ground-to-cloud (usually originating from a tail structure) and cloud-to-cloud strikes. These strikes are further defined into normal lightning, sheet lightning, heat lightning, ball lightning, red sprite, blue jet, and others that are lesser defined. For more information on lightning, see: http://science.howstuffworks.com/lightning.htm.

Satellites are more often used to follow lightning strikes around the world but haven't advanced to the point where they can accurately map local areas. There are two major types of sensors commonly used—magnetic direction finders and VHF Interferometery.

The National Lightning Detection (NLDN), which is operated by Global Atmospherics, Inc., (GAI) in Tucson, AZ, is a network of more than 130 magnetic direction finders that covers the entire USA—more than twice the coverage of existing weather radar networks.

Figure 16-1 *Lightning*

Each direction finder determines the location of a lightning discharge using triangulation and is capable of detecting cloud-to-ground lightning flashes at distances of up to 250 miles and more. Processed information is transmitted to the Network Control Center where it's displayed in the form of a grid map showing lightning across the USA: (www.lightningstorm.com/tux/jsp/gpg/lex1/mapdisplay_free.jsp).

Recently, NASA has improved the resolution of the system by adding acoustical measurements to the mix. Although the flash and resulting thunder occur at essentially the same time, light travels at 186,000 miles per second, whereas sound travels at the relative snail pace of one-fifth of a mile in the same time. Thus, the flash—if not obscured by clouds—is seen before the thunder is heard. By counting the seconds between the flash and the thunder and dividing by 5, an estimate of the distance to the strike (in miles) can be made.

In the NASA lightning sensor, a low frequency receiver detects the lightning strike. The leading edge of the electric-field pulse is used to start a timer and the leading edge of the thunder pulse is used to stop the timer. A microcontroller in each receiver transmits the time measured to a processing station, where the times are converted to distances that are used to compute the location of the lightning strike to within l2 inches. However, the NASA sensors have to be located within a 30 mile radius of the strike to be accurate.

If you are interested in monitoring static levels around you in stormy weather, and the ability to have some advance warning of an impending storm, then this circuit will be of great interest to you especially if you are involved in the radio hobby and have antennas high in the air. The Lightning Storm Monitor has proven to be very reliable and useful for advanced storm warning activities.

The Lightning Monitor circuit is shown in the schematic in Figure 16-2. The Lightning Monitor is actually two receivers in one, a spheric monitor and a static electricity monitor. The static monitor portion of the circuit begins at the outdoor Antenna-2, a capacitive hat type antenna which is fed with coax from the antenna to the receiver. The gate of the P JFET is tied

to ground since a dual polarity supply is used, through a very high resistance. In the original prototype, I experimented with an 11,000 megohm resistor. These high value resistors are hard to find; you may notice that it is a moot point if there is too much leakage in your circuit. In that light, it is best to standoff the gate and use a high quality new coax to your outside antenna, usually a capacitive hat type. You must also come up with a mount design which keeps rain from the point on the mount where current could flow to ground, or you will notice that your meter becomes very insensitive as it starts raining.

The prototype used a 22″ shaft from an amateur radio antenna in a mobile antenna mount, with two nuts on top to hold the capacitive hat and a plastic umbrella to protect the mount from moisture. Likewise the coax connection must be well sealed from moisture, an SO-239 type connectors at the antenna and on the chassis for the meter inside the house. As far as the resistance load goes, if you cannot locate a high value for R9, you can fabricate a high value type if need be, for the strong field load. A 10 meg potentiometer which could be switched out of circuit was used in the prototype. For the switch at S2, you could use a ceramic high voltage type to minimize leakage. The FET type is not critical; in the prototype a J176 came from All Electronics, also the meter and the 10 meg potentiometer came from them as well.

Through experimentation it was found that controlling the offset of an op-amp gave a very sensitive way to control meter balance, far superior to trying to shift the meter itself. If you cannot locate a zero center meter you might ground the end, or put it on a trimmer tap where the ends of the pot are on the plus and minus of the supply, say a 5 or 10 K pot. If you can find it, a 250-0-250 µA meter is suggested. In the maximum gain mode you can notice field gradient changes in clear weather from morning to night, as well as detect storms more than a state away. One problem you will notice with this circuit, especially at high gain settings, is that you have to re-zero the meter often as the polarity changes overhead in stormy weather.

The higher the gain of the op-amp or the higher the input impedance of the FET gate, the more this becomes a problem, which is why a provision was made to lower the impedance of the gate circuit and reduce the op-amp gain in strong fields. Note the provision for audio to be taken from the op-amp, and mixed with separate levels for the static and RF signals, as well as a master volume.

In the Spheric, or RF section of the Lightning Monitor, the whip antenna at Antenna-1 was fed to a coil consisting of a 4′ foot long 6″ inch diameter PVC pipe, the coil consists of about 3000 turns of insulated wire on it. You will find that just a straight whip antenna works fine, so it was found that the large coil is not mandatory. The original thought for using the coil at the antenna was to have a lot of signal at low frequencies with a high Q inductor, to give more signal while trying to reduce the overall gain of the circuit, to minimize 60 cycle hum. On that note, long whips or especially long wires are not very desirable here, so stay with a 5′ to 6′ vertical whip antenna.

The input signal is amplified with a JFET input op-amp at U1, with selectable input range through a small value capacitor to allow high gain to be achieved with minimum 60 cycle hum. A LM741 op-amp gives gain to provide audio signal and then another LM741 is used to drive a 500 µA single ended meter for a reading of RF levels. You may find it easier to make the series resistance control for the meter to be a front mounted control as well as the gain control for the meter driver, i.e. the 741 op-amp, as it give much more flexibility under differing weather conditions. This meter is very helpful in determining the number of lightning strokes per unit time in severe weather.

The audio output from the Spheric monitor section is derived form an LM380 IC circuit; you will notice interaction between controls if you build it as shown. A buffer and mixer circuit might be helpful here, but in the original design we decided to keep the parts count low. Also, an equalizer circuit for the signal out is a very good addition, so you can tailor the output response and reduce unwanted signals such as line power noise. A signal output is provided so the output can be fed to a digital multi-meter with PC interface, if desired to log readings of the Lightning Monitor over time.

Building the lightning monitor

Prior to constructing the Lightning Monitor, you will want to locate a well lit and well ventilated work area. A large clean work bench or work table would be suitable for building the project. Grab a 27 to 33 watt pencil tipped soldering iron, a roll of 22 gauge 60/40 tin/lead rosin core solder. You should also have a small jar of "Tip Tinner," a soldering iron tip dresser which is available from your local Radio Shack store. You'll probably want to gather a few tools, such as a pair of end-cutters, a small pair of needle-nose pliers, a pair of tweezers, a magnifying glass, a small Phillips screwdriver as well as a small flat-blade screwdriver. Place your schematic diagram along with your circuit layout diagram and various charts and tables in front of you on your work table. Place your project components and circuit board in front of you and we can begin constructing the Lightning Monitor. A printed circuit is highly recommended for building this project rather than trying to use perf-board construction to permit more reliable operation from your circuit. Warm up your soldering iron and we will begin construction!

Let's begin building the monitor by first identifying the project resistors. Locate the resistors from the parts pile. Refer to the chart in Table 16-1, which illustrates the resistor color codes and their values. Resistor R1, for example, is a 47k ohm ¼ watt 5% resistor. Try and locate it from the parts pile. The first color band at one edge of the resistor body should be yellow, which is the number (4). The second color band should be violet or number (7) on the chart. The third color band is the multiplier and should be orange in color and represents a multiplier value of 1000, so 47 times 1000 is 47,000 ohms or 47k ohms. The fourth color band on resistors represents the resistor's tolerance. A silver band denotes a 10% tolerance, a gold band represents a 5% tolerance resistor and no color band denotes a 20% tolerance resistor. Once you have found R1, you can try and locate resistor R2 and so on. You can place the resistors on the circuit board in groups of four or so in their respective locations on the circuit board. Once you have the first four resistors placed on the PC board, you can go ahead and solder them in place on the board. After the resistors have been soldered onto the circuit board, you can cut the excess component leads flush to the edge of the circuit board using your end-cutters. Now, you can locate the next batch of four resistors and place them in their respective locations on the circuit board, then go ahead and solder them in place. Remember to trim the excess component leads. Finish up installing the resistors and then we will move on to installing the two silicon diodes.

There are two silicon diodes in this project, and they are located in the meter range and display circuit. Diodes have two leads, a cathode lead and an anode lead. Take a look at the resistors and you will notice that there will be either a black or white color band at one edge of the diode's body. The color band denotes the cathode lead of the diode. It is important that you install

the diode correctly with respect to this polarity. One you have installed the two diodes in their proper place, you can solder them in place on the circuit board. Don't forget to cut the extra component lead lengths.

Next, we will try and locate the capacitors for the Lightning Monitor project. This project uses two types of capacitors, small ceramic disk types and the larger electrolytic types which have polarity. The small capacitors come in many different styles and shapes and sometimes they are so small that there is not enough room to print their actual value on the component, so a three-digit code is used. Refer to the chart shown in Table 16-2 when installing the small capacitors. For example, a .1 μF capacitor would have a code value of (104). The Lightning Monitor also utilizes larger value electrolytic capacitors, these capacitors are usually large and have polarity marking on them, such as a black or white color band or a plus (+) or minus (−) marking on them. These polarity markings must be observed when installing the capacitors on the circuit board. Failure to observe the correct polarity could result in either a damaged component or a damaged circuit when first power-up.

Look through your component parts pile and let's try and identify some capacitors. Let's begin with some of the small types such as C1 and C2. Capacitor C1 may be marked 2.2 or 2n2, while Capacitor C2 will most likely be labeled 181. Try and locate the lower value capacitor from the parts stock and place about four components at a time on the PC board in their respective locations. After placing four or so of the first lot of capacitors, you can go ahead and solder them in place. Remember to trim the excess component leads from the board. Take the next grouping of four capacitors and install them on the PC board while referring to the schematic and parts layout diagrams. Go ahead and solder the next group of four capacitors and trim the excess lead lengths. Install the remaining smaller capacitors and then we will move on to installing the larger value electrolytic capacitors. As mentioned, electrolytic capacitors will have polarity markings on them and they must be installed correctly in order for the circuit to work properly. Take your time when identifying the electrolytic capacitors. Observe their polarity marking and then make sure you orient them correctly and in their proper location on the PC board. Refer to the schematic and parts layout diagram. Install a few electrolytic capacitors at one time, and them solder them in place, follow up by removing the excess lead lengths. Install the remaining electrolytic capacitors and solder them in place. Use your end-cutters to remove the extra lead lengths by cutting them flush to the edge of the circuit board.

The Lightning Monitor uses a single FET transistor at Q1, which is connected to antenna-2. The P channel J-FET at Q1 is a J176 FET, which must be handled with care using an anti-static wrist band to avoid damage. This component is very sensitive to static electricity and can be easily damaged in handling. The three leads of the transistor Q1 are all in a single row with the Drain lead at one end and the Gate lead in the center and the Source lead at the opposite end of the plastic case of the transistor. Refer to Figure 16-3, which illustrates the semiconductor pin-outs.

Before we install the integrated circuits in this project, we would highly recommend using IC sockets. Integrated circuit sockets are good insurance in the event of a possible circuit failure at some possible distant point in time. It is much easier to simply unplug a defective IC, rather than trying to un-solder a 14-pin IC from the circuit board. Integrated circuit sockets are inexpensive and easy to locate. There a number of integrated circuits in this project, from 8-pin to 14-pin dual in-line types. In order to install the integrated circuits correctly, you must observe the correct orientation. Failure to install the integrated circuits correctly can cause serious damage to the IC and to the circuit itself, so you must get it right the first time! Each plastic IC package will have either a cut-out, a notch or small indented circle at one end of the plastic package. Looking just to the left of the notch or cut-out you will find pin 1 of the IC. You must align pin 1 of the IC to pin 1 of the IC socket when installing the chip on the PC board. Take a look at U1, this is an 8-pin dual in-line IC. Since we will not be using pin 1 on this IC, you will have to make sure that pin 2 or the minus (−) input is connected or aligns with C1 and R2, while pin 3 of U1 is connected to resistor R1 and so on. Now, go ahead and insert the integrated circuit into their respective sockets.

There are a number of potentiometers in this project, some of which are chassis mounted controls, while other potentiometers will be circuit board mounted types. Refer to the parts list below and Table 16-3. You can locate the circuit board trimmer type potentiometer and install them at their respective locations on the

Table 16-2

Capacitor code information

This table is designed to provide the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Most capacitors actually have the numeric values stamped on them; however, some are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

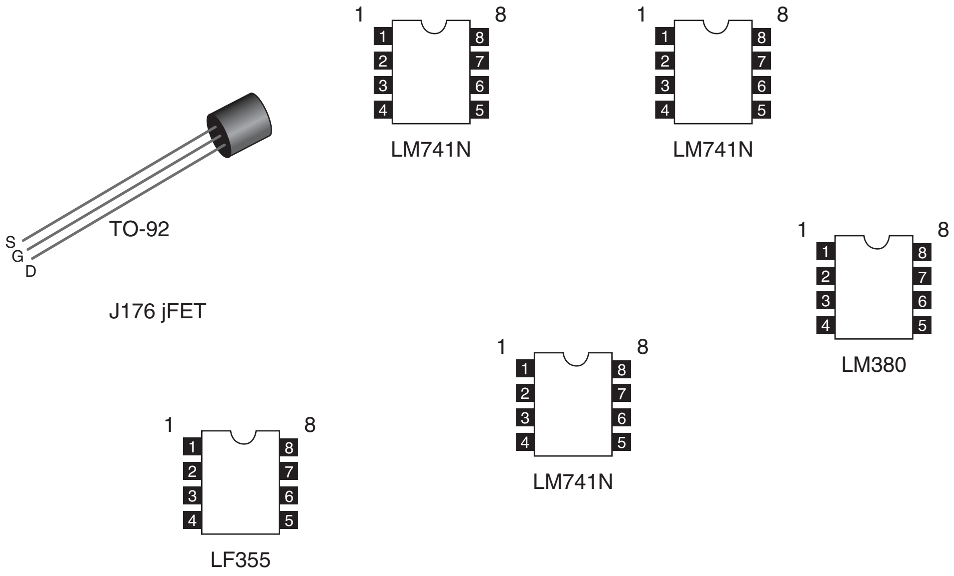

Figure 16-3 *Semiconductor pin-outs*

circuit board. Solder them in place and then trim the excess leads if necessary.

Let's take a well deserved break and when we return we will inspect the circuit board for possible "short" circuits and "cold" solder joints. Pick up the Lightning Monitor circuit board with the foil side of the board facing upwards towards you. First we will inspect the PC board for possible "cold" solder joints. Take a look at the solder joints, they should all look clean, shiny and bright. If you see any solder joints that appear dull, dark or "blobby," then you should remove the solder from the joint and re-solder the joint all over again until it looks good. Once you are confident that all looks well, we can move on to inspecting the PC board for possible "short" circuits. There are two main causes for "short" circuits, small round solder blobs laying across a PC "trace" can cause a circuit to "short-out." The second cause of "short" circuits is a "stray" component lead. Often when cutting excess component leads, they will "stick" to the circuit board from rosin core solder residue. Make sure that there are no "stray" leads bridging between the circuit board traces. Once you are confident that there are no "shorts," we can move on to finishing the project.

Now, let's move on to mounting the larger components and hardware on the chassis box. The chassis mounted

Table 16-3
Potentiometer functions

Potentiometer	*Function*	*Type*

VR7	Static Range Control	25k trimmer
VR8	Static Gain Control	10M chassis mount
VR9	Static Meter Balance Control	1 megohm trimmer
VR10	Load Control	10 megohm trimmer

potentiometers were all mounted on the front of the metal chassis used to house the project, and wired to the circuit board with 20 ga. insulated wire. The two toggle switches, S1 and S2, were also mounted on the front panel of the chassis and were wired to the circuit board using 22 ga. insulated wire.

The Lightning Monitor utilizes two analog meters, one for each monitoring circuit. The meter for the Spheric circuit at M1, was a 500 µA meter, while the Static meter circuit uses a 250-0-250 µA center reading meter at M2. Both of these meters were found surplus and were mounted on the front panel of the metal chassis.

The speaker was mounted on the rear panel of the chassis and wired to the circuit board using two 6″ lengths or #22 ga. insulated wire. A ⅛″ switched mini audio panel jack for headphone use was mounted on the front panel. An RCA jack was provided for antenna-1; you can use a whip antenna or an outdoor whip antenna. An SO-239 antenna connector was mounted at the rear panel to allow the Capacitive Hat antenna-2 to connect to the circuit board, via a small piece of coax cable. The Capacitive Hat antenna is shown in Figure 16-4, it can be built with an antenna bracket mounted on a pole outdoors. An SO-239 jack was mounted on the small antenna bracket. A threaded shaft was silver soldered to the center terminal of the connector with a small rain guard on it. At the top of the threaded shaft a metal coffee can lid is held in place with two nuts. The antenna can be placed outdoor on a pole near the house with a length of coax cable leading from the antenna to the antenna jack on the Lightning Monitor.

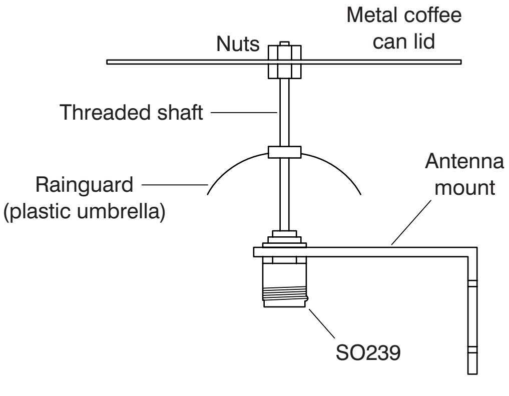

Figure 16-4 *Antenna-2 – Capacitive hat antenna*

If you wish to experiment, you can try an indoor 5′ whip without the coil and see how the circuit performs. You could also experiment with an outdoor whip antenna without the coil and you could build the coil and place it in series with an outdoor whip antenna if desired.

The Lightning Monitor needs a power supply which can provide a 12 volt source for the audio amplifier circuit as well as a plus and minus power supply for the op-amps. The diagram in Figure 16-5 illustrates a 12 volt and dual plus/minus 5 volt power supply which can be used to power the Lightning Monitor. The prototype Lightning Monitor incorporated the power supply in the same chassis as the actual monitor. You will need to locate a 12 volt, 250 mA center-tapped transformer ahead of the rectifier circuit. The rectifier circuit is fed directly to the regulator integrated circuits as shown. You will need to connect the dual voltage power supply to the Lightning Monitor. The plus voltage is connected to pins 7 on both the LM741 and the LF355 op-amp as well as to the J-FET at Q1. The negative voltage supply is connected to pin 4 of both the LM741 and the LF355 op-amp, as well as to the JFET at Q1. The 12 volt power supply is used to power the LM380 audio amplifier.

Once the power supply and Lightning Monitor have been completed, you connect the whip antenna-1 and the Capacitive Hat antenna-2 and prepare for testing the Lightning Monitor. To best test the circuit you will need to wait for a thunderstorm. However, you can do some testing of the circuit. First, apply power to the Lightning Monitor circuit, turn the Off-On switch to the "On" position. Make sure both antennas are connected. Turn up the main volume and the Static Volume controls past the ½ position and adjust VR7 to past ½. You will need to generate some static electricity by rubbing a lucite rod with some animal fur to create a static charge. Bring the lucite rod near the Capacitive Hat antenna and you should see the Static Meter at M2 swing into action. This will give you a good indication that the Static portion of the meter is working. You may be able to test the Spheric Meter portion of the circuit if you have an RF broadband noise generator.

If the Lightning Monitor doesn't seem to work at all or appears DEAD, then you will want to turn "Off" the circuit and remove the power and inspect the circuit board once again. While inspecting the circuit board

you will be looking to make sure that the electrolytic capacitors have been installed correctly, to be sure that the diodes and the JFET have been installed correctly as well. Have a knowledgeable electronic hobbyist inspect the circuit, since it is easy to overlook something and not catch it the second time. Make sure that your power supplies are connected to the correct points and that the op-amps have been installed correctly. Once you are confident of your inspection and hopefully you found your error, you can re-apply power and re-test the circuit again. Good luck and be safe when experimenting with outdoor antennas, keeping them away from power lines.

Chapter 17

Ambient Power Receiver

Parts list

Original Ambient Power Module I

C2,C3 .047µF, 50 volt capacitor

C1,C4 40µF, 50 volt electrolytic capacitor

D1,D2 1N34 diodes

D3,D4 1N34 diodes

ANT 50+ foot broadband monopole antenna

GND Earth ground stake

Misc PC board, wire, hardware, enclosure

Ambient Power Module II

D1,D2,D3,D4,D5,D6 1N60 germanium diodes

D7,D8,D9,D10,D11,D12 1N60 germanium diodes

C1,C2,C3,C4,C5,C6 470µF, 50 volt electrolytic capacitors

C7,C8,C9,C10,C11,C12 470µF, 50 volt electrolytic capacitors

L1 480 turns #22 wire on 3″ plastic tube

ANT 50+ foot broadband monopole antenna

GND earth ground stake

Misc printed circuit board, wire, hardware, case

In 1979, Joe Tate began experimenting with methods of turning radio energy in the air into usable electric power. He first developed a clock which drew its power from an antenna that was just a long piece of wire stretched out horizontally about 20 feet above the ground. The power supply for the clock worked something like an old-style crystal radio, except that it did not have a tuning circuit. Because of this, the “Crystal Clock” was able to absorb a wide spectrum of radio noise from the antenna and yield electric power. The power supply was able to deliver much more current than was developed in a crystal radio, although its output was just still just a few millivolts.

Joe began recording the power supply’s output over a long period of time to determine its dependability. After all, the device relied completely on whatever stray signals happened to be in the air. Using an Atari computer, the output of the clock’s power supply was measured continuously and recorded on floppy disk. This was done by feeding the unregulated voltage output directly into the computer’s joystick port.

Joe began calling this power supply the “Ambient Power Module” (APM) because it extracted power from ambient background radio noise. This small circuit, when connected to antenna and ground, used the potential difference between air and ground to generate a small direct current continuously. Joe’s original claims stated that the APM could produce up to 36 volt/9 watts. Joe applied for a US Patent and was later granted patent #4,628,299. As he studied the recorded data, mild fluctuations were noted in a daily cycle. The patterns were consistent over long periods of time, though they differed in different locations. Aside from that, the APM looked like a very dependable source of power. In the spring of 1984, he discovered an interesting correlation between voltage fluctuations from the APM and a local earthquake event; this point will be discussed later.

The APM operates, as a broadband receiver of energy in the lower portion of the radio spectrum, receiving

Ambient power module

Figure 17-1 *Ambient power module*

most of its power from below 1 MHz. The basic circuit may be combined with a variety of voltage regulation schemes.

The original Ambient Power Module is shown in Figure 17-1 and the schematic diagram circuit in Figure 17-2 is used to convert the ambient RF energy to a direct voltage which can be used and handled by data processing equipment. This design makes use of doubler, splitter and rectifier circuit configurations. Designated as an ambient power module (APM), the circuit is connected to an antenna, preferably a 50 foot or greater broadband monopole antenna. The antenna is connected to the APM circuit via two capacitors C2 and C3, each being in series with the antenna input line for coupling and each having a value of 0.047 microfarad. Taking the left or negative side of the circuit first, it comprises two rectifiers (diodes) D3 and D4 (1N34 type) and a filter capacitor C4 (40 microfarads). Rectifier D2 is connected in parallel to the signal path and rectifier D1 is connected in series, in the well-known voltage multiplier arrangement. Capacitor C1 is connected in parallel across the output of the APM to smooth the rectified output. The right or positive side of the circuit is similar, except for the polarity of the diodes.

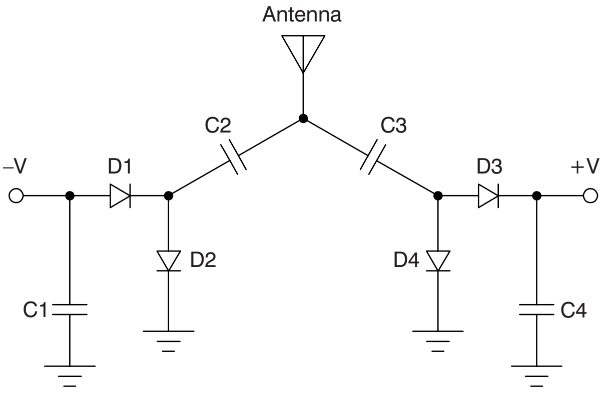

Figure 17-2 *Ambient power module 1*

In operation, an RF voltage is developed across the antenna; this voltage is voltage multiplied by the two rectifiers on each side of the circuit. The resultant voltage output is smoothed or filtered by capacitors C2 and C4. The circuit is very symmetrical with the plus side mirroring the minus side of the circuit. The output of the APM is ideal for low voltage, high impedance devices, like digital clocks, calculators, radios and smoke alarms, which are the most likely applications for this power source.

One possible application for the APM is to charge small NiCad batteries which provide effective voltage regulation as well as convenient electrical storage. Charging lead acid batteries is not practical because their internal leakage is too high for the APM to keep up with. Similarly, this system will not provide enough power for incandescent lights except in areas of very high radio noise. The APM could also be used to power small electronic devices with CMOS circuitry, like clocks and calculators. Smoke alarms and low voltage LEDs, and small emergency power/lighting circuits can also be powered by the APM. Use your imagination to devise an application for the APM.

Building the APM circuit

The builder has a choice of wiring techniques which may be used to construct the module. It may be hand wired onto a terminal strip, laid out on a bread board, experiment board, or printed circuit. We chose to build the original circuit on a small printed circuit board. Locate a clean well lit work table to build the APM. Find a small 27 to 33 watt pencil-tipped soldering iron, as well as some “Tip Tinner.” “Tip Tinner” is a soldering iron tip cleaner/dressing compound which helps to clean the soldering tip after use and can be obtained at your local Radio Shack store. Try and locate a pair of end-cutters, a pair of small needle-nose pliers and a set of screwdrivers. Grab your schematic diagram and look closely at it, before we begin construction.

The APM power receiver consists mainly of diodes and capacitors and you will recall that both of these type of components have polarity which must be observed for the circuit to function correctly. The diodes used in the APM circuit are germanium diodes and NOT silicon diodes which have a voltage drop. Diodes will have either a white or black band at one side of the diode's body. This colored band denotes the cathode end of the diode. When installing the diodes on the PC board make sure you observe the correct placement of all the diodes.

The APM circuit utilizes various capacitors, both electrolytic and non-electrolytic types. Electrolytic capacitors are often larger size capacitors with larger values. Electrolytic capacitors have polarity and may have either a black or white color bands with plus or minus marking at one end of the capacitor body. When installing the electrolytic capacitors make sure that you orient the capacitors correctly with respect to the circuit diagram. The chart in Table 17-1 may help you to identify the small value capacitors. In many instances, small value/size capacitors often use a three-digit code to represent a capacitor value.

Once all the components have been placed on the PC board, you can take a short break and when we return we will inspect the circuit board for possible "short" circuits and "cold" solder joints. Pick up the circuit board with the foil side facing upwards toward you. Look over the board carefully and inspect the solder connections. The solder joints should all look clean, smooth and shiny. If any of the solder joints look dull, dirty or "blobby" then remove the solder from the joint and re-solder the connection over again so that it looks good.

Next we will inspect the circuit board for any "short" circuit which could result from solder blobs or remaining component leads left from the building process. A component lead resting across a PC trace can result in a "short" circuit which could cause the circuit to fail.

Once you are satisfied that your circuit looks good, you can move on to testing the APM receiver. First you will need to attach a good antenna ground connection to the APM receiver module.

Antenna requirements

The antenna needs to be of sufficient size to supply the APM with enough RF current to cause conduction in the germanium diodes and charge the ground coupling capacitors. It has been found that a long horizontal antenna wire works best. A fifty foot monopole, or long-wire antenna will work well, but a small antenna should work, and of course you can experiment with your own antenna ideas. The antenna will work best when elevated to 20–30 feet. Lower elevations will work, but a longer wire may be necessary for best results.

In most locations, possible supporting structures already exist. The wire may be stretched between the top of a building and some nearby tree or telephone pole, see Figure 17-3. If live wires are present on the building or pole, care should be taken to keep your antenna and body well clear of these hazards. To mount the wire, standard commercial insulators may be used as well as homemade devices. Plastic pipe makes an excellent antenna insulator. Synthetic rope also works very well, and has the advantage of being secured simply by tying a knot. It is convenient to mount a pulley at some elevated point so the antenna wire may be pulled up to it using the rope which doubles as an insulator.

Grounding the APM

The APM requires a good ground circuit in order to operate efficiently. Usually a good ground can be established by connecting a wire to the water or gas pipes of a building. Solder or screw the wire to the APM ground terminal. In buildings with plastic pipes or joints, some other hookup must be used. A metal rod or pipe may be driven into the ground in a shady location where the earth usually is damper. Special copper coated steel rods are made for grounds, which have the advantage of good bonding to copper wire. A ground of this type is usually found within the electrical system of most buildings. Conduit is a convenient ground provided that the conduit is properly grounded. This may be checked with an ohmmeter by testing continuity between the conduit and system ground (ground rod). Just as with the antenna, keep the ground

Table 17-1
Capacitance code information

This table provides the value of alphanumeric coded ceramic, mylar and mica capacitors in general. They come in many sizes, shapes, values and ratings; many different manufacturers worldwide produce them and not all play by the same rules. Most capacitors actually have the numeric values stamped on them; however, some are color coded and some have alphanumeric codes. The capacitor's first and second significant number IDs are the first and second values, followed by the multiplier number code, followed by the percentage tolerance letter code. Usually the first two digits of the code represent the significant part of the value, while the third digit, called the multiplier, corresponds to the number of zeros to be added to the first two digits.

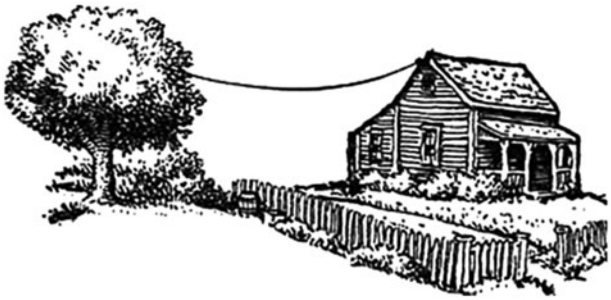

Figure 17-3 *Horizontal long-wire antenna*

wire away form the hot wires. The APM's ground wire may pass through conduit with other wires but should only be installed by qualified personnel. Grounding in extremely dry ground can be enhanced by burying some salt around the rod. The salt will increase the conductivity of the soil and also help retain water content around the ground rod. Some researchers have found that it is much better to get the largest surface area of metal in contact with the ground as possible, and have tried digging a hole and planting aluminum foil sheets in the ground.

Once you have tested the operation of the APM, you can disconnect the antenna and decide how you wish to enclose the APM circuit. You may want to experiment with the housing, since researchers have discovered that the germanium diodes are sensitive to sunlight and the voltage output is increased when the circuit is in sunlight. If you want to experiment along these lines, then you may wish to enclose the circuit in a clear plastic box. You can drill holes for two terminals posts for the plus and minus output connections, an RCA jack for the antenna input connection, a terminal for the ground connection, and your APM is complete and ready for operation.

The APM-II

The original APM is a great circuit for experimentation. It has been found that the germanium diodes are also sensitive to light, so if you house the APM in a clear plastic box and have it exposed to sunlight it will produce more output. Have fun experimenting with the APM receiver and you may find the perfect application for it, such as powering another receiver or night light, clock, emergency radio/lighting, etc.

Over time experimenters have improved upon the original APM design and claim increased output from the original design, so the reader is free to experiment and build both versions of the APM if desired. The second APM receiver, shown in Figure 17-4, illustrates the newer version of the APM with increased output voltage and current. The APM-II has quite a few more stages and has many more diodes and capacitors. You will note that the APM-II also uses germanium diodes which have more output than trying to use silicon diodes. Also note the higher capacitance values in the second design which were used to increase the output considerably. When constructing the APM-II be sure to pay careful attention to mounting the diode and capacitors; since there are many more components and they all have polarity marking on them, it is much more possible to make a mistake in orientation. Take your time when constructing the circuit. The APM-II also uses an input coil, which is said to improve the output. Some experimenters claim that the antenna can be eliminated and that the antenna connection can be connected to another separate ground, but this has not been verified. The APM-II is also sensitive to light which can increase the output if used outside. Some users claim that the power produced by the APM also seems to improve near bridges, ships and anything containing a great deal of metal.

Over time many scientists and researchers have reported bright flashes in the sky during strong earthquakes, as well as computer breakdowns during severe tremors. Scientists have long suspected that seismic activity is associated with a variety of electrical effects. Researchers have been taking a careful look at this link, with an eye toward using it to predict earthquakes.

Joseph Tate and William Daily of Lawrence Livermore National Laboratory in Livermore, CA. created a system of radio wave monitors distributed along California's San Andreas fault using the APM design. Tate and Daily recorded two kinds of changes in atmospheric radio waves prior to earthquakes that occurred between 1983 and 1986. Joe was able to witness and record the output of the APM during the earthquakes that followed, since he continuously monitored the output of the APM on a computer, so he could go back and look at the output on any given day.

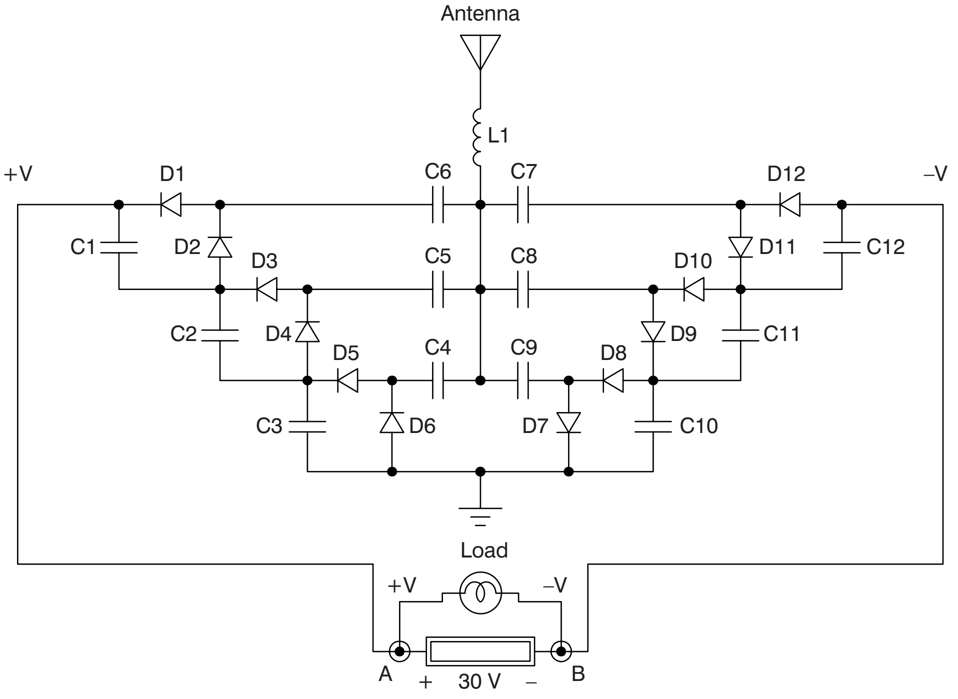

Figure 17-4 *Ambient power module II*

The most common change is a drop in the radio signals that normally pervade the air as a result of lightning and human sources such as car ignition systems and electric power grids. This reduction typically occurs one to six days before an earthquake and can last for many hours. For example, a magnitude 6.2 earthquake that shook Hollister, CA, in April 1984 was preceded six days earlier by a 24-hour drop in radio signals being monitored 30 miles from the quake's epicenter. Tate and Daily have found that the larger the earthquake, the longer the time between the radio wave depression and the quake.

Laboratory studies have shown that the electrical conductivity of rocks increases as they are stressed. Based on this and their electrical modeling of the ground, Tate and Daily think the increased conductivity of stressed rocks near the fault causes more radio waves to be absorbed by the ground rather than their traveling through the air. They also plan to test a possible link between radio wave drops and the emission of radon gas, which itself is thought to be a quake precursor. The radon may ionize the air, making it temporarily more absorptive than the detector antenna.

The researchers have also found, in addition to these drops, another pre-quake phenomenon in which short pulses of increased radio wave activity are emitted. For example, five days before the magnitude 6.5 earthquake hit palm Springs, CA, in July 1986, a station 15 miles from the epicenter detected a rise in radio signals. This sort of emission is consistent with laboratory work showing that cracking rocks release electromagnetic signals.

Tate says that in their first attempts at predicting earthquakes, they did not miss a single event, so he is optimistic about using this technique for short-term forecasting of San Andreas quakes.

If you live in an earthquake prone area such as California, you could use you APM not only for small low voltage emergency power/lighting system but you could connect the APM to an analog to digital converter card in a personal computer and record the fluctuations during earthquakes. The APM will provide many avenues for the builder and/or researcher. Disconnect your APM during thunderstorm activity to avoid damage to the APM and other household devices. Have fun and be safe.

Chapter 18

Earth Field Magnetometer Project

Parts list

Earth Field Magnetometer

R1,R3,R4,R5 4.7 k ohm, $\frac{1}{4}$ w, 5% resistor

R2 100 ohms, $\frac{1}{4}$ w, 5% resistor

R6 10k ohm $\frac{1}{4}$ w, 5% resistor

C1,C2 15 pF, 35 volt capacitor

C3,C4 47 nF, 35 volt electrolytic capacitor

C5 10 μF, 35 volt capacitor

C6,C8 1 μF, 35 volt capacitor

C7 22 μF, 35 volt electrolytic capacitor

C9 10 μF, 35 volt Tantalum capacitor

D1,D2 1N914 silicon diode

D3 1N4001 silicon diode

X1 10 MHz crystal

U1 SCL006A - magnetometer output IC

U2 AD-557 - digital to analog converter chip

U3,U4 LM7805, 5 volt regulator

J1,J2 wire jumpers

S1 4-position rotary gain switch

S2 normally open pushbutton switch

S3 SPST toggle power switch

Logger HOBO H08-002-02 (ONSET)

Misc PC board, wire, IC sockets, chassis, etc.

Optional Field Magnetometer Power Supply

C1 470 μF, 50 volt electrolytic capacitor

C2 1 μf, 50 volt ceramic capacitor

C3 15 μf, 50 volt electrolytic capacitor

BR1 diode bridge rectifier 100v/2-amp

T1 24 volt center tapped transformer -.5 A

U1 LM7809 IC regulator 9 volts

S1 SPST power switch

PL1 115 VAC power plug

MISC PC board, wire, hardware, etc.

Magnetic fields are all around us. The Earth itself produces a magnetic field, which is why compasses work. Anytime an electrical current flows in a conductor, a magnetic field is generated. That is why transformers, inductors, and radio antennas work. There are several different devices that could be used to sense a magnetic field. One of the most familiar to electronics hobbyists is the Hall-effect device. However, in this chapter we'll take a look at a magnetic sensor that is as easy to use, but is more sensitive, more linear, and more temperature stable than typical Hall-effect devices. And just like Hall-effect devices, it can be used to make a variety of instruments, including magnetometers and gradiometers.

For those unfamiliar with them, magnetometers are used in a variety of applications in science and engineering. One high-tech magnetometer is used by Navy aircraft to locate submarines. Radio scientists use magnetometers to monitor solar activity. Earth scientists use magnetometers to study diurnal changes in the Earth's magnetic field. Archeologists use magnetometers to locate buried artifacts, while marine archeologists and treasure hunters use the devices to locate sunken wrecks and sunken treasure.

The Earth Field Magnetometer that we will be exploring uses a "flux-gate magnetic sensor." The device, in essence, is basically an over-driven magnetic-core transformer which the "transducible" event is the saturation of the magnetic material. These devices can be made very small and compact, yet will still provide reasonable accuracy.

In its most simple form the flux-gate magnetic sensor consists of a nickel-iron rod used as a core, wound, with two coils. One coil is used as the excitation coil, while the other is used as the output or sensing coil. The excitation coil is driven with a square-wave signal with an amplitude high enough to saturate the core. The current in the output coil will increase in a linear manner so long as the core is not saturated. But when the saturation point is reached, the inductance of the coil drops and the current rises to a level limited only by the coil's other circuit resistances.

If the simple flux-gate sensor was in a magnetically pure environment, then the field produced by the excitation coil would be the end of the story. But there are magnetic fields all around us, and these either add to or subtract from the magnetic field in the core of the flux-gate sensor. Magnetic field lines along the axis of the core have the most effect on the total magnetic field inside the core. As a result of the external magnetic fields, the saturation condition occurs either earlier or later than would occur if we were only dealing with the magnetic field of interest. Whether the saturation occurs early or later depends on whether the external field opposes or reinforces the intended field.

Flux-gate magnetometer

The Earth Field Magnetometer project is illustrated in Figure 18-1 and the remotely located FM-3 flux-gate sensor is depicted in Figure 18-2.

The heart of the magnetometer is of course the flux-gate sensor. A compact low-cost line of flux-gate sensors are manufactured by Speake & Co. Ltd. and distributed in the United States by Fat Quarters Software. The FGM-3 sensor is the device used in

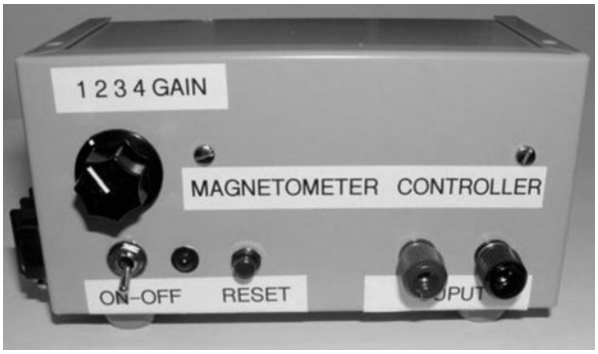

Figure 18-1 *Magnetometer*

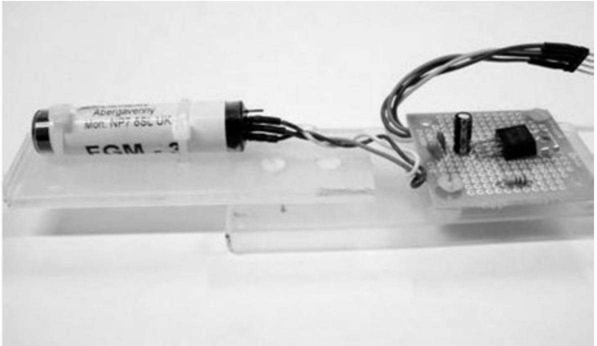

Figure 18-2 *FGM-3 Magnetometer sensor*

this project. It is a 62 mm-long by 16 mm-diameter (2.44 by 0.63 inch) device. Like all the devices in the line, it converts the magnetic field strength to a signal with a proportional frequency. The FGM-3 sensor has only three leads: Red: +5 VDC (power), Black: 0 volts (ground), and White: output signal (a square-wave whose frequency varies with the applied field). The output signal is a train of TTL compatible pulses with a period that ranges from 8 to 25 mS, or a frequency range of 40 to 125 kHz. The detection sensitivity of the FGM-3 device is +/– 0.5 oersted (+50 utesla). That range covers the Earth's magnetic field, making it possible to use the sensor in Earth-field magnetometers. Using two or three sensors in conjunction with each other provides functions such as compass orientation, three-dimensional orientation measurement systems, and three-dimensional gimbaled devices such as virtual-reality helmet display devices. It can also be used in applications such as ferrous metal detectors, underwater shipwreck finders, and in factories as conveyer-belt sensors or counters. There are a host of other applications where a small change in a magnetic field needs to be detected.

The FGM series also includes two other devices, the FGM-2 and the FGM-3h. The FGM-2 is an orthogonal sensor that has two FGM-1 devices on a circular platform at right angles to one another. That orthogonal arrangement permits easier implementation of orientation measurement, compass, and other applications. The FGM-3h is the same size and shape as the FGM-3, but is about 2.5 times more sensitive. Its output frequency changes approximately 2 to 3 Hz per gamma of field change, with a dynamic range of +/– 0.15 oersted (about one-third the Earth's magnetic field strength).

The output signal in all the devices in the FGM series is +5 volt (TTL-compatible) pulse whose period is directly proportional to the applied magnetic field strength. This relationship makes the frequency of the output signal directly proportional to the magnetic field strength. The period varies typically from 8.5 μs to 25 μs or a frequency of about 120 kHz to 50 kHz. For the FGM-3 the linearity is about 5.5% over its +/– 0.5 oersted range.

The response pattern of the FGM-x series sensors is shown in Figure 18-3. It is a "figure-8" pattern that has major lobes (maxima) along the axis of the sensor, and nulls (minima) at right angles to the sensor axis. This pattern suggests that for any given situation there is a preferred direction for sensor alignment. The long axis of the sensor should be pointed towards the target source. When calibrating or aligning sensor circuits, it is common practice to align the sensor along the east-west direction in order to minimize the effects of the Earth's magnetic field.

The flux-gate sensor is coupled directly to a special interface chip, manufactured by Speake. This special SCL006A integrated circuit is shown in the main schematic diagram shown in Figure 18-4. It provides the circuitry needed to perform the Earth field magnetometry sensing. It integrates field fluctuations in one-second intervals, producing very sensitive output variations in response to small field variations. The magnetometer is of special interest to people doing radio-propagation studies, and those who want to monitor for solar flares. It also works as a laboratory magnetometer for various purposes. The SCL006A is housed in an 18-pin DIP IC package and is shown at U1. The FGM-3

flux-gate sensor is coupled to the input pin at pin 17 of U1. The reference oscillator of the SCL0006A is controlled by components X1, C1, C2 and R2. A sensitivity switch, S1, provides four positions, each with a different overall sensitivity range. Switch S2 is used to reset the SCL0006A, when applied for about two seconds.

The second op-amp at U2, is an Analog Devices AD557 D/A converter. The magnetometer circuit is designed so that it could be run from a 9 to 15 volt battery for use in the field. Power supplied from the battery is controlled by power switch S3 which supplies 9 volts to the regulator. For stationary research, the magnetometer should be powered from an 110 volt AC to 9–15 volt DC power supply. The regulator U3 drops the 9 volt input supply power down to 5-volts to power the magneto-meter circuit. The output signal is a DC voltage that can be monitored by a strip-chart or X-Y paper recorder, a voltmeter or the signal can be fed into a computer using an A-to-D converter. In the prototype we used the output to drive a portable mini data-logger such as the ONSET corporation HOBO H08-002-02. You will want to select the 2.5 volt model logger. You could also elect to use a digital multi-meter with RS-232 output which can be fed to a computer's serial port for data-logging.

Construction

The Earth-field magnetometer project was built on two printed circuit boards. The main circuit board is shown in Figure 18-5, was constructed on a 3½″ × 4½″ PC board, while the remotely located FGM-3 sensor was paired with a second 5-volt regulator shown in Figure 18-6. Regulator U4 was mounted on a 2″ × 3″ PC board, which was attached to a sheet of flexible plastic using plastic screws. The FGM-3 sensor probe was then mounted on the 2″ × 4½″ plastic sheet. The plastic sheet was used to mount the probe, ahead of the regulator in order to give the flux-gate probe some isolation from surrounding metal. The flux-gate probe is mounted length-wise and parallel to the length of the PVC pipe. The FGM-3 sensor and remote regulator were then housed in a 2½″ diameter × 12″ long PVC pipe, which is separated by a length of three-conductor cable. Note that you could also elect to purchase a flux-magnetometer kit including PC board, the FGM-3

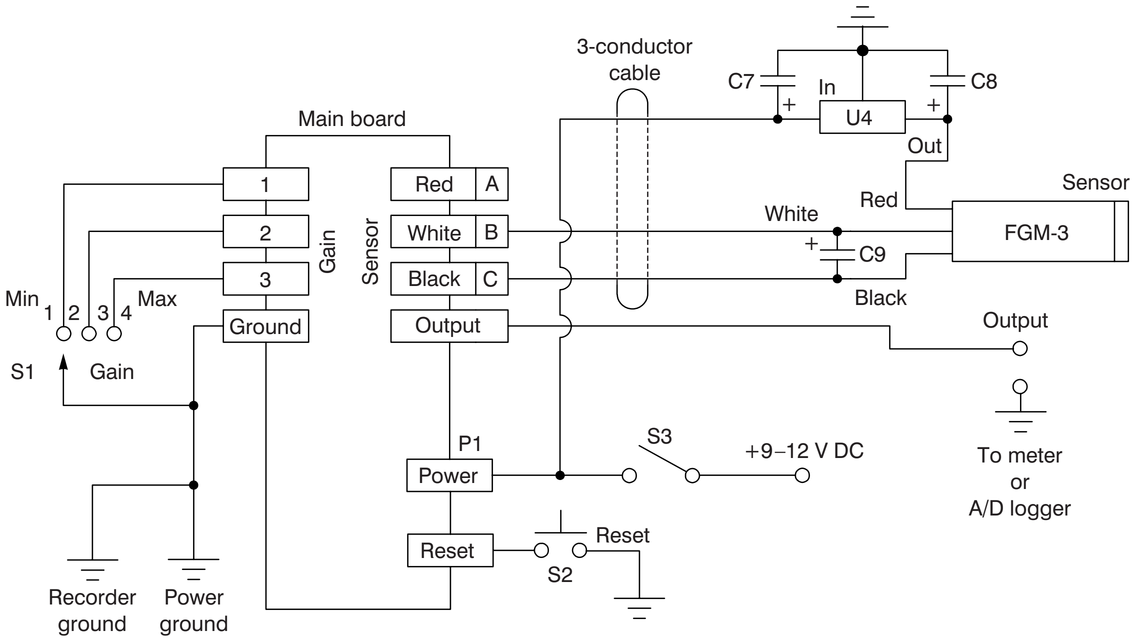

Figure 18-5 *Magnetometer connection diagram*

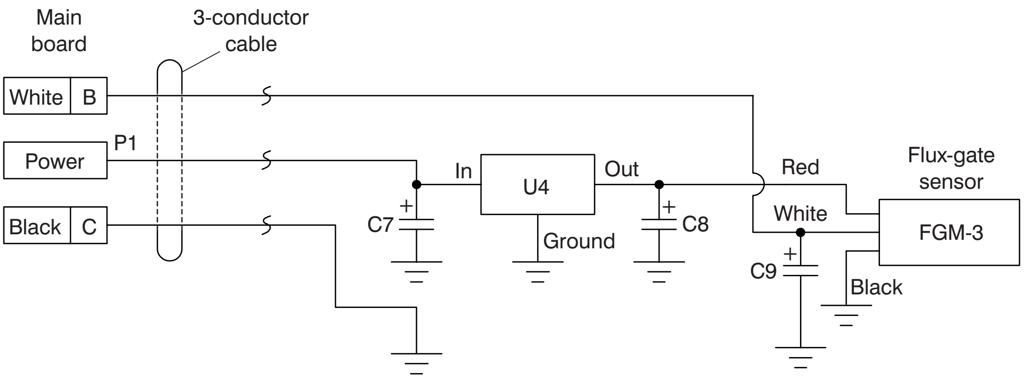

Figure 18-6 *Flux-gate sensor board*

sensor, ICs, and most other parts, but less the gain switch, can be from Fat Quarters Software for about $80.00.

Are you ready to begin constructing the flux-gate magnetometer? Before we begin you will want to secure a well lit and well ventilated work area, as well as a bench or large table for assembling your magnetometer project. Locate a small pencil-tipped 27 to 33 watt soldering iron, as well as a roll of 22 ga. 60/40 tin/lead rosin core solder. Go to your local Radio Shack store and purchase a small jar of “Tip Tinner”; this is a soldering iron tip cleaner/dresser compound, which works wonders. You will also need a few hand tools for the project. You will need a pair of small end-cutters, a pair of needle-nose pliers, a pair of tweezers, and a magnifying glass. A small flat-blade screwdriver and a small Phillips screwdriver should round out your tool requirements.

While you could build the magnetometer project on a perf-board or you could use point-point wiring it is recommended that you build the circuit on a printed circuit board for most reliable circuit operation and long life. Prepare your circuit board, and then we will be able to go ahead and build the magnetometer receiver project.

Locate all of the project diagram, such as the schematic, parts layout diagrams and the component pin-out sheets as well as the resistor and capacitor identification tables and we will be almost ready to begin. Place all of the magnetometer project components on the work bench in front of you, warm up your soldering iron and let’s get going.

First, refer to the chart in Table 18-1, which illustrates the resistor color code. The resistor for this project will have three or four color bands on them. The first color band is closest to one end of the resistor body. The first color band represents the first digit of the resistor’s value, the second color represents the second digit of the resistor value, the third color band represents the resistor’s multiplier value, and the fourth band denotes the resistor’s tolerance value. A silver fourth band denotes a 10% tolerance value, while a gold band represents a 5% tolerance value; no fourth color band denotes a resistor with 20% tolerance. Resistors R1, R3, R4 and R5, for example, are 4.7k ohm types. The first color band is yellow, which represents a four (4), while the second color band is violet or seven (7), and the third color band is red denoting a multiplier of (100), so you see (4) (7) times (100) equals 4700 or 4.7k ohms. Identify all of the 4.7k ohm resistors and place them on the circuit board at their correct location. Next, solder these resistors to the circuit board. Then follow-up by cutting the excess component leads flush to the edge of the circuit board with your end-cutters. Now locate R2 and R6 and install them in their proper locations, then solder them in place on the PC board. Remember to trim the excess resistor leads with your end-cutter.

Next we will move to identifying and installing the capacitors for the project. Capacitors are available in two major categories—electrolytic and non-electrolytic types. Electrolytic capacitors are generally both larger in size and larger in value than non-electrolytic types. Electrolytic capacitors have polarity and hence, they will have polarity marking on them to identify

Table 18-1
Resistor color code chart

Color Band	*1st Digit*	*2nd Digit*	*Multiplier*	*Tolerance*
Black	0	0	1	
Brown	1	1	10	1%
Red	2	2	100	2%
Orange	3	3	1,000 (K)	3%
Yellow	4	4	10,000	4%
Green	5	5	100,000	
Blue	6	6	1,000,000 (M)	
Violet	7	7	10,000,000	
Gray	8	8	100,000,000	
White	9	9	1,000,000,000	
Gold			0.1	5%
Silver			0.01	10%
No color				20%

their leads. You will usually find a black or white colored band or a plus (+) or minus (–) marking near one of the capacitor leads; this denotes the polarity. You will have to orient an electrolytic capacitor onto the circuit board with respect to the capacitor's polarity. When you mount electrolytic capacitors on the circuit board, you will have to refer to both the circuit schematic and the parts layout diagrams in order to install the capacitor properly. Failure to install electrolytic capacitors correctly may result in damage to the capacitor itself and perhaps damage to the circuit as well. Non-electrolytic capacitors will generally be smaller in value and physical size. Sometimes the non-electrolytic capacitors will have their value printed on them, and at other times the capacitor may be physically very small when a three-digit code is used to identify the capacitor. The chart in Table 18-2, helps to identify capacitors based on this code. Use the chart to help identify the capacitors. You will want to make sure that you install the correct value capacitor into the right location on the circuit board in order for the circuit to work correctly. For example, a capacitor marked with (102) denotes a value of .001 µF, while a capacitor with a marking of (103) denotes a capacitor value of .01 µF.
